Concerns for all forms of deionization units include microbial and endotoxin control, chemical additive impact on resins and membranes, and loss, degradation, and fouling of resin. Issues of concern specific to deionization units include regeneration frequency and completeness, channeling caused by biofilm agglomeration of resin particles, organic leaching from new resins, complete resin separation for mixed bed regeneration, and bed fluidization air contamination (mixed beds).

Control measures may include continuous recirculation loops, effluent microbial control by UV light, conductivity monitoring, resin testing, microporous filtration of bed fluidization air, microbial monitoring, frequent regeneration to minimize and control microorganism growth, sizing the equipment for suitable water flow and contact time, and use of elevated temperatures. Internal distributor and regeneration piping for deionization bed units should be configured to ensure that regeneration chemicals contact all internal bed and piping surfaces and resins.

Rechargeable canisters can be the source of contamination and should be carefully monitored. Full knowledge of previous resin use, minimum storage time between regeneration and use, and appropriate sanitizing procedures are critical factors for ensuring proper performance.

### 5.1.7 REVERSE OSMOSIS

Reverse osmosis units use semipermeable membranes. The "pores" of reverse osmosis membranes are intersegmental spaces among the polymer molecules. They are big enough for permeation of water molecules, but they limit the passage of hydrated chemical ions, organic compounds, and microorganisms. reverse osmosis membranes can achieve chemical, microbial, and endotoxin quality improvement. Many factors, including pH, temperature, source water hardness, permeate and reject flow rate, and differential pressure across the membrane, affect the selectivity and effectiveness of this permeation. The process streams consist of supply water, product water (permeate), and waste water (reject). Depending on the source water, pretreatment and system configuration variations and chemical additives may be necessary to achieve the desired performance and reliability. For most source waters, a single stage of reverse osmosis filtration is usually not enough to meet Purified Water conductivity specifications. A second pass of this permeate water through another reverse osmosis stage usually achieves the necessary permeate purity if other factors such as pH and temperature have been appropriately adjusted and the ammonia from source water that has been previously treated with chloramines is removed.

Concerns associated with the design and operation of reverse osmosis units include membrane materials that are sensitive to sanitizing agents and to particulate, chemical, and microbial membrane fouling; membrane and seal integrity; and the passage of dissolved gases, such as carbon dioxide and ammonia. Failure of membrane or seal integrity will result in product water contamination. Methods of control involve suitable pretreatment of the influent water stream; appropriate membrane material selection; membrane design and heat tolerance; periodic sanitization; and monitoring of differential pressures, conductivity, microbial levels, and TOC.

The development of reverse osmosis units that can tolerate sanitizing water temperatures and also operate efficiently and continuously at elevated temperatures has added greatly to their microbial control ability and to the avoidance of biofouling. Reverse osmosis units can be used alone or in combination with deionization and CEDI units, as well as ultrafiltration, for operational and quality enhancements.

### 5.1.8 ULTRAFILTRATION

Ultrafiltration is a technology that is often used near the end of a pharmaceutical water purification system for removing endotoxins from a water stream though upstream uses are possible. Ultrafiltration can use semipermeable membranes, but unlike reverse osmosis units, these typically use polysulfone with intersegmental "pores" that have been purposefully enlarged. Membranes with differing molecular weight "cutoffs" can be created to preferentially reject molecules with molecular weights above these ratings.

Ceramic ultrafilters are another molecular sieving technology. Ceramic ultrafilters are self-supporting and extremely durable; they can be backwashed, chemically cleaned, and steam sterilized. However, they may require higher operating pressures than do membrane-type ultrafilters.

All ultrafiltration devices work primarily by a molecular sieving principle. Ultrafilters with molecular weight cutoff ratings in the range of 10,000–20,000 Da are typically used in water systems for removing endotoxins. This technology may be appropriate as an intermediate or final purification step. As with reverse osmosis, successful performance is dependent upon pretreatment of the water by upstream unit operations.

Issues of concern for ultrafilters include compatibility of membrane material with heat and sanitizing agents, membrane integrity, fouling by particles and microorganisms, and seal integrity. Control measures involve filter membrane composition, sanitization, flow design (dead end versus tangential), cartridge replacement, elevated feed water temperature, and monitoring TOC and differential pressure.

### 5.1.9 MICROBIAL-RETENTIVE FILTRATION

Microbial-retentive membrane filters have a larger effective "pore size" than ultrafilters and are intended to prevent the passage of microorganisms and similarly sized particles without unduly restricting flow. This type of filtration is widely employed within water systems for filtering the bacteria out of both water and compressed gases as well as for vent filters on tanks and stills and other unit operations.

In water systems, a filter's microbial retention characteristics exhibit different phenomena than in other aseptic filtration applications.

The following factors interact to create the retention phenomena for water system microorganisms: the variability in the range and average pore sizes created by the various membrane fabrication processes; the variability of the surface chemistry and three-dimensional structure related to the different polymers used in these filter matrices; and the size and surface properties of the microorganism intended to be retained by the filters. In some situations, the appearance of water system microorganisms on the downstream sides of some 0.2- to 0.22-µm rated filters after a period of use (days to weeks) seems to support the idea that water-borne microorganisms can penetrate the 0.2- to 0.22-µm rated filters. It is not known whether this downstream appearance is caused by exceeding the retentive capabilities of the filters due to high prefiltration bioburden levels of water-borne microorganisms and extended filtration times. These conditions can lead to a "pass-through" phenomenon resulting from tiny cells or less cell "stickiness", or perhaps by a "grow-through" phenomenon in which cells hypothetically replicate their way through the pores to the downstream side. Whatever the penetration mechanism, 0.2- to 0.22-µm rated membranes may not be the best choice for some water system uses (see *Sterility Assurance* ⟨1211⟩).

Nevertheless, microbial retention success in water systems has been reported with the use of filters rated as 0.2 or 0.1 µm. There is general agreement that, for a given manufacturer, its 0.1-µm rated filters are tighter than its 0.2- to 0.22-µm rated filters. However, comparably rated filters from different manufacturers may not have equivalent performance in water filtration applications because of the different filter materials, different fabrication processes, and nonstandardized microbial retention challenge processes currently used for defining the 0.1-µm filter rating. It should be noted that filters with a 0.1-µm rating may result in a lower flow rate compared to 0.2- to 0.22-µm filters, so whatever filters are chosen for a water system application, the user must verify that they are suitable for their intended application, use period, and use process, including flow rate.

For microbial retentive gas filtrations, the same sieving and adsorptive retention phenomena are at work as in liquid filtration, but the adsorptive phenomenon is enhanced by additional electrostatic interactions between the particles and filter matrix. These electrostatic interactions are so strong, particle retention for a given filter rating is significantly more efficient in gas filtration than in water or product-solution filtrations. These additional adsorptive interactions render filters rated at 0.2–0.22 µm unquestionably suitable for microbial retentive gas filtrations. When microbial retentive filters are used in these applications, the membrane surface is typically hydrophobic (non-wettable by water). A significant area of concern for gas filtration is blockage of tank vents by condensed water vapor, which can cause mechanical damage to the tank. Control measures include electrical or steam tracing and a self-draining orientation of vent filter housings to prevent accumulation of vapor condensate. However, a continuously high filter temperature will take an oxidative toll on polypropylene components of the filter, so sterilization of the unit prior to initial use and periodically thereafter, as well as regular visual inspections, integrity tests, and filter cartridge changes, are recommended control methods.

In water applications, microbial retentive filters may be used downstream of unit operations that tend to release microorganisms or upstream of unit operations that are sensitive to microorganisms. Microbial retentive filters also may be used to filter water feeding the distribution system. It should be noted that regulatory authorities allow the use of microbial retentive filters within distribution systems or even at use points if they have been properly validated and are appropriately maintained. A point-of-use filter should only be intended to "polish" the microbial quality of an otherwise well-maintained system and not to serve as the primary microbial control device. The efficacy of system microbial control measures can only be assessed by sampling the water upstream of the filters. As an added measure of protection, in-line UV lamps, appropriately sized for the flow rate (see *5.3 Sanitization*), may be used just upstream of microbial retentive filters to inactivate microorganisms prior to their capture by the filter. This tandem approach tends to greatly delay potential microbial penetration phenomena and can substantially extend filter service life.

### 5.1.10 ULTRAVIOLET LIGHT

The use of low-pressure UV lights that emit a 254-nm wavelength for microbial control is discussed in *5.3 Sanitization*, but the application of UV light in chemical purification is also emerging. This 254-nm wavelength is also useful in the destruction of ozone. At wavelengths around 185 nm (as well as at 254 nm), medium-pressure UV lights have demonstrated utility in the destruction of the chlorine-containing disinfectants used in source water as well as for interim stages of water pretreatment. High intensities of 185 nm alone or 254 nm in combination with other oxidizing ▲sanitizing agents,▲ (USP 1-Dec-2021) such as hydrogen peroxide, have been used to lower TOC levels in recirculating distribution systems. The organics are typically converted to carbon dioxide, which equilibrates to bicarbonate, and incompletely oxidized carboxylic acids, both of which can easily be removed by polishing ion-exchange resins.

Areas of concern include inadequate UV intensity and residence time, gradual loss of UV emissivity with bulb age, gradual formation of a UV-absorbing film at the water contact surface, incomplete photodegradation during unforeseen source water hyperchlorination, release of ammonia from chloramine photodegradation, unapparent UV bulb failure, and conductivity degradation in distribution systems using 185-nm UV lights.

Control measures include regular inspection or emissivity alarms to detect bulb failures or film occlusions, regular UV bulb sleeve cleaning and wiping, downstream chlorine detectors (when used for dechlorination), downstream polishing deionizers (when used for TOC reduction), and regular (approximately yearly) bulb replacement. UV lamps generate heat during operation, which can cause failure of the lamps or increase the temperature of the water. Precautions should be in place to ensure that water flow is present to control excessive temperature increase.

### 5.1.11 DISTILLATION

Distillation units provide chemical and microbial purification via thermal vaporization, mist elimination, and water vapor condensation. A variety of designs is available, including single effect, multiple effect, and vapor compression. The latter two configurations are normally used in larger systems because of their generating capacity and efficiency. Source water controls must provide for the removal of hardness and silica impurities that may foul or corrode the heat transfer surfaces, as well as the removal of those impurities that could volatilize and condense along with the water vapor. In spite of general perceptions, even the best distillation process does not ensure absolute removal of contaminating ions, organics, and endotoxins. Most stills are recognized as being able to accomplish at least a 3–4 log reduction in these impurity concentrations. They are highly effective in sterilizing the feed water.

Areas of concern include carryover of volatile organic impurities such as trihalomethanes (see *2. Source Water Considerations*) and gaseous impurities such as ammonia and carbon dioxide, faulty mist elimination, evaporator flooding, inadequate blow down, stagnant water in condensers and evaporators, pump and compressor seal design, pinhole evaporator and condenser leaks, and conductivity (quality) variations during start-up and operation.

Methods of control may involve the following: preliminary steps to remove both dissolved carbon dioxide and other volatile or noncondensable impurities; reliable mist elimination to minimize feed water droplet entrainment; visual or automated high-water-level indication to detect boiler flooding and boil over; use of sanitary pumps and compressors to minimize microbial and lubricant contamination of feed water and condensate; proper drainage during inactive periods to minimize microbial growth and accumulation of associated endotoxin in boiler water; blow down control to limit the impurity concentration effect in the boiler to manageable levels; on-line conductivity sensing with automated diversion to waste to prevent unacceptable water upon still start-up or still malfunction from getting into the finished water distribution system; and periodic testing for pinhole leaks to routinely ensure that condensate is not compromised by nonvolatilized source water contaminants.

### 5.1.12 STORAGE TANKS

Storage tanks are included in water distribution systems to optimize processing equipment capacity. Storage also allows for routine maintenance within the purification system while maintaining continuous supply to meet manufacturing needs. Design and operation considerations are needed to prevent or minimize the development of biofilm, to minimize corrosion, to aid in the use of chemical sanitization of the tanks, and to safeguard mechanical integrity.

Areas of concern include microbial growth or corrosion due to irregular or incomplete sanitization and microbial contamination from unalarmed rupture disk failures caused by condensate-occluded vent filters.

Control considerations may include the use of closed tanks with smooth interiors, the ability to spray the tank headspace using spray balls on recirculating loop returns, and the use of heated, jacketed/insulated tanks. ▲These minimize▲ (USP 1-Dec-2021) corrosion and biofilm development and ▲aid▲ (USP 1-Dec-2021) in thermal or chemical sanitization. Storage tanks require venting to compensate for the dynamics of changing water levels. This can be accomplished with a properly oriented and heat-traced filter housing fitted with a hydrophobic microbial retentive membrane filter affixed to an atmospheric vent. Alternatively, an automatic membrane-filtered compressed gas blanketing system may be used. In both cases, rupture disks equipped with a rupture alarm device should be used as a further safeguard for the mechanical integrity of the tank.

### 5.1.13 DISTRIBUTION SYSTEMS

Distribution system configuration should allow for the continuous flow of water in the piping by means of recirculation. Use of no recirculating, dead-end, or one-way systems or system segments should be avoided whenever possible. If not possible, these systems should be flushed periodically and monitored more closely. Experience has shown that continuously recirculated systems are easier to maintain. Pumps should be designed to deliver fully turbulent flow conditions to facilitate thorough heat distribution (for hot-water sanitized systems) as well as thorough chemical ▲sanitizing agent▲ (USP 1-Dec-2021) distribution. Turbulent flow also appears to either retard the development of biofilms or reduce the tendency of those biofilms to shed bacteria into the water. If redundant components, such as pumps or filters, are used, they should be configured and used to avoid microbial contamination of the system.

Components and distribution lines should be sloped and fitted with drain points so that the system can be completely drained. In distribution systems, dead legs and low-flow conditions should be avoided, and valved tie-in points should have length-to-diameter ratios of six or less. In systems that operate at self-sanitizing temperatures, precautions should be taken to avoid cool points where biofilm development could occur. If drainage of components or distribution lines is intended as a microbial control strategy, they also should be configured to be dried completely using dry compressed gas because drained but still-moist surfaces will still support microbial proliferation. Water exiting from the distribution system should not be returned to the system without first passing through all or a portion of the purification system.

The distribution design should include the placement of sampling valves in the storage tank and at other locations, such as in the return line of the recirculating water system. Direct connections to processes or auxiliary equipment should be designed to prevent reverse flow into the controlled water system. Hoses and heat exchangers that are attached to points of use to deliver water must not chemically or microbiologically degrade the water quality. The distribution system should permit sanitization for microorganism control. The system may be continuously operated at sanitizing conditions or sanitized periodically.

### 5.1.14 NOVEL/EMERGING TECHNOLOGIES

New water treatment technologies are being developed continuously. Before these technologies are utilized in pharmaceutical water systems, they should be evaluated for acceptable use in a GMP environment. Other considerations should include the treatment process, reliability and robustness, use of added substances, materials of construction, and ability to validate. Consideration should be given to recognize the areas of concern during the evaluation and to identify control measures for the technology. This should include impact on chemical and microbial attributes.

## 5.2 Installation, Materials of Construction, and Component Selection

Installation techniques are important because they can affect the mechanical, corrosive, and sanitary integrity of the system. Valve installation should promote gravity drainage. Pipe supports should provide appropriate slopes for drainage and should be designed to support the piping adequately under worst-case thermal and flow conditions. The methods of connecting system components—including units of operation, tanks, and distribution piping—require careful attention to preclude potential operational and microbial problems.

Stainless steel welds should provide reliable joints that are internally smooth and corrosion-free. Low-carbon stainless steel, compatible wire filler where necessary, inert gas, automatic welding machines, and regular inspection and documentation help to ensure acceptable weld quality. Follow-up cleaning and passivation of metal surfaces after installation are important for removing contamination and corrosion products and to re-establish the passive corrosion-resistant surface.

Plastic materials can be fused (welded) in some cases, and also require smooth, uniform internal surfaces. Adhesive glues and solvents should be avoided due to the potential for voids and organic extractables. Mechanical methods of joining, such as flange fittings, require care to avoid the creation of offsets, gaps, penetrations, and voids. Use of plastic materials may contribute to TOC levels.

Control measures include good alignment, properly sized gaskets, appropriate spacing, uniform sealing force, and the avoidance of threaded fittings.

Materials of construction should be selected to be compatible with control measures such as sanitizing, cleaning, or passivation. Temperature rating is a critical factor in choosing appropriate materials because surfaces may be required to handle elevated operating and sanitization temperatures. If chemicals or additives will be used to clean, passivate, or sanitize the system, materials resistant to these chemicals or additives must be utilized. Materials should be capable of handling turbulent flow and elevated velocities without erosion of the corrosion-resistant film (e.g., the passive chromium oxide surface of stainless steel) or reduction in wall thickness for plastics. The finish on metallic materials such as stainless steel, whether it is a refined mill finish, polished to a specific grit, or an electropolished treatment, should complement the system design and provide satisfactory corrosion and microbial activity resistance. The finish also should be a material that can be chemically sanitized. Auxiliary equipment and fittings that require seals, gaskets, diaphragms, filter media, and membranes should exclude materials that permit the possibility of extractables, shedding, and microbial activity. Insulating materials exposed to stainless steel surfaces should be free of chlorides to avoid the phenomenon of stress corrosion cracking that can lead to system contamination and the destruction of tanks and critical system components.

Specifications are important to ensure proper selection of materials and to serve as a reference for system qualification and maintenance. Information such as the manufacturer's metallurgical reports for stainless steel and reports of composition, ratings, and material-handling capabilities for nonmetallic substances should be reviewed for suitability and retained for reference. Component (auxiliary equipment) selection should be made with assurance that it does not create a source of contamination intrusion. Heat exchangers should be constructed to prevent leakage of heat transfer medium into the pharmaceutical water and, for heat exchanger designs where prevention may fail, there should be a means to detect leakage. Pumps should be of sanitary design with seals that prevent contamination of the water. Valves should have smooth internal surfaces with the seat and closing device exposed to the flushing action of water, such as occurs in diaphragm valves. Valves with pocket areas or closing devices (e.g., ball, plug, gate, globe) that move into and out of the flow area should be avoided.

## 5.3 Sanitization

Microbial control in water systems is achieved primarily through sanitization practices. Systems can be sanitized using either thermal chemical or photochemical means.

### 5.3.1 THERMAL SANITIZATION

Thermal approaches to system sanitization include periodic or continuously circulating hot water and the use of steam. Temperatures of 65°–80° are most commonly used for thermal sanitization. Continuously recirculating water of at least 65° at the coldest location in the distribution system also has been used effectively in stainless steel distribution systems when attention is paid to uniformity and distribution of such self-sanitizing temperatures. These techniques are limited to systems that are compatible with the higher temperatures needed to achieve sanitization. Frequent use of thermal sanitization at appropriate temperatures should eliminate the need for other sanitization methods.

The use of thermal methods at temperatures above 80° is contraindicated because it does not add to microbial control of the system or reduction of biofilm. Some methods (e.g., steam sanitizing, hot water circulation at temperatures ≥100°) can be less effective or even destructive because of the need to eliminate condensate or manipulate system components, stress materials of construction, deform filters, and its adverse impact on instrumentation.

Although thermal methods control biofilm development by either continuously inhibiting its growth or, in intermittent applications, by killing the microorganisms within developing biofilms, they are not effective in removing established biofilms. Killed but intact biofilms can become a nutrient source for rapid biofilm regrowth after the sanitizing conditions are removed or halted. In cases of infrequent thermal sanitizations that allow biofilm development between treatments, a combination of routine thermal treatment and periodic supplementation with chemical sanitization may be more effective. The more frequent the thermal sanitization, the more likely it is that biofilm re-development can be eliminated.

### 5.3.2 CHEMICAL SANITIZATION

Chemical methods, where compatible, can be used on a wider variety of construction materials. These methods typically use oxidizing agents such as ozone, hydrogen peroxide, peracetic acid, or combinations thereof. Halogenated compounds can be effective sanitizers but are less aggressive oxidizing agents and may be difficult to flush from the system. Chemical agents may not penetrate the full biofilm matrix or extend into all biofilm locations (e.g., crevices at gasketed fittings) and may leave

https://nhathuocngocanh.com/

Status: Currently Official on 05-Jan-2024
Official Date: Official as of 01-Dec-2021
DOI Ref: 56bn3
DocId: GUID-07416921-813B-43A7-A494-F190E610AD6F_7_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M99956_07_01
@2024 USPC

biofilms incompletely inactivated. Compounds such as ozone, hydrogen peroxide, and peracetic acid oxidize bacteria and biofilms with reactive peroxides and by forming very reactive free radicals (notably hydroxyl radicals). The short half-life of ozone in particular, and its limitation on achievable concentrations, require that it be added continuously during the sanitization process. Hydrogen peroxide and ozone rapidly degrade to water and/or oxygen, and peracetic acid degrades to oxygen and acetic acid. The ease of degradation of ozone to oxygen using 254-nm UV lights in circulating loops allows it to be used effectively on a continuously sanitizing basis in holding tanks and on an intermittent basis (e.g., daily or weekly) in the distribution loops. The highly reactive nature of ozone requires the use of system materials and components that are even more oxidation resistant than those typically used with the other oxidizing agents.

It is important to note that microorganisms in a well-developed biofilm can be extremely difficult to kill, even by using aggressive oxidizing chemicals. The less developed and therefore thinner the biofilm, the more effective the biofilm inactivation. Therefore, optimal microbial control is achieved by using oxidizing chemicals at a frequency that does not permit significant biofilm development between treatments.

Validation of chemical sanitization requires demonstration of adequate chemical concentrations throughout the system, exposure to all wetted surfaces including the body of use point valves, and complete removal of the ▲sanitizing agent▲ (USP 1-Dec-2021) from the system at the completion of treatment. Methods validation for the detection and quantification of residues of the ▲sanitizing agent▲ (USP 1-Dec-2021) or its objectionable degradants is an essential part of the validation program.

#### 5.3.3 UV SANITIZATION

In-line UV light at a wavelength of 254 nm also can be used to continuously “sanitize” only the water circulating in the system, but these devices must be properly sized for the water flow. Such devices inactivate a high percentage (but not 100%) of microorganisms that flow through the device but cannot be used to directly control existing biofilm upstream or downstream of the device. However, when coupled with conventional thermal or chemical sanitization technologies or located immediately upstream of a microbially retentive filter, UV light is most effective and can prolong the interval between needed system re-sanitizations.

#### 5.3.4 SANITIZATION PROCEDURES

Sanitization steps require validation to demonstrate the ability to reduce and hold microbial contamination at acceptable levels. Validation of thermal methods should include a heat distribution study to demonstrate that sanitization temperatures are achieved throughout the system, including the body of use point valves; sampling ports; instrument side branches; and fittings, couplings, and adapters, relying on water convection and thermal conduction through system materials for heat transfer to wetted surfaces.

The routine frequency of sanitization should be supported by the results of system microbial monitoring. Conclusions derived from trend analysis of the microbiological data should be used as the alert mechanism for the need for extraordinary maintenance. The routine frequency of sanitization should be established in such a way that the system operates in a state of microbiological control and does not regularly exceed Alert and Action Levels (see *9.4 Defining Alert and Action Levels and Specifications*).

### 5.4 Operation, Maintenance, and Control

A preventive maintenance program should be established to ensure that the water system remains in a state of control. The program should include 1) procedures for operating the system, 2) monitoring programs for critical quality attributes and operating conditions including calibration of critical instruments, 3) schedule for periodic sanitization, 4) preventive maintenance of components, and 5) control of changes to the mechanical system and to operating conditions.

#### 5.4.1 OPERATING PROCEDURES

Operating procedures for the water system and for performing routine maintenance and corrective action should be written, and they should also define the point when action is required. The procedures should be well documented and should detail the function of each job, assign who is responsible for performing the work, describe how the job is to be done, and identify acceptable operating parameters. The effectiveness of these procedures should be assessed during water system validation.

#### 5.4.2 PROCESS MONITORING PROGRAM

A process-monitoring program should establish the critical quality attributes and operating parameters that are documented and monitored. The program may include a combination of in-line sensors and/or automated instruments (e.g., for temperature, TOC conductivity, hardness, and chlorine), automated or manual documentation of operational parameters (e.g., flow rates or pressure drop across a carbon bed, filter, or reverse osmosis unit), and laboratory tests (e.g., total microbial counts). The frequency of sampling, the requirement for evaluating test results, and the necessity of initiating corrective action should be included.

#### 5.4.3 ROUTINE MICROBIAL CONTROL

Sanitization may be integral to operation and maintenance, and necessary on a routine basis, depending on system design and the selected units of operation, to maintain the system in a state of microbial control. Technologies for sanitization are described above in more detail in *5.3 Sanitization*.

#### 5.4.4 PREVENTIVE MAINTENANCE

A preventive maintenance program should be in effect. The program should establish what preventive maintenance is to be performed, the frequency of maintenance work, and how the work should be documented.

#### 5.4.5 CHANGE CONTROL

The mechanical configuration, operating conditions, and maintenance activities of the water system must be controlled. Proposed changes should be evaluated for their impact on the whole system. The need to requalify the system after changes are made should be determined. After a decision is made to modify a water system, the affected drawings, manuals, and procedures should be revised. Portions or operations of the water system that are affected by the modification should be tested to demonstrate a continued state of control. The extent and duration of testing should be related to the risk impact of the change to the system.

## 6. SAMPLING

The testing of water samples from a water system is critical to the ongoing control of the system and assessment of the quality of the water being used. If improperly collected, a sample could yield a test result that is unrepresentative of the sample's purpose. This could lead to inaction when remediation is needed or to unnecessary remediation when none is necessary. It could also lead to misinterpretations of product impact. Therefore, properly collecting water samples, understanding their purpose, and establishing appropriate water system sampling plans are essential to water QC and system control.

### 6.1 Purposes and Procedures

To assess a particular water attribute, a sample of the water usually must be removed from a water system for specific attribute testing. The sample needs to be obtained from specific locations that are representative for the purpose being monitored. This sample may be analyzed by in-line/on-line instruments or it may be completely removed from the system as a "grab sample" in a container for off-line testing. In-line/on-line testing avoids the exogenous contamination potential of grab samples that could lead to artifactually variable data trends and incorrect decisions on system performance, maintenance, and utilized water, as well as initiating fruitless causative investigations. Grab samples may be appropriate where the water in the system is not homogeneous for certain attributes.

The data from water testing are generally used for one of two purposes: for PC of the water purification and distribution system or for release or QC of the water being drawn from the system for some application or use. In many cases, depending on the sampling location and sampling process, the resulting data can be used for both PC and QC purposes.

#### 6.1.1 PROCESS CONTROL SAMPLING

Because PC sampling is intended to reflect the quality of the water behind the valve and within the distribution system, coming from the purification system, or between its purification steps, efforts should be made to avoid contaminating the water as it is drawn from the system so that its test results accurately reflect the water quality within the system at that location. This may require the use of strategically located sampling ports, in addition to points of use.

If microbial testing is needed for PC purposes, the sampling valve should have a properly installed, sanitary design that uses vigorous pre-sampling flushing. This flushing shears off fragile biofilm structures growing on surfaces within the valve and water path before the sample is collected. This avoids biasing the microbial count of perhaps pristine water in the system behind that valve. A fully open valve flush (at >8 ft/s velocity within the valve and connector) for at least 30 s typically provides sufficient shear forces to adequately remove any fragile biofilm structures. Additional control measures for preventing sample contamination could also include stringent pre- and post-sampling outlet sanitation, the use of sterile hoses and gaskets or other connectors to direct the water flow, and other measures.

The data from PC sampling indicate how well the system is maintaining the water quality at that sampling location. These data are subsequently used to signal when some extraordinary intervention might be needed, in addition to normal maintenance and system sanitization operations, to restore the system to the expected level of purity.

PC sampling can only be used to indicate the quality of the water being delivered to the points of use (for QC purposes) if it has been shown to be representative of that point-of-use quality. This may be possible with chemical attributes that are typically not affected by the fluid path of the water delivery process, but is generally not possible with microbial attributes, which can be greatly affected by localized biofilms along that fluid path. If this fluid path is not utilized for PC sampling, then the resulting data typically cannot be used for QC purposes.

#### 6.1.2 QUALITY CONTROL SAMPLING

QC sampling is intended to reflect the quality of water that is being used. These samples should be collected at the true point of use; that is, where the water is delivered for use, not where it leaves the water system. QC sampling must utilize that same delivery path and components utilized for a water transfer during actual water use. This includes the same valves, hoses, heat exchangers, flow totalizers, hard-piped connections, and other components utilized during water use.

In addition to the water transfer components, QC sampling must also use the same water transfer process employed during water use, including the same pre-use outlet and delivery path flushing procedure and the same outlet, fitting, and hose sanitization practices employed during actual water use. The water delivery process and components used for QC sampling must be identical to manufacturing practices at every system outlet for the QC sample to mimic the quality of water being used by accumulating the same chemical and microbial contaminant levels it would during actual use from that outlet location.

Where permanent connections from the water system to equipment are present, accommodation should be made in the design to collect samples from locations as close to the equipment as possible. For example, samples can be collected from special sample ports or other valves near the equipment connection that allow the collected water sample to accurately reflect the water quality that is used. Where the water transfer conduit is designed and/or definitively treated to eliminate all contaminating influences prior to water transfer through that conduit, PC sampling locations within the distribution system can reflect the quality of the water that is actually used for QC purposes at those permanent connections. However, the success of the design and treatments intended to eliminate these contaminating influences must be verified. This is typically done during water system validation.

Where routine water use practices involve contamination-prone activities, such as no pre-use flushing or poor hose storage/sanitization/replacement practices, these water use practices should be improved to reduce the potential for delivering contaminated water from the water system and for unacceptable QC sample testing results that reflect that same contamination.

## 6.2 Attributes and Sampling Locations

The tests being performed on the samples are relevant to the sampling location and purpose of the sample. In-process monitoring of non-monograph attributes may be indicated for specific unit operations. For instance, before and after a softener, it may be important to determine water hardness to verify softener efficacy. Before and after an activated carbon bed/filter, it may be important to verify chlorine or TOC removal and/or reduction or test for an increase in microbial count. Before a distillation unit, it may be important to quantitate the incoming bacterial endotoxin level to ensure that the still is not being over-challenged beyond its typical 3–4 log purification capability. However, once the water is in the distribution system, the compendial attributes of importance typically include at least conductivity, TOC, and microbial count. In Water for Injection systems and other systems or system locations where bacterial endotoxin control is important, endotoxin is also assayed. Other tests may be necessary depending on the intended uses of the water.

### 6.2.1 CHEMICAL ATTRIBUTES

Dissolved chemical contaminants detected by conductivity or TOC testing tend to be uniformly distributed in the water throughout the water system. However, there are exceptions where localized chemical contamination sources can occur, such as from a coolant-leaking heat exchanger in a sub-loop, or at a point of use, or within a dead leg. These chemical contaminants may only be seen at the associated outlets and not systemically. However, in the absence of localized contamination influences, chemical attributes are candidates for on-line testing at fixed strategic locations within the distribution system, such as near a circulating loop return, and are generally reflective of the same chemical quality at all locations and points of use within the distribution system. Nevertheless, the suitability of the on-line locations of these instruments for QC release purposes must be verified as being representative of the use-point water quality. This is usually done during water system validation.

### 6.2.2 MICROBIAL ATTRIBUTES

The same uniformity scenario cannot be assumed for microbial attributes. Planktonic organisms in a water sample could have originated from biofilms in the purification or distribution systems releasing more or less uniform levels of planktonic organisms into the circulating water, as detectable in samples from all outlets. However, a local biofilm developing within a water delivery conduit (e.g., a use-point outlet valve and transfer hose) in an otherwise pristine biofilm-free water system could release planktonic organisms detectable only in water delivered through that conduit. Therefore, QC release samples for assessing the quality of water that is delivered by the system during water use must be collected after the water has traversed the same fluid conduit (including the same preparatory activities such as outlet sanitization and pre-flushing) from the water distribution system to the specific locations where the water is used.

On-line microbial water sampling/testing has value in pharmaceutical water systems only for PC purposes unless the water is taken from the point of use in the same manner as routine water usage, in which case the data can also have a QC release purpose. Microbial counts detected from strategic sampling ports continue to have PC and investigational value, but generally cannot be substituted for QC release testing except in certain scenarios, as described in *6.1.2 QC Sampling*.

## 6.3 Validation Sampling Plans

The initial sampling plan for a pharmaceutical water system is usually developed for a validation program (see *4. Validation and Qualification of Water Purification, Storage, and Distribution Systems*). This strategy is for characterization of the system's ability to purify, distribute, and deliver pharmaceutical water. Typically, the initial validation sampling is for a short duration (e.g., at least 2–4 weeks) at a high sampling frequency to generate a significant body of data that will allow detection of short-term or localized chemical or microbial quality deviations from all outlets. These data provide an initial assessment of system performance to guide decisions about using the water for operational purposes.

The initial validation sampling plan is re-evaluated when the pharmaceutical water is placed into operation, typically to reduce the amount of data being generated while not compromising the ability to identify anomalous operations/events, especially during the early life cycle of the water system. In the absence of such quality deviations during the initial sampling period, the sampling frequency can be lessened for a period of time (e.g., at least 2–4 additional weeks) to ensure that somewhat longer-term adverse quality trends are not apparent. During this second period of time, the water may be considered for at-risk routine use, pending the acceptable completion of the second validation sampling period. After successful completion, monitoring can be eventually lessened again to what will become the routine sampling plan.

Periodic review of the water system operation and monitoring needs to be performed to assess seasonal source water variability, effectiveness of sanitization, and routine maintenance events. Periodic review should be performed during the complete life cycle of the water system, typically annually, for evidence of longer-term data trends and quality deviations.

The routine sampling plan should be re-evaluated periodically based on the available data to determine the appropriate frequency and sample locations. This review offers an opportunity to improve data evaluation and reduce workloads based on what that data indicate relative to process and QC. The routine sampling plan should have a rationale for the frequency and locations that are selected to justify how the resulting data will be used to characterize the overall operation of the system and the release of the water for use.

## 6.4 Routine Sampling Plans

### 6.4.1 SOURCE WATER SAMPLING

As mentioned in earlier sections, the source water for pharmaceutical water systems must comply with the standards for one of the drinking waters listed in the associated compendial water monograph or in *General Notices*. When a municipality or other water authority is providing this drinking water, they are required to comply with the local drinking water regulations for the water supplied to a drinking or potable water distribution piping grid for that region. The quality of that water by the time it reaches the pharmaceutical user is dependent on a number of factors, including distance from the input source, duration of travel within the piping, and condition of the piping in that potable water distribution grid, any of which could have adversely affected some of its initial chemical and/or microbial attributes. Based on a risk assessment, it may be prudent to verify full compliance with regulations using water collected from sample ports prior to the pretreatment system, or other equivalent drinking water outlets within the facility. If the water complies, then continued assurance of compliance could be verified using drinking water regulation test results provided by the water authority or by periodic retesting of selected or all the drinking water attributes by the user or by both the user and the water authority. If private sourced water is utilized, it is the user's responsibility to demonstrate full drinking water regulation compliance, using water samples from such sampling ports on a periodic basis as determined by a risk analysis.

These pre-pretreatment sampling ports could be used, at the user's discretion, to periodically monitor other source water attributes that could affect specific pretreatment or purification unit operations. Depending on the user's source water quality consistency and a risk assessment of its potential impact on the purification process, the periodically monitored attributes could include microbial count, absence of coliforms, bacterial endotoxin levels, conductivity, TOC, pH, hardness, chlorine, silica, turbidity or silt density index, and others. These data could be useful in investigations and for operational adjustments to critical unit operation parameters and maintenance procedures, or for feedback to the potable water provider if unusual trends are observed.

### 6.4.2 PRETREATMENT AND PURIFICATION SYSTEM SAMPLING

The location and frequency of sampling from ports within the pretreatment and purification systems may be selected based on a risk analysis of unit operation purpose. For example, the purpose of this sampling for PC is primarily to ensure maintenance of acceptable unit operation performance, to assess maintenance procedure efficacy, and to investigate the need for remedial action. Quality deviations in the early portions of the purification process can affect unit operation efficiency but usually do not affect the finished water quality or acceptable use.

### 6.4.3 PURIFIED WATER DISTRIBUTION SYSTEM SAMPLING

Purified Water distribution system sampling is intended to provide continuing assurance of ongoing PC and compliance with the user's finished water chemical and microbiological requirements. Generally, the locations for that sampling and the frequency of testing the specific attributes are a matter of process and QC consistency, as well as risk tolerance in the event of a deviation.

Depending on the water system design, the chemical attributes of a water system tend to be relatively constant and more uniformly distributed than the microbiological attributes. Therefore, less frequent sampling at only selected locations could be justified for chemical testing based on familiarity with system design and the existence of historically consistent operational data. However, with some purification system designs, the chemical quality could change dramatically in a short period of time (e.g., from the exhaustion of deionization beds), so frequent or even continuous in-line/on-line monitoring of the chemical attributes would be advisable to be able to recognize and correct the cause of the problem before non-compliant water is produced and used.

For microbial testing, all use points and critical sample ports in a distribution system are typically sampled routinely, including those that are infrequently used by manufacturing. There is no prescribed sampling frequency for Purified Water system outlets, so typical outlet sampling frequencies vary from daily to monthly, with sampling occurring somewhere in the system at least at weekly intervals.

A risk analysis is suggested for determining the sampling plan for a Purified Water system. Factors in this analysis could include (but are not limited to) the test result history for the entire water system as well as specific outlets, the criticality of specific outlets to manufacturing, the usefulness of selected sample ports as indicators of ongoing system control, and the scope of impact on products and activities should an unfavorable test result occur. For the scope of impact, the less frequent the sampling, the more products and processes will be affected by an unfavorable test result.

### 6.4.4 WATER FOR INJECTION DISTRIBUTION SYSTEM SAMPLING

The sampling plans for Water for Injection distribution systems (as well as any water system where some level of bacterial endotoxin control is needed) utilize the same general sampling approaches as do Purified Water systems. However, the regulatory expectations for Water for Injection distribution system sampling plans are more prescriptive because microbial control must be much more stringent as it is related to the bacterial endotoxin attribute. In general, water sampling for microbial

@2024 USPC

and bacterial endotoxin testing is expected to occur daily somewhere in the system, with each outlet being sampled periodically, based on a risk assessment, to characterize the quality of the water.

### 6.5 Non-Routine Sampling

Non-routine sampling also can be performed on the water system for episodic events or reasons for which the routine sampling plans are insufficient to capture the needed information. Examples include change control purposes such as evaluating potential changes to sampling, testing, maintenance procedures, or system design; data or event excursion investigation purposes; or simply for long-term informational purposes and establishing baselines for future investigational value. The purpose of the non-routine sampling dictates the sampling procedures to be used, the attributes to be tested, and the location and repeating occurrence (if any) of that testing. It also should be noted that such non-routine sampling may be done from sampling ports that may or may not be routinely tested. Sampling ports can be positioned in a water system purely for investigational, non-routine sampling, and as such, they do not need to be part of a routine sampling plan.

## 7. CHEMICAL EVALUATIONS

### 7.1 Chemical Tests for Bulk Waters

The chemical attributes of *Purified Water* and *Water for Injection* that were in effect prior to *USP 23* were specified by a series of chemistry tests for various specific and nonspecific attributes with the intent of detecting chemical species indicative of incomplete or inadequate purification. Although these methods could have been considered barely adequate to control the quality of these waters, they nevertheless stood the test of time. This was partly because the operation of water systems was, and still is, based on on-line conductivity measurements and specifications generally thought to preclude the failure of these archaic chemistry attribute tests.

In 1996, USP moved away from these chemical attribute tests, switching to contemporary analytical technologies for the bulk waters Purified Water and Water for Injection. The intent was to upgrade the analytical technologies without tightening the quality requirements. The two contemporary analytical technologies employed were TOC and conductivity. The TOC test replaced the test for *Oxidizable Substances* that primarily targeted organic contaminants. A multi-staged conductivity test that detects ionic (mostly inorganic) contaminants replaced, with the exception of the test for *Heavy Metals*, all of the inorganic chemical tests (i.e., *Ammonia*, *Calcium*, *Carbon Dioxide*, *Chloride*, *Sulfate*).

Replacing the heavy metals attribute was considered unnecessary because 1) the source water specifications (found in the US EPA NPDWR) for individual heavy metals were tighter than the approximate limit of detection of the *Heavy Metals* test for *USP XXII* Water for Injection and Purified Water (approximately 0.1 ppm), 2) contemporary water system construction materials do not leach heavy metal contaminants, and 3) test results for this attribute have uniformly been negative. There has not been a confirmed occurrence of a singular test failure (failure of only the *Heavy Metals* test with all other attributes passing) since the current heavy metal drinking water standards have been in place.

*Total Solids* and *pH* were the only tests not covered by conductivity testing. The test for *Total Solids* was considered redundant because the nonselective tests of conductivity and TOC could detect most chemical species other than silica, which could remain undetected in its colloidal form. Colloidal silica in Purified Water and Water for Injection is easily removed by most water pretreatment steps, and even if present in the water, it constitutes no medical or functional hazard except in extreme and rare situations. In such extreme situations, other attribute extremes are also likely to be detected. It is, however, the user's responsibility to ensure fitness for use. If silica is a significant component in the source water, the purification unit operations could fail and selectively allow silica to be released into the finished water (in the absence of co-contaminants detectable by conductivity);therefore, either silica-specific testing or a total-solids type testing should be utilized to monitor for and control this rare problem.

The *pH* attribute was eventually recognized to be redundant to the conductivity test (which included *pH* as an aspect of the test and specification); therefore, *pH* was discontinued as a separate attribute test.

The rationale used by USP to establish its Purified Water and Water for Injection conductivity specifications took into consideration the conductivity contributed by the two least-conductive former attributes of *Chloride* and *Ammonia*, thereby precluding their failure had those wet chemistry tests been performed. In essence, the *Stage 3* conductivity specifications (see ⟨ 645⟩ , *Bulk Water, Procedure, Stage 3*) were established from the sum of the conductivities of the limit concentrations of chloride ions (from pH 5.0 to 6.2) and ammonia ions (from pH 6.3 to 7.0), plus the unavoidable contribution of other conductivity-contributing ions from water ($H^+$ and $OH^-$), dissolved atmospheric carbon dioxide [as bicarbonate ($HCO_3^-$)], and an electro-balancing quantity of either sodium ($Na^+$) or chlorine ($Cl^-$), depending on the pH-induced ionic imbalance (see *Table 1*). The *Stage 2* conductivity specification is the lowest value in this table, 2.1 µS/cm. The *Stage 1* specifications, designed primarily for on-line measurements, were derived by essentially summing the lowest values in individual ($H^+$, $OH^-$, $HCO_3^-$) and group ($Cl^-$, $Na^+$, $NH_4^+$) contributing ion columns for each of a series of tables similar to *Table 1*, created for each 5° increment between 0° and 100°. For purpose of an example, the italicized values in *Table 1*, the conductivity data table for 25°, were summed to yield a conservative value of 1.3 µS/cm, the *Stage 1* specification for a nontemperature-compensated, nonatmosphere-equilibrated water sample that actually had a measured temperature of 25°–29°. Each 5° increment in the table was similarly treated to yield the individual values listed in the *Stage 1* specifications (see ⟨ 645⟩ , *Table 1*).

▲Although *Stage 1* is intended for on-line measurement, it can be used off-line provided it is understood that the sample is subject to contamination by absorption of atmospheric carbon dioxide ($CO_2$), which will result in higher conductivities than on-line measurements. This absorption results in the formation of conductive ions, hydrogen ($H^+$) and bicarbonate ($HCO_3^-$). The quantity of the increase is dependent on the temperature, surface exposure, ambient carbon dioxide concentration, and amount of time the water sample is exposed to air, but the absorption begins immediately upon contact with air. The

DOI: https://doi.org/10.31003/USPNF_M99956_07_01
@2024 USPC

conductivity will vary with time unless a steady state is achieved. These higher conductivities may not pass the *Stage 1* test requirements, which in turn would require the performance of *Stage 2* and possibly *Stage 3* testing to achieve a passing result. If the off-line tested sample passes *Stage 1*, no further work is needed because *Stage 1* is not subject to false negatives—only false positives. Consequently, because of the variable influence of atmospheric carbon dioxide from sample to sample, these off-line *Stage 1* test results should not be used for trending purposes because they do not accurately reflect water system performance.▲ (USP 1-Dec-2021)

**Table 1. Contributing Ion Conductivities of the Chloride-Ammonia Model as a Function of pH (in atmosphere-equilibrated water at 25°)**

| | Conductivity (µS/cm) | | | | | | | |
|---|---|---|---|---|---|---|---|---|

| 6.9 | 0.04 | 0.02 | 1.56 | 0 | 0.93 | 1.22 | 3.77 | 3.8 |
| *7* | *0.03* | 0.02 | 1.97 | 0 | 1.39 | 1.22 | 4.63 | 4.6 |

As stated above, this rather radical change to utilizing a conductivity attribute as well as the inclusion of a TOC attribute allowed for on-line measurements. This was a major philosophical change and allowed industry to realize substantial savings. The TOC and conductivity tests also can be performed off-line in the laboratories using collected samples, although sample collection tends to introduce opportunities for adventitious contamination that can cause false high readings. The collection of on-line data is not, however, without challenges. The continuous readings tend to create voluminous amounts of data, where previously only a single data point was available. As stated in *6. Sampling*, continuous in-process data are excellent for understanding how a water system performs during all of its various usage and maintenance events in real time, but this is too much data for QC purposes. Instead, one can use a justifiable portion of the data (at a designated daily time or at the time of batch manufacturing) or the highest value in a given period as a worst case representation of the overall water quality for that period. Data averaging is generally discouraged because of its ability to obscure short-lived extreme quality events.

## 7.2 Chemical Tests for Sterile Waters

Packaged/sterile waters present a particular dilemma relative to the attributes of conductivity and TOC. The package itself is the major source of chemicals (inorganics and organics) that leach over time into the packaged water and can easily be detected by the conductivity and TOC tests. The ▲historic test for▲ (USP 1-Dec-2021) "organic purity" ▲in▲ (USP 1-Dec-2021) bulk and packaged ▲waters was the *Oxidizable Substances* test. The▲ (USP 1-Dec-2021) insensitivity of that test to many of the organic leachables from plastic and elastomeric packaging materials was largely unrecognized, allowing organic levels in ▲some▲ (USP 1-Dec-2021) packaged/sterile waters to be ▲historically▲ (USP 1-Dec-2021) quite high (possibly ▲as much as 10- to 100-fold higher than▲ (USP 1-Dec-2021) the TOC specification for bulk water).

Similarly, glass containers can also leach inorganics, such as sodium, which are easily detected by conductivity ▲and not▲ (USP 1-Dec-2021) detected by the former wet chemistry attribute tests. Most of these ▲inorganic▲ (USP 1-Dec-2021) leachables are considered harmless based on current perceptions and standards at the ▲low▲ (USP 1-Dec-2021) concentrations present.

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M99956_07_01
@2024 USPC

Nevertheless, ▲both organic and inorganic leachables▲ (USP 1-Dec-2021) degrade the quality of the high-purity waters placed into these packaging systems. Some packaging materials contain more leachables than others and may not be as suitable for ▲some applications as other packaging systems. Not all packaging materials are suitable for holding bulk water.

Because Sterile Water for Injection is Water for Injection that has already met its monographed requirements for low conductivity and TOC, the Sterile Water for Injection▲ (USP 1-Dec-2021) attributes of conductivity and TOC ▲▲ (USP 1-Dec-2021) reveal more about the packaging leachables than they do about the water's original purity. ▲The historically ▲ (USP 1-Dec-2021) "allowed" leachables ▲(due to the insensitivity and selective reactivity of the historic water purity tests)▲ (USP 1-Dec-2021) could render the sterile packaged ▲waters▲ (USP 1-Dec-2021) unsuitable for many uses where the bulk waters are perfectly adequate. ▲Therefore, usage of these packaged waters for analytical, manufacturing, and cleaning applications should be only exercised after the purity of the water for the application has been confirmed and documented as suitable for its intended use.

### 7.2.1 CONDUCTIVITY FOR STERILE WATERS

To better control the ionic packaging leachables, ⟨ 645⟩ is divided into two sections. The first, ⟨ 645⟩ , *Bulk Water*, applies to *Purified Water*, *Water for Injection*, *Water for Hemodialysis*, and *Pure Steam*, and includes the three-stage conductivity testing instructions and specifications. The second, ⟨ 645⟩ , *Sterile Water*, applies to *Sterile Purified Water*, *Sterile Water for Injection*, *Sterile Water for Inhalation*, and *Sterile Water for Irrigation*. The *Sterile Water* section includes a conductivity testing approach similar to ⟨ 645⟩ , *Bulk Water, Procedure, Stage 2* because it is intended as a laboratory test. Because these sterile waters were made from bulk water that already complied with the 3-stage conductivity test, the packaging leachables are the primary target analytes of the conductivity specifications in ⟨ 645⟩ , *Sterile Water*.The effect on potential leachables concentrations as a function of surface area-to-volume ratio differences of different container sizes is the rationale for having two different specifications: one for small packages containing nominal volumes of 10 mL or less and another for larger packages. These conductivity specifications are harmonized with the *European Pharmacopoeia* conductivity specifications for Sterile Water for Injections. All *USP* monographed waters, except Bacteriostatic Water for Injection, have a conductivity specification that directs the user to either ⟨ 645⟩ , *Bulk Water* or ⟨ 645⟩ , *Sterile Water*. For the sterile packaged water monographs, this water conductivity specification replaces the previous wet chemistry limit tests intended for inorganic contaminants that had been previously specified in these monographs prior to *USP 32* (May 1, 2009).

### 7.2.2 TOTAL ORGANIC CARBON FOR STERILE WATERS

Controlling the organic purity of these sterile packaged waters, particularly those in plastic packaging, is more challenging. The TOC test can better detect these impurities and therefore can be better used to monitor and control these impurities than the previous *Oxidizable Substances* test prior to *USP 23 Supplement 5*.

Therefore, to better control the organic packaging leachables, *Total Organic Carbon* ⟨ 643⟩ is divided into two sections, similar to ⟨ 645⟩ . The first section, ⟨ 643⟩ , *Procedures, 1. Bulk Water*, applies to *Purified Water*, *Water for Injection*, *Water for Hemodialysis*, and condensate form of *Pure Steam*. The second section, ⟨ 643⟩ , *Procedures, 2. Sterile Water*, applies to *Sterile Purified Water*, *Sterile Water for Injection*, *Sterile Water for Inhalation*, and *Sterile Water for Irrigation*.

The effect on potential leachables concentrations as a function of surface area-to-volume ratio differences of different container sizes is the rationale for having different container volume-based specifications for TOC. Low volume containers (<5 mL) that are intended for single administration (e.g., syringes) have a higher surface area-to-volume ratio than large volume packages (e.g., intravenous packages). This results in potentially high concentrations of leachables appearing in the smaller doses/packages. Additionally, packages like prefilled syringes may have innocuous organic silicone-based plunger lubricants contributing to the water TOC. A volume breakpoint was also created for intermediate-sized containers at 100 mL [for containers between 5 and 100 mL] as one group and then for large volume parenteral (LVP) containers larger than 100 mL. Therefore, there are three TOC specifications that are related to the volume of the container and created by the volume ranges for breakpoints at 5 mL and again at 100 mL.

The rationale for establishing staged limits for organic carbon concentration from low to high volume containers is based on the smaller patient doses being administered from the smaller containers. (Dose is proportional to the container size.) The actual dose of leachables administered to a patient would be higher from the large volume containers.

The specification for each nominal container volume has two limit response levels. This is to limit the maximal potential leachables for a particular packaging type and volume that could be considered acceptable. If the TOC response is NMT limit response 1, the sample meets the test requirements with no further justification of acceptability needed. If the TOC response exceeds limit response 1, it is compared to limit response 2. If the response exceeds limit response 2, the sample does not meet the test requirements, the test is ended, and the sample fails.

If the response is more than limit response 1 and less than limit response 2, then a further justification of suitability is needed. That justification requires the identification and quantification of each individual organic impurity whose carbon composition exceeds a concentration of 0.20 mg/L of carbon. If no individual impurities exceed 0.20 mg/L of carbon, the water sample meets the test requirements.

For individual impurities that exceed 0.20 mg/L of carbon, their dose to the patient must be evaluated for its impact on patient safety based on toxicological studies whose publications must be cited. The water sample meets the test requirements if all such impurities are identified and quantified and their patient doses are deemed safe and documented. The water sample does not meet the test requirements if one of the following two results occur:

1. Any of the impurities at greater than 0.20 mg/L of carbon are not identified or quantified
2. Any of such impurities do not have referenced toxicological/safety documentation for the patient doses received

These test requirements apply to individual batches of product. They cannot be broadly applied to a given product or container type or grandfathered as acceptable by previously approved packaging configurations. The rationale for this requirement lies in the composition of the leachables that can be variable from batch to batch and even unit to unit of a given batch of product, depending on the PC used for the packaging fabrication and component assembly processes. In addition, there can be variability in the polymeric resin raw material composition used in some of the packaging components based on

@2024 USPC

batch-to-batch variability or variability between suppliers of the same raw material. Therefore, the product batch sampling plan must be able to detect these potential variabilities, if present.

The system suitability for the TOC testing must be performed using the concentration that corresponds to the highest TOC concentration for the container volume that could be considered acceptable for a given batch of product. This corresponds to limit response 2 for the corresponding nominal container volume.

Additional testing considerations include the following:

1. Vigorous shaking of the container is needed prior to withdrawing a sample in order to release superficial organic residues from the internal surfaces of the containers.
2. Each sampled container must be individually tested and compared to the specification.
3. Pooling of container contents may be needed *only* when individual containers do not contain enough volume to be tested individually. In such cases, the lowest number of containers needed to achieve the minimal pooled volume required by the testing apparatus should be used.▲ (USP 1-Dec-2021)

## 7.3 Storage and Hold Times for Chemical Tests

Because of the homogeneous nature of chemical impurities in water, the storage requirements and impact of holding times are very practically determined, unlike the challenges of microbial impurities. In general, the chemical purity of high-purity water samples can only degrade over time, possibly generating a failed result of the sample that would have passed if it were tested immediately or on-line. The general fact is that the longer samples are stored, the greater the potential to be adversely affected by containers or conditions.

For off-line chemical tests ▲for▲ (USP 1-Dec-2021) waters, there are no compendial requirements for storage time and conditions. However, the general recommendation is to perform testing as soon as practical to avoid false adverse results. Where possible, store ▲water samples in▲ (USP 1-Dec-2021) cool ▲conditions▲ (USP 1-Dec-2021) and measure as quickly as practical. This reduces the chances that a water sample gets contaminated over time, and this would reduce unwarranted and unnecessary investigations of false positives.

### 7.3.1 CONTAINERS

When sampling water for off-line analysis, the selection and cleanliness of the container play a significant part in obtaining accurate data. For samples to be tested for chemical impurities according to ⟨ 643⟩ and ⟨ 645⟩ , the proper container should be one that does not contaminate the sample during the storage/hold time. For example, the use and preparation of glass containers could be very acceptable for storing samples for TOC testing, but some glass containers do leach ions over time (hours and days), and they can adversely affect a conductivity test by creating a false positive result—if the storage time is too long. Likewise, there are some polymer materials that can adversely affect the TOC chemical impurity in water. However, many polymer materials are very inert.

In any case, cleanliness of the container is crucial because trace quantities of soaps and fingerprints will adversely affect the chemical purity of the water. Properly cleaned containers are acceptable because chemical impurities are easily rinsed away. Extensive chemical cleaning methods such as acid or caustic rinsing should never be needed. If they are needed, consider replacing the containers.

### 7.3.2 STORAGE TIME AND CONDITIONS

There are no specific recommendations for storage of samples for water analyses. If there is some trace interaction of the container and water, then generally colder and shorter storage times are better than warmer and longer storage times. Chemical dissolution and reactivity are usually enhanced by increased temperature. Furthermore, time is always an element because the water sample can only get worse in a container, and it never gets better with time.

## 7.4 Elemental Impurities in Pharmaceutical Waters

Elemental impurities (EI) have the most restrictive limits for Water for Injection used in manufacturing parenterals, in particular large-volume injections (see *Injections and Implanted Drug Products* ⟨ 1⟩ for a definition of large-volume injections) because of the large dose. The most restrictive permissible daily exposure (PDE) of EI resides with lead, mercury, cadmium, and arsenic. Other EI listed in ⟨ 232⟩ permit a substantially higher PDE, and are therefore less restrictive.

Water that meets US EPA NPDWR or WHO Drinking Water Guidelines that has been purified by conventional technologies used to produce Water for Injection can comply with ⟨ 232⟩ for parenterals.

*Table 2* shows that source water that meets US EPA NPDWR or WHO Drinking Water Guidelines has maximum contaminant levels (concentration) for lead, mercury, cadmium, and arsenic that are NMT 10 times (1-log) higher than the EI limits for parenterals, based on a daily dose of 2000 mL. For a smaller volume injection, the allowed parenteral daily dose of EI is correspondingly higher. The purification technologies needed to produce Water for Injection that reduce the impurities by a factor of 100 to 1000 will assure compliance with ⟨ 232⟩ , provided no elemental impurities are added during processing, packaging, delivery, or storage.

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M99956_07_01
@2024 USPC

**Table 2. Elemental Impurity Limits for Drug Products and Their Water Components per** ⟨ 232⟩

| Element | Parenteral PDE (µg/day) | Parenteral Daily Dose (µg/mL[a]) | US EPA National Primary Drinking Water Regulations (µg/mL[b]) | WHO Drinking Water Guidelines (µg/mL[b]) | Result of 2-Log Reduction of EI Concentration for Water for Injection (µg/mL[c]) |
|---|---|---|---|---|---|
| Cadmium | 2 | 0.001 | 0.005 | 0.003 | 0.00005 |
| Lead | 5 | 0.0025 | 0.015 | 0.01 | 0.00015 |
| Inorganic arsenic | 15 | 0.0075 | 0.01 | 0.01 | 0.0001 |
| Inorganic mercury | 3 | 0.0015 | 0.002 | 0.006 | 0.00006 |

[a] Concentration based on a daily dose of 2000 mL, and all drug product elemental impurities coming from the water component.
[b] Drinking Water regulations state these Maximum Contaminant Levels (MCLs) as mg/L, which equals µg/mL or ppm.
[c] Determined from the greater of the US EPA regulations column and WHO guidelines column for each element, and then divided by 100 (2-log).

Chemical purification technologies for Purified Water are similarly efficient in removing EI as those for Water for Injection production. Because all sterile waters are prepared from Purified Water or Water for Injection, the assurance of compliance to ⟨ 232⟩ extends to sterile waters, provided no elemental impurities added are during processing, packaging, delivery, or storage.

Further discussion can be found in *Pharmacopeial Forum* (*1*).

# 8. MICROBIAL EVALUATIONS

This section presents a discussion about the types and sources of microorganisms and whether certain microbes are prone to colonize pharmaceutical water systems. This section also addresses microbiological examination of water samples, including a discussion on recovery methods.

## 8.1 Microorganism Types

Microorganisms are ubiquitous and their natural habitats are extremely diverse. Based on comparative ribosomal RNA sequencing, the phylogenetic tree of life consists of three domains: Bacteria and Archaea (both prokaryotes), and Eukarya (eukaryotes). Most microorganisms that contaminate pharmaceutical products are prokaryotic bacteria and eukaryotic fungi (yeasts and molds). These microbes are typical isolates from pharmaceutical environments, including the associated personnel, and a few are frank or opportunistic pathogens. Contamination with viruses is a concern in bioprocessing that uses animal cells.

### 8.1.1 ARCHAEANS

Microbes from the domain Archaea are phylogenetically related to prokaryotes but are distinct from bacteria. Many are extremophiles, with some species capable of growing at very high temperatures (hyperthermophiles) or in other extreme environments beyond the tolerance of any other life form. In general, most extremophiles are anaerobic or microaerophilic chemolithoautotrophs. Because of their unique habitats, metabolism, and nutritional requirements, Archaeans are not known to be frank or opportunistic pathogens, and they are not capable of colonizing a pharmaceutical water system.

### 8.1.2 BACTERIA

Bacteria are of immense importance because of their rapid growth, mutation rates, and ability to exist under diverse and adverse conditions; some of them are human pathogens. Some are very small and can pass through 0.2-µm rated filters. Others form spores, which are not part of their reproductive cycle. Bacterial spore formation is a complex developmental process that allows the organisms to produce a dormant and highly resistant cell in times of extreme stress. Bacterial endospores can survive high temperatures, strong UV irradiation, desiccation, chemical damage, and enzymatic destruction, which would normally kill vegetative bacteria.

Using a traditional cellular staining technique based on cell wall compositional differences, bacteria are categorized into gram positive and gram negative, although many sub-groups exist within each category based on genomic similarities and differences.

**8.1.2.1 Gram-positive bacteria:** Gram-positive bacteria are common in a pharmaceutical manufacturing environment but not in water systems. This is because they are generally not suited to surviving in a liquid environment that has the chemical purity of a pharmaceutical-grade water system. Gram-positive bacteria include the spore-forming bacteria from the genus *Bacillus*, which are common soil and dust microorganisms, and the non-sporulating bacteria from the genera *Staphylococcus*, *Streptococcus*, and *Micrococcus*, which normally colonize human skin and mucous membranes. Other types of gram-positive bacterial microorganisms include organisms from the genera *Corynebacterium*, *Mycobacterium*, *Arthrobacter*, *Propionibacterium*, *Streptomyces*, and *Actinomyces.* This latter group of microbes can be found in various natural habitats including the human skin and soil.

Although gram-positive bacteria can be detected in pharmaceutical water samples, their recovery is often associated with faulty aseptic technique during sampling or testing, or associated with exogenous contamination sources. Although these non-aquatic microorganisms could be present in source water and could, in rare circumstances, make their way into the early stages of a water purification unit operation, gram-positive bacteria are not known to colonize water systems. In addition, these

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M99956_07_01
@2024 USPC

microbes will likely be removed by one or more of the purification unit operations prior to the ultimate creation of the pharmaceutical-grade water.

**8.1.2.2 Gram-negative bacteria:** These types of bacteria are found in soil, water, plants, and animals. Gram-negative bacteria are relevant to pharmaceutical manufacturers, primarily due to their production of endotoxins as well as their ability to populate water systems, a topic discussed in *8.4 Endotoxin*. Some gram-negative bacteria prefer aquatic habitats and tend to colonize water systems and other wet environments as biofilms, a topic discussed in *8.2 Biofilm Formation in Water Systems*.

**8.1.2.3 Mycoplasma:** Organisms from the genus Mycoplasma are the smallest of the bacteria. Unlike other bacteria, these organisms do not have a cell wall and many exist as intracellular or animal/plant parasites. Mycoplasmas also may require specific nutrients for survival, including sterols, and they cannot survive in a hypotonic environment such as pure water. Based on these facts, this type of bacteria is not a concern for pharmaceutical-grade water systems.

### 8.1.3 FUNGI

Fungi are mainly aerobic mesophilic microbes. They exist as unicellular (yeast) and multicellular filamentous (mold) organisms. Molds are often found in wet/moist ▲environments▲ (USP 1-Dec-2021) but usually non-aquatic environments, such as soil and decaying vegetation. Yeasts are often associated with humans and vegetation, and both yeasts and molds also can be found in pharmaceutical environments. As mold matures it develops spores, which, unlike bacterial spores, are part of its reproductive cycle and are less resistant to adverse conditions. Mold spores are easily spread through air and materials, and could contaminate water samples.

Neither yeasts nor molds are suited for colonization or survival in pharmaceutical water systems. Their recovery is often associated with faulty aseptic technique during sampling or testing, or associated with exogenous contamination sources. These non-aquatic microorganisms, if present in source water, could make their way into the early stages of a water purification system; however, they will likely be removed by one or more of the purification unit operations.

### 8.1.4 VIRUSES

A virus is a small infectious agent unlike eukaryotes and prokaryotes. This is because viruses have no metabolic abilities of their own. Viruses are genetic elements containing either DNA or RNA that replicate within host cells. Human pathogenic viruses, especially those of fecal origin, could be present in source water. However, they are easily neutralized by typical water purification treatments, such as chlorination. Therefore, it is unlikely that human pathogenic viruses will be present or will proliferate (due to the absence of host cells) in pharmaceutical-grade waters.

### 8.1.5 THERMOPHILES

Thermophiles are heat-loving organisms and can be either bacteria or molds. Thermophilic and hyperthermophilic aquatic microorganisms (see *8.1.1 Archaeans*) require unique environmental and nutritional conditions to survive (e.g., presence of specific inorganic or organic nutrients and their concentrations, extreme pH, presence or absence of oxygen). These conditions do not exist in the high-purity water of pharmaceutical water systems, whether ambient or hot, to support their growth. Bacteria that are able to inhabit hot pharmaceutical water systems are invariably found in much cooler locations within these hot systems (e.g., within infrequently used outlets, ambient subloops off of hot loops, use-point and sub-loop cooling heat exchangers, transfer hoses and connecting pipes, or dead legs). These bacterial contaminants are the same mesophilic (moderate temperature-loving) types found in ambient water systems and are not thermophiles. Based on these facts, thermophilic bacteria are not a concern for hot pharmaceutical-grade water systems.

## 8.2 Biofilm Formation in Water Systems

A biofilm is a three-dimensional structured community of sessile microbial cells embedded in a matrix of extracellular polymeric substances (EPS). Biofilms form when bacteria attach to surfaces in moist environments and produce a slimy, glue-like substance, the EPS matrix, while proliferating at that location. This slimy matrix facilitates biofilm adhesion to surfaces as well as the attachment of additional planktonic cells to form a microbial community.

The EPS matrix of biofilms that colonize water systems also facilitates adsorption and concentration of nutrients from the water and retains the metabolites and waste products produced by the embedded biofilm cells, which can serve as nutrients for other biofilm community members.

This EPS matrix is also largely responsible for biofilm's resistance to chemical sanitizers, which must penetrate completely through the matrix to contact and kill the biofilm cells within the matrix. Heat sanitization approaches do not generally have these EPS matrix penetration difficulties, so they are usually considered superior to chemicals in killing biofilms where materials of construction allow.

The three-dimensional structure of a well-developed biofilm, as well as the biofilm's creation and release of small, motile "pioneer cells" for further colonization, are facilitated through gene expression modulating "quorum sensing" chemicals released in tiny amounts by individual biofilm cells and concentrated to a functional level within this same EPS matrix. So, the EPS matrix of biofilms is primarily responsible for the biofilm's success in colonizing and proliferating in very low nutrient-containing high-purity water systems. The EPS matrix also explains the difficulty in killing and/or removing biofilms from water purification and distribution system surfaces.

### 8.2.1 BIOFILM-FORMING BACTERIA IN WATER SYSTEMS

Common microorganisms recovered from water system samples include gram-negative bacteria from the genera *Pseudomonas*, *Ralstonia*, *Burkholderia*, *Stenotrophomonas*, *Comamonas*, *Methylobacterium*, and many other types of *Pseudomonas*-like organisms known collectively as pseudomonads (members of the family *Pseudomonadaceae*). These types of

Status: Currently Official on 05-Jan-2024
Official Date: Official as of 01-Dec-2021
DOI Ref: 56bn3
DocId: GUID-07416921-813B-43A7-A494-F190E610AD6F_7_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M99956_07_01
@2024 USPC

microbes, found in soil and source water, tend to colonize all water system distribution and purification system surfaces including activated carbon beds, deionizing resin beds, reverse osmosis systems, membrane filtration modules, connecting piping, hoses, and valves. If not controlled, they can compromise the functionality of purification steps in the system and spread downstream, possibly forming biofilms on distribution system surfaces (e.g., tanks, piping, valves, and hoses), from where they can be sheared or otherwise released into the finished water used in processes and products.

Some of the biofilm pseudomonads are opportunistic human pathogens and may possess resistance to commonly used pharmaceutical product preservatives, particularly when embedded in EPS matrix flocs sheared from water system biofilms. Several pseudomonads are also capable of utilizing a wide variety of carbon sources as nutrients, allowing them to colonize austere, adventitious nutrient environments such as water systems. This nutritional diversity also makes them capable of growing to very high numbers in some pharmaceutical products and raw materials, thus leading to product adulteration and potential risk to patient health. Given that these bacteria are commonly found in aqueous environments, endotoxin control for Water for Injection systems (and some Purified Water systems) through biofilm control becomes critical.

#### 8.2.2 NON-BIOFILM-FORMING BACTERIA IN WATER SYSTEMS

Other types of non-pseudomonad gram-negative bacteria, such as the genera *Escherichia*, *Salmonella*, *Shigella*, *Serratia*, *Proteus*, *Enterobacter*, and *Klebsiella*, are used as indicators of fecal contamination. Although some of these bacteria are also plant pathogens, others can be human enteric pathogens and can contaminate potable water supplies. These non-pseudomonads are not suited to colonizing or surviving in pharmaceutical water systems owing to the water's chemical purity. In fact, non-pseudomonad enteric bacteria are extremely unlikely contaminants of pharmaceutical water systems unless local sewage and source water controls are not in place. Such controls are required in order to comply with the source water requirements for making USP-grade waters as described in their respective monographs.

## 8.3 Microorganism Sources

#### 8.3.1 EXOGENOUS CONTAMINATION

Exogenous microbial contamination of bulk pharmaceutical water comes from numerous possible sources, including source water. At a minimum, source water should meet the microbial quality attributes of drinking water, which is the absence of fecal coliforms (*Escherichia coli*). A wide variety of other types of microorganisms, chiefly gram-negative bacteria, may be present in the incoming water. If appropriate steps are not taken to reduce their numbers or eliminate them, these microorganisms may compromise subsequent water purification steps.

Exogenous microbial contamination can also arise from maintenance operations, equipment design, and the process of monitoring, including the following:

- Unprotected, faulty, or absent vent filters or rupture disks
- Backflow from interconnected equipment
- Non-sanitized distribution system openings for component replacements, inspections, repairs, and expansions
- Inadequate drain air-breaks
- Innate bioburden of activated carbon, ion-exchange resins, regenerant chemicals, and chlorine-neutralizing chemicals
- Inappropriate rinsing water quality after regeneration or sanitization
- Poor sanitization of use points, hard-piped equipment connectors, and other water transfer devices such as hoses
- Deficient techniques for use, sampling, and operation

The exogenous contaminants may not be normal aquatic bacteria but rather microorganisms of soil, air, or even human origin. The detection of non-aquatic microorganisms may be an indication of sampling or testing contamination or a system component failure, which should trigger investigation and remediation. Sufficient care should be given to sampling, testing, system design, and maintenance to minimize microbial contamination from exogenous sources.

#### 8.3.2 ENDOGENOUS CONTAMINATION

Endogenous sources of microbial contamination can arise from unit operations in a water purification system that is not properly maintained and operated. Microorganisms present in source water may adsorb to carbon bed media, ion-exchange resins, filter membranes, and other equipment surfaces, and initiate the formation of biofilms.

Downstream colonization can occur when microorganisms are shed from existing biofilm-colonized surfaces and carried to other areas of the water system. Microorganisms may also attach to suspended particles such as carbon bed fines or fractured resin particles. When the microorganisms become planktonic, they serve as a source of contamination to subsequent purification equipment and to distribution systems.

Another source of endogenous microbial contamination is the distribution system itself. Microorganisms can colonize pipe surfaces, rough welds, misaligned flanges, valves, and dead legs, where they proliferate and form biofilms. Once formed, biofilms can become a continuous source of microbial contamination, which is very difficult to eradicate. Therefore, biofilm development must be managed by methods such as frequent cleaning and sanitization, as well as process and equipment design.

## 8.4 Endotoxin

Bacterial endotoxin is a lipopolysaccharide (LPS) that is a component of the outer cell membrane of gram-negative bacteria. Endotoxins may occur as collections of LPS molecules associated with living microorganisms, fragments of dead microorganisms, the EPS matrix surrounding biofilm bacteria, or free molecular clusters or micelles containing many

Official

https://pharmacopeia.cn/v-cn/

lipopolysaccharide molecules. The monomeric form of the endotoxin molecule does not exist in high-purity water because of the molecule's amphipathic nature. Some grades of pharmaceutical waters, such as those used in parenteral applications (e.g., Water for Injection, Water for Hemodialysis, and the sterilized packaged waters made from Water for Injection) strictly limit the amount of endotoxins that may be present because these compounds are pyrogenic.

#### 8.4.1 SOURCES

Endotoxins may be introduced into the system from the source water or may be released from cell surfaces of bacteria in water system biofilms. For example, a spike in endotoxin may occur following sanitization as a result of endotoxin release from killed cells. Endotoxin quantitation in water samples is not a good indicator of the level of biofilm development in a water system because of the multiplicity of endotoxin sources.

#### 8.4.2 REMOVAL AND CONTROL

To control endotoxin levels in water systems, it is important to control all potential sources of contamination with gram-negative bacteria as well as free endotoxin in the water. Contamination control includes the use of upstream unit operations to reduce bioburden from incoming water, as well as engineering controls (e.g., heat sanitization, equipment design, UV sanitizers, filters, material surface, and flow velocity) to minimize biofilm development on piping surfaces and to reduce re-inoculation of the system with free-floating bacteria.

Endotoxin remediation may be accomplished through the normal exclusion or removal action afforded by various unit operations within the treatment system. Examples of endotoxin removal steps in a water purification train include reverse osmosis, deionization, ultrafilters, distillation, and endotoxin-adsorptive filters.

## 8.5 Test Methods

Microbes in water systems can be detected as exampled in this section or by methods adapted from *Microbial Enumeration Tests* ⟨ 61⟩ , *Tests for Specified Microorganisms* ⟨ 62⟩ , or the current edition of *Standard Methods for the Examination of Water and Wastewater* from the American Public Health Association. This section describes classical culture approaches to bioburden testing, with a brief discussion on rapid microbiological methods.

Every water system has a unique microbiome. It is the user's responsibility to perform method validation studies to demonstrate the suitability of the chosen test media and incubation conditions for bioburden recovery. In general, users should select the method that recovers the highest planktonic microbial counts in the shortest time, thus allowing for timely investigations and remediation. Such studies are usually performed before or during system validation.

The steady state condition can take months or even years to be achieved, and can be affected by a change in source water quality, changes in finished water purity by using modified or increasingly inefficient purification processes, changes in finished water use patterns and volumes, changes in routine and preventative maintenance or sanitization procedures and frequencies, or any type of system intrusion (e.g., component replacement, removal, or addition).

#### 8.5.1 MICROBIAL ENUMERATION CONSIDERATIONS

Most microbial contaminants in water systems are found primarily as biofilms on surfaces, with only a very small percentage of the microbiome suspended in the water, or planktonic, at any given time. Although it would seem logical to directly monitor biofilm development on surfaces, current technology for surface evaluations in an operating water system makes this impractical in a GMP environment. Therefore, an indirect approach must be used: the detection and enumeration of planktonic microorganisms that have been released from biofilms. This planktonic microbiome will affect the processes or products where the water is used.

The detection and enumeration of the planktonic microbiome can be accomplished by collecting samples from water system outlets. Planktonic organisms are associated with the presence of biofilms as well as free-floating bacteria introduced into the system (pioneer cells), which may eventually form new biofilms. Therefore, by enumerating the microorganisms in water samples, the overall state of control over biofilm development can be assessed. This assessment has historically been accomplished with classical cultural techniques, which are viewed as the traditional method. However, nutritional limitations of the growth media may not satisfy growth requirements of organisms present in the water system that originated from a biofilm. As a result, traditional cultural methods may only detect a fraction of the biofilm bacteria present in the water sample. Other options are available, such as rapid microbiological methods.

There is no ideal cultural enumeration method that will detect all microorganisms in a water sample, although some media or incubation temperatures may be better than others. However, from a PC perspective, this limitation is acceptable because it is the relative changes in the trends for water sample microbial counts that indicate the state of PC.

Consideration also should be given to the timeliness of microbial testing after sample collection. The number of detectable organisms in a sample collected in a sterile, scrupulously clean sample container will usually decrease as time passes. The organisms within the sample may die or adhere to the container walls, reducing the number that can be withdrawn from the sample for testing. The opposite effect can also occur if the sample container is not scrupulously clean and contains a low concentration of nutrients that could promote microbial growth. Because the number of organisms in the water can change over time after sample collection, it is best to test the samples as soon as possible. If it is not possible to test the sample within 2 h of collection, the sample should be held at refrigerated temperatures (2°–8°) and tested within 24 h. In situations where even 24 h is not possible (such as when using off-site contract laboratories), it is particularly important to qualify the microbiological sample hold times and storage conditions to avoid significant changes in the microbial population during sample storage.

## 8.5.2 THE CLASSICAL CULTURAL APPROACH

Classical cultural approaches for microbial testing of water include but are not limited to pour plates, spread plates, membrane filtration, and most probable number (MPN) tests. These methods are generally easy to perform, and provide excellent sample processing throughput. Method sensitivity can be increased via the use of larger sample sizes. This strategy is used in the membrane filtration method. Cultural approaches are further defined by the type of medium used in combination with the incubation temperature and duration. This combination should be selected according to the monitoring needs of a specific water system and its ability to recover the microorganisms of interest; that is, those that could have a detrimental effect on the products manufactured or process uses, as well as those that reflect the microbial control status of the system.

**8.5.2.1 Growth media:** The traditional categorization is that there are two basic forms of media available: "high nutrient" and "low nutrient". Those media traditionally categorized as high-nutrient include Plate Count Agar (TGYA), Soybean Casein Digest Agar (SCDA or TSA), and m-HPC Agar (formerly m-SPC Agar). These media are intended for the general isolation and enumeration of heterotrophic or copiotrophic bacteria. Low-nutrient media, such as R2A Agar and NWRI Agar (HPCA), have a larger variety of nutrients than the high-nutrient media. These low-nutrient media were developed for use with potable water due to their ability to recover a more nutritionally diverse population of microorganisms found in these environments. The use of R2A may not be the best choice for high-purity water systems. Even though high-purity water creates an oligotrophic environment, it has been shown empirically that in many high-purity compendial waters, the microbial count disparity between low- and high-nutrient media is dramatically less to nil, as compared to potable water. Nevertheless, using the medium that has been demonstrated as acceptable through comparative media analysis is recommended.

**8.5.2.2 Incubation conditions:** Duration and temperature of incubation are also critical aspects of microbiological testing. Classical compendial methods (e.g., ⟨ 61 ⟩) specify the use of high-nutrient media, typically incubated at 30°–35° for NLT 48 h. Given the types of microbes found in many water systems, incubation at lower temperatures (e.g., ranges of 20°–25° or 25°–30°) for longer periods (at least 4 days) could recover higher microbial counts than classical compendial methods. Low-nutrient media typically require longer incubation conditions (at least 5 days) because the lower nutrient concentrations promote slower growth. Even high-nutrient media can sometimes yield higher microbial recovery with longer and cooler incubation conditions.

**8.5.2.3 Selection of method conditions:** The decision to test a particular system using high- or low-nutrient media, higher or lower incubation temperatures, and longer or shorter incubation times should be based on comparative cultivation studies using the native microbiome of the water system. The decision to use media requiring longer incubation periods to recover higher counts also should be balanced with the timeliness of results. Detection of marginally higher counts at the expense of a significantly longer incubation period may not be the best approach for monitoring water systems, particularly when the slow growers are not new species but the same as those recovered within shorter incubation times. Some cultural conditions using low-nutrient media lead to the development of microbial colonies that are much less differentiated in colonial appearance, an attribute that microbiologists rely on when selecting representative microbial types for further characterization. The nature of some of the slow growers and the extended incubation times needed for their development into visible colonies also may lead to those colonies becoming dysgonic and difficult to subculture. That could limit their further characterization, depending on the microbial identification technology used. The selection of method parameters should provide conditions that adequately recover microorganisms from the water system, including those that are objectionable for the intended water use.

## 8.5.3 SUGGESTED CLASSICAL CULTURAL METHODS

Example methods are presented in *Table 3*.

**Table 3. Example Culture Methods**

| Type of Water | Method |
|---|---|
| Drinking water | Pour plate method or membrane filtration method[a] |
| | Suggested sample volume: 1.0 mL[b] |
| | Growth medium: Plate Count Agar[c] |
| | Incubation time: 48–72 h[d] |
| | Incubation temperature: 30°–35°[e] |
| Purified Water | Pour plate method or membrane filtration method▲[a]▲ (USP 1-Dec-2021) |
| | Suggested sample volume: 1.0 mL for pour plate or up to 100 mL for membrane filtration[b] |
| | Growth medium: Plate Count Agar[c] |
| | Incubation time: 48–72 h[d] |
| | Incubation temperature: 30°–35°[e] |
| Water for Injection | Membrane filtration method[a] |
| | Suggested sample volume: 200 mL[b] |
| | Growth medium: Plate Count Agar[c] |
| | Incubation time: 48–72 h[d] |
| | Incubation temperature: 30°–35°[e] |

[a] A membrane filter with a rating of 0.45 µm is generally considered preferable to smaller porosity membranes.
[b] Sample size must be appropriate for the expected microbial count of the water in order to derive statistically valid colony counts.

Official

https://mhathaway.com/

[c] For optimum recovery, an alternative medium may be more appropriate (e.g., m-HPC, TSA/SCDA, R2A).
[d] For optimum recovery, alternative incubation times may be needed.
[e] For optimum recovery, alternative incubation temperatures may be needed.

For media growth promotion, use at a minimum *Pseudomonas aeruginosa* ATCC 9027 and *Bacillus subtilis* ATCC 6633. Additional organisms should be used to represent those that are considered objectionable and/or typically isolated from the water system (house isolates).

#### 8.5.4 MICROBIAL IDENTIFICATION

In addition to the enumeration of the bioburden in the water, there is a need to identify and/or select certain microbial species that could be detrimental to products or processes. Some bacteria also may be resistant to preservatives and other antimicrobial chemicals used in nonsterile liquid and semi-solid products, thus leading to potential product spoilage. For example, *Pseudomonas aeruginosa* and *Burkholderia cepacia*, as well as some other pseudomonads, are known opportunistic pathogens under certain conditions. As such, it may be appropriate to consider these species as objectionable microorganisms for the type of water used to manufacture nonsterile liquid and semi-solid products. There is a higher risk of infection if these organisms are found in products targeted for susceptible patient populations (e.g., the very young, the very old, and the immunocompromised) or products contacting highly susceptible tissues (e.g., inhaled products or some topical products). However, if the product where the water is used carries an absence specification for a particular pathogenic species that is not capable of living in a high-purity water system (e.g., *Staphylococcus aureus* or *E. coli*), then these non-aquatic species should not be candidates for routine recovery testing from water samples. For more information, see *Microbiological Examination of Nonsterile Products: Acceptance Criteria for Pharmaceutical Preparations and Substances for Pharmaceutical Use* ⟨ 1111⟩ , *Microbial Characterization, Identification, and Strain Typing* ⟨ 1113⟩ , and *Microbiological Best Laboratory Practices* ⟨ 1117⟩ .

For PC and QC, it is valuable to know the microbial species present in the normal microbiome of a water system, even if they are not specifically objectionable. If a new species is detected, it may be an indication of a subtle process change or an exogenous intrusion. The identity of the microorganism may be a clue as to its origin and can help with implementation of corrective or preventive action. Therefore, it is industry practice to identify the microorganisms in samples that yield results exceeding established Alert and Action Levels. It is also of value to periodically identify the normal microbiome in a water system, even if counts are below established Alert Levels. This information can provide perspective on the species recoveries from Alert and Action Level excursion samples, indicating whether they are new species or just higher levels of the normal microbiome. Water system isolates may be incorporated into a company culture collection for use in tests such as antimicrobial effectiveness tests, microbial method validation/suitability testing, and media growth promotion. The decision to use water isolates in these studies should be risk-based because many such isolates may not grow well on the high-nutrient media required. And because once adapted to laboratory media, they may not perform like their wild type progenitors.

#### 8.5.5 RAPID MICROBIOLOGICAL METHODS

In recent years, new technologies that enhance microbial detection and the timeliness of test results have been adopted by pharmaceutical QC testing labs. Rapid microbiological methods (RMM) are divided into four categories: growth-based, viability-based, metabolite-based, and nucleic acid-based. Examples of RMM used for the evaluation of microbial quality of water systems include the following:

- Microscopic visual epifluorescence membrane counting techniques
- Automated laser scanning membrane counting approaches
- Early colony detection methods based on autofluorescence, adenosine triphosphate (ATP) bioluminescence, or vital staining
- Genetic-based detection/quantitation

See *Validation of Alternative Microbiological Methods* ⟨ 1223⟩ for further information on rapid microbiological methods.

## 9. ALERT AND ACTION LEVELS AND SPECIFICATIONS

### 9.1 Introduction

Establishment of Alert and Action Levels for any manufacturing process facilitates appropriate and timely control. In the case of a pharmaceutical water system, the key PC parameters can be specific chemical, physical, and microbiological attributes of the water produced. Typically, most chemical attributes can be determined in real time or in the lab within a few minutes after sample collection. Physical attributes such as the pressure drop across a filter, temperature, and flow rate—which are sometimes considered critical for operation or sanitization of the water system—must be measured in situ during operation. Obtaining timely microbial data is more challenging compared to chemical and physical attributes, often taking several days. This limits the ability to control microbial attributes in a timely manner, and therefore requires a more challenging evaluation of the test results and conservative implementation of PC levels. This section provides guidance on the establishment and use of Alert and Action Levels, as well as Specifications to assess the suitability of the water and the water system for use in production.

### 9.2 Examples of Critical Parameter Measurements

Examples of measurements and parameters that are important to water system processes and products are described below. The list, which is not intended to be exhaustive or required, contains some examples of parameters that could be measured to demonstrate that the system is in a state of control.

@2024 USPC

Examples of measurements that could be critical to the purification or sanitization process include the following:

- Temperature, for thermally sanitized systems
- Percent rejection of a reverse osmosis system
- Endotoxin levels of feed water to a distillation system
- Chlorine presence immediately prior to a reverse osmosis system

Examples of measurements that could be critical to the water distribution process include the following:

- Return/end-of-loop line pressure, to forewarn of the potential to aspirate air or fluids because of simultaneous use of too many outlets
- Temperature to assure the self-sanitizing conditions are maintained for a hot water system
- Flow rate, to ensure that sufficient water is available for operations

Examples of measurements that could be critical to final water quality include the following:

- Conductivity
- TOC
- Endotoxin—for Water for Injection systems
- Bioburden
- Ozone or other chemicals—for chemically sanitized systems

## 9.3 Purpose of the Measurements

Although the purpose of each measurement varies, the results can be used to provide system performance feedback, often immediately, serving as ongoing PC and product quality indicators. At the same time, the results provide information necessary for making decisions regarding the immediate processing and usability of the water (see *6.1 Purposes and Procedures*). However, some attributes may not be monitored continuously or may have a long delay in data availability (e.g., microbial data). Regardless, both real-time data and data with longer cycle times can be used to properly establish Alert and Action Levels, which can serve as an early warning or indication of a potentially approaching quality shift.

As PC indicators, Alert and Action Levels are trigger points for the potential need for investigation and/or remedial action, to prevent a system from deviating from normal conditions and producing water unsuitable for its intended use. This “intended use” minimum quality is sometimes referred to as a “Specification” or “Limit”, and may include limits for conductivity and TOC listed in water monographs, or other specifications required for these waters that have been defined by the user internally.

In all cases, the validity of the data should be verified to ensure that the data are accurate and consistently representative of the water quality in the system, regardless of whether the sample was collected from a sampling port or use point. The resulting data must not be unduly biased, positively or negatively, because of the sampling method, the environment in the vicinity of the sampling location, the test procedure, instrumentation, or other artifacts that could obscure or misrepresent the true quality of the water intended by the purpose of the sampling (i.e., for PC or for QC).

## 9.4 Defining Alert and Action Levels and Specifications

Data generated from routine water system monitoring should be trended to ensure that the system operates in a state of chemical and microbiological control. To assist with the evaluation of system performance, companies should establish in-process control levels based on historical data or a fraction of the water Specifications (as long as this latter approach yields values with relevance to process performance).

When establishing Alert and Action Levels and Specifications, a two- or three-tier approach is typically used. In a three-tier approach, the typical structure is to establish in-process controls using “Alert Level”, “Action Level”, and “Specifications”. Alert and Action Levels are used as proactive approaches to system management prior to exceeding Specifications. The criteria for defining and reacting to adverse trends should be set by the user. These levels should be set at values that allow companies to take action to prevent the system from producing water that is unfit for use. Water Specifications or Limits represent the suitability for use of the water.

In a two-tier approach, a combination of the above terminology is used, depending on the parameter to be monitored. For example, if the attribute does have a monograph specification, the two tiers are Alert Level (or Action Level) and Specification. If the attribute does not have a limit or specification, the two tiers are usually Alert Level and Action Level.

A single-tier approach is possible, but this is risky and difficult to manage. With this approach, where the water/system is either acceptable or not acceptable, the single-tier method does not allow for any adjustment, correction, or investigation prior to stopping production.

However, certain sampling locations, such as sampling ports that are not used for manufacturing products or processes, do not represent the finished water quality where a Specification could be applied. In these locations, a two-tier approach (Alert and Action Levels only) could be applied. In some sampling locations, a single PC level might possibly be appropriate, depending on the attribute.

### 9.4.1 ALERT LEVEL

An Alert Level for a measurement or parameter should be derived from the normal operating range of the water system. Specifically, Alert Levels are based on the historical operating performance under production conditions, and then are established at levels that are just beyond the majority of the normal historical data. The Alert Level for a parameter is often a single value or a range of values, such as the following:

- Higher than typical conductivity or TOC
- Higher than typical microbial count

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M99956_07_01
@2024 USPC

- Higher than typical endotoxin level
- Low temperature during thermal sanitization
- pH range control prior to a reverse osmosis
- Ozone concentration in a storage tank

Various methods, tools, and statistical approaches are available for establishing Alert Levels, and the user needs to determine the approaches that work for their application. Some numerical examples are two or three standard deviations (or more) in excess of the mean value, or some percentage above the mean value but below a Specification. An event-based example could be the appearance of a new microorganism or a non-zero microbial count where zero is the norm.

When an Alert Level is exceeded, it indicates that a process or product may have drifted from its normal operating condition or range. Alert Level excursions represent a warning and do not necessarily require a corrective action. However, Alert Level excursions may warrant notification of personnel involved in water system operation, as well as the quality assurance (QA) personnel. Alert Level excursions may also lead to additional monitoring, with more intense scrutiny of the resulting and neighboring data as well as other process indicators.

### 9.4.2 ACTION LEVEL

An Action Level is also based on the same historical data, but the levels are established at values (or ranges) that exceed the Alert Levels. The values/ranges are determined using the same types of numerical or event-based tools as the Alert Levels, but at different values/ranges.

In a three-tier approach, it is good practice to select an Action Level that is more than the Alert Level, but less than the Specification to allow the user to make corrective actions before the water would go out of compliance.

Exceeding a quantitative Action Level indicates that the process has allowed the product quality or other critical parameter to drift outside of its normal operating range. An Action Level also can be event-based. In addition to exceeding quantitative Action Levels, some examples of event-based Action Level excursions include, but are not limited to, the following:

- Exceeding an Alert Level repeatedly
- Exceeding an Alert Level in multiple locations simultaneously
- The recovery of specific objectionable microorganisms
- A repeating non-zero microbial count where zero is the norm

An Action Level being exceeded should prompt immediate notification of both QA staff and the personnel involved in water system operations and use so that corrective actions can be taken to restore the system back to its normal operating range. Such remedial actions should also include investigative efforts to understand what happened and eliminate or reduce the probability of recurrence. Depending on the nature of the Action Level excursion, it may be necessary to evaluate its impact on the water uses during the period between the previous acceptable test result and the next acceptable test result.

### 9.4.3 SPECIAL ALERT AND ACTION LEVEL SITUATIONS

In new or significantly altered water systems, where there is limited or no historical data from which to derive trends, it is common to establish initial Alert and Action Levels based on equipment design capabilities. These initial levels should be within the process and product Specifications where water is used. It is also common for new water systems, especially ambient water systems, to undergo changes, both chemically and microbiologically, over time as various unit operations (e.g., reverse osmosis membranes) exhibit the effects of aging. This type of system aging effect is most common during the first year of use. As the system ages, a steady state microbiome (microorganism types and levels) may develop due to the collective effects of system design, source water, maintenance, and operation, including the frequency of re-bedding, backwashing, regeneration, and sanitization. This established or mature microbiome may be higher than the one detected when the water system was new. Therefore, there is cause for the impurity levels to increase over this maturation period and eventually stabilize.

Some water systems are so well controlled microbially—such as continuously or intermittently hot Water for Injection distribution systems—that microbial counts and endotoxin levels are essentially nil or below the limit of reasonable detectability. This common scenario often coincides with a very low Specification that is poorly quantifiable due to imprecision (as much as two-fold variability) of the test methods that may be near their limits of detection. In such systems, quantitative data trending has little value, and therefore, quantitative PC levels also have little value. The non-zero values in such systems could be due to sporadic sampling issues and not indicative of a water system PC deviation; however, if these non-zero values occur repeatedly, they could be indicative of process problems. So, an alternative approach for establishing Alert and Action Levels with these data could be the use of the incident rate of non-zero values, with the occasional single non-zero “hit” perhaps being an Alert Level (regardless of its quantitative value), and multiple or sequential “hits” being an Action Level. Depending on the attribute, perhaps single hits may not even warrant being considered an Alert Level, so only a multiple-hit situation would be considered actionable. It is up to the user to decide on their approach for system control (i.e., whether to use one, two, or three levels of controls for a given water system and sampling location, and whether to establish Alert and Action Levels as quantitative or qualitative hit-frequency values).

### 9.4.4 SPECIFICATIONS

Water Specifications or Limits are set based on direct potential product and/or process impact and they represent the suitability for use of the water. The various bulk water monographs contain tests for *Conductivity*, *TOC*, and *Bacterial Endotoxins* (for *Water for Injection*). Aside from the monographs for *Water for Hemodialysis* and multiple sterile waters, microbial specifications for the bulk waters are intentionally not included in their monograph tests.

The need for microbial specifications for bulk waters (*Purified Water* and *Water for Injection*) depends on the water use(s), some of which may require strict control (e.g., very low bioburden, absence of objectionable organisms, or low ionic strength) while others may require no specification due to the lack of impact. For example, microbial specifications are appropriate and

Do Not Distribute
Status: Currently Official on 05-Jan-2024
Official Date: Official as of 01-Dec-2021
DOI Ref: 56bn3
DocId: GUID-07416921-813B-43A7-A494-F190E610AD6F_7_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M99956_07_01

typically expected for water that is used in product formulations and final equipment rinses. Where the water is used for analytical reagent preparations and the analytical method is not affected by microbial contaminants, or for cleaning processes that conclude with a final antimicrobial heat drying or solvent rinsing step, the microbial quality of the water is likely less of a concern. The decision to establish microbial Specifications for bulk pharmaceutical waters should be based on a formal risk assessment of its uses and justified by scientific rationale.

It is very important to understand the chemical and microbial quality of the water in its final form as it is delivered from a water system to the locations where it is used in manufacturing activities and other points of use. The quality of the water within the water system could be compromised if it picks up chemical or microbial contaminants during its delivery from the system to the points of use. These points of use, where cumulative contamination could be present, are the locations where compliance with all the water Specifications is mandated.

As discussed above, compliance with chemical Specifications can be confirmed periodically between uses, immediately prior to use, or even while the water is being utilized in product manufacturing. Although the use of RMM may provide for timely microbial data, the use of conventional cultivative microbiological testing usually delays confirmation of microbial compliance until after the water has been used. However, for some applications, this logistical limitation should not eliminate the need for establishing microbial Specifications for this very important raw material.

The manufacturing risk imposed by these logistics accentuates the value of validated microbial control for a water system. It also emphasizes the value of unbiased sampling for microbial monitoring (e.g., influences from technique, hoses, flushing) of samples collected from pertinent locations, with evaluation of the resulting data against well-chosen and preferably trend-derived Alert and Action Levels, which can facilitate remedial PC to preclude Specification excursions.

Users should establish their own quantitative microbial Specifications suited to their water uses. But these values should not be greater than 100 cfu/mL for *Purified Water* or 10 cfu/100 mL for *Water for Injection* unless specifically justified, because these values generally represent the highest microbial levels for pharmaceutical water that are still suitable for manufacturing use.

A Specification excursion should prompt an out-of-specification (OOS) investigation. The investigation is performed to determine 1) the root cause of the excursion so that CAPA may be taken for remediation purposes, and 2) assess the impact on affected processes and finished products where the water was used. Product disposition decisions must be made and are dependent on factors that could include the following:

- Role of water in the product or in-process material
- Chemical or microbial nature of the attribute whose Specification value was exceeded
- Level of product contamination by the water
- Presence of objectionable microorganisms
- Any downstream processing of affected in-process materials that could mitigate the OOS attribute
- Physical and chemical properties of the finished product where the water was used that could mitigate the OOS attribute
- Product administration routes and potentially sensitive/susceptible users

### 9.4.5 SOURCE WATER CONTROL

The chemical and microbial attributes of the starting source water are important to the ability of the water system to remove or reduce these impurities to meet the finished water Specifications (see *2. Source Water Considerations*). Using the example microbial enumeration methods in *Table 3* a reasonable maximum bacterial Action Level for source water is 500 cfu/mL. This number is derived from US EPA NPDWR where it is used as an Action Level for the water authority indicating the need for improving disinfection and water filtration to avoid the penetration of viral, bacterial, and protozoal pathogens into the finished drinking water. It is not, however, a US EPA heterotrophic plate count Specification or Maximum Contaminant Level (MCL) for Drinking Water.

Nevertheless, of particular importance could be the microbial and chemical quality of this starting water because the water is often delivered to the facility at a great distance from its source and in a condition over which the user has little or no control. High microbial and chemical levels in source water may indicate a municipal potable water system upset, a change in the supply or original water source, a broken water main, or inadequate disinfection, and thus potentially contaminated water with objectionable or new microorganisms or coincidental chemical contaminants may be present.

Considering the potential concern about objectionable microorganisms and chemical contaminants in the source water, contacting the water provider about the problem should be an immediate first step. In-house remedial actions also could be needed, including performance of additional testing on the incoming water (as well as the finished water in some cases) or pretreating the water with additional microbial and chemical purification operations (see *5.1 Unit Operations Considerations*).

# ⟨1234⟩ VACCINES FOR HUMAN USE—POLYSACCHARIDE AND GLYCOCONJUGATE VACCINES

## INTRODUCTION

This chapter describes best practices for production, conjugation, and characterization of polysaccharide and glycoconjugate vaccines. It describes key quality attributes at each step of the process and suggests best methods to assess these attributes. The scope of this chapter includes vaccines consisting of one or more purified polysaccharides (such as pneumococcal, meningococcal, and Typhoid Vi vaccines) and components involved in their production, and vaccines consisting of one or more glycoconjugate immunogens in which a saccharide has been covalently attached to a suitable carrier protein. The latter category includes *Haemophilus influenzae* type b (Hib), meningococcal, and pneumococcal conjugate vaccines. The chapter does not include combination vaccines in which Hib conjugates are combined with unrelated immunogens against diphtheria, tetanus, and pertussis.

## BACKGROUND

### Occurrence of Capsular Polysaccharides

Many pathogenic bacteria possess a polysaccharide capsule that encloses the cell, modulates the flow of nutrients to the cell surface, and protects against dehydration. When a bacterium establishes an infection in a mammalian host, the polysaccharide capsule hides cell surface components from elements of the mammalian immune system, such as antibodies and complement proteins that otherwise would activate mechanisms to kill the pathogen. Although polysaccharide capsules are themselves immunogenic in children and adults, development of a protective immune response may be too slow to defend the host against disease. In many cases, antibodies directed against the capsular polysaccharide are protective, and the prior existence of these antibodies prevents establishment of the infection; this is the basis for their use as vaccines or components of conjugate vaccines. Many bacterial species can be divided into serogroups or serotypes that express structurally and immunologically distinct capsular polysaccharides. The number of known serotypes differs between organisms. There are six known *Haemophilus influenzae* serotypes and more than 90 *Streptococcus pneumoniae* serotypes. Different serotypes (or serogroups) of the same organism may have different infectivities. For instance, the large majority of disease caused by *H. influenzae* is due to the b serotype. Different serotypes may cause disease in different geographical regions, may produce a different spectrum of disease, or may be prevalent in different age groups. The serotype-specific pattern of disease may change with time within a given geographical region. For these reasons, many polysaccharide and conjugate vaccines contain multiple saccharide immunogens.

### Structures of Capsular Polysaccharides

Capsular polysaccharides are high molecular weight polymers that contain a strict repeat unit. This repeat unit can be a single monosaccharide unit or can be an oligosaccharide unit that contains as many as eight sugar residues. The repeat units can be linear or branched, and are sometimes linked together by phosphodiester bonds. Bacterial polysaccharides often contain unusual sugar residues that are not found elsewhere, and may be substituted with a wide range of acylating groups (*O*-acetyl groups are the most common) and phosphorylated substituents such as phosphoglycerol. Incomplete *O*-acetylation and migration of *O*-acetyl groups between different hydroxyl groups leads to a degree of heterogeneity in the polysaccharides.

### Immune Responses to Capsular Polysaccharides

Capsular polysaccharides are T-cell–independent type 2 immunogens. These immunogens do not evoke antibody isotype switching, affinity maturation, or immunological memory. Because of the relatively late development of the relevant arm of the human immune system, unconjugated polysaccharide vaccines usually induce only a poor immune response in infants under the age of two and thus are not used for this population group. Adjuvants in polysaccharide vaccines do not improve the immune response. In a typical adult target population only a single dose is required to induce a protective immune response. In the absence of immunological memory, regular revaccination is required, often at five-year intervals. Repeated vaccination can lead to hyporesponsiveness to the vaccine.

### Conjugation of Polysaccharides to Carrier Protein

Covalent attachment of a capsular polysaccharide, or an oligosaccharide derived from it, to a protein carrier creates a conjugate vaccine. Immunization with a conjugate vaccine induces humoral immunity by means of a different molecular mechanism that does not require cross-linking of immune cell surface proteins. For this reason, effective conjugate vaccines can be produced using oligosaccharide haptens that may be derived from a capsular polysaccharide or from inherently lower molecular weight polysaccharides such as the *O*-chain of a lipopolysaccharide. Conjugates can also be produced using naturally high-mass polysaccharides or by controlled size reduction to shorter chains. Depending on the manufacturing process there are three basic structural models for conjugate vaccines:

- conjugates in which a carrier protein is modified with multiple oligosaccharide chains that have one or two activation sites to allow attachment to a carrier protein, resulting in a monomeric glycoconjugate or a glycoconjugate with limited cross-linking

https://pharmacopeia.com/
Printed on: Fri Jan 05 2024 06:35:26 AM(EST)
Printed by: USP NF
Do Not Distribute

- cross-linked conjugates in which multiple activated polysaccharide chains and carrier proteins couple to multiple polysaccharide chains, creating a cross-linked network of proteins and glycans
- conjugates in which a size-reduced polysaccharide is covalently attached to a complex of proteins, typically bacterial outer proteins, via multiple attachments.

### The Carrier Protein

The most widely used carrier proteins are related to bacterial toxins that are detoxified by chemical or genetic means. Conjugate vaccines induce a T-cell–dependent response that is developed early in life and leads to immunological memory and boosting of the response by further doses of the vaccine, thus they are suitable for infant immunization. The role of the carrier protein in modulating the immune response is discussed below.

### Conjugation Chemistry

Polysaccharides can be covalently attached to proteins, although activation of the polysaccharide is required. Sometimes the carrier protein is also activated to create compatible reactive groups. Polysaccharides can be activated initially by creation of reactive aldehyde groups, by periodate oxidation or uncovering of the reducing terminal of sugars, by reaction of hydroxyl groups with highly reactive reagents such as cyanogen bromide (or 1-cyano-4-dimethylamino-pyridinium tetrafluoroborate [CDAP] as a crystalline alternative) or carbonyldiimidazole, by use of carboxylic acid groups, or, if available, by free amino groups or phosphate groups. Periodate oxidation, dilute acid hydrolysis, and some other approaches to polysaccharide activation may, depending on the structure of the polysaccharide, lead to depolymerization of oligosaccharides, which are typically fractionated by size and an appropriate fraction coupled to the carrier. The "natural" reactive groups on proteins include lysine ε-amino groups, *N*-terminal amino groups, carboxylic acids in aspartate or glutamate, or thiol groups. Carrier protein activation may also involve the creation of hydrazide groups or thiols for linkage. Covalent attachment between the activated polysaccharide and the carrier protein, activated or not, can take place via the use of activated esters, sometimes created *in situ* with a water-soluble carbodiimide reagent, by reduction of Schiff's bases, by reaction of a thiol with maleimide, or by elimination of bromide. Conjugation can either be direct, as in reductive amination, or via the introduction of a suitable bifunctional linker. In general, the choice of conjugation chemistry is defined by either the structure of the polysaccharide repeat unit or the desire to produce a conjugate of a specific structural family.

### Immune Responses to Conjugate Vaccines

The immune response to the saccharide component of conjugate vaccines is T-cell–dependent and is similar to the response for proteins, although this process is still not fully understood with respect to glycoconjugates. Because this immunological pathway is in place even in infants, conjugate vaccines were developed initially for use in infants. Following interaction with antigen-presenting cells such as dendritic cells, macrophages, and B-cells, glycoconjugate vaccines are internalized and processed into small peptides and glycopeptides that then are re-exposed and presented to T-lymphocytes in association with the major histocompatibility complex class II molecules. Multiple immunizations of an immunologically naive infant are normally required to raise an antibody response, but processes such as isotype switching and affinity maturation take place and immunological memory is stimulated. In general terms, these processes result in induction of long-lasting high-affinity antibodies that are effective at preventing bacterial pathogens from establishing an infection. Adjuvants in glycoconjugate vaccines are effective at boosting immune responses. These vaccines have also been shown, in the cases of Hib, meningococci, and pneumococci, to eliminate nasopharyngeal carriage of organisms, thus an important aspect of their effectiveness arises from suppressing transmission of infectious serotypes between individuals, called a *herd effect*.

## KEY QUALITY PARAMETERS FOR BULK POLYSACCHARIDES

Bulk monovalent polysaccharide is purified from bacterial cell culture and is a key stable intermediate in the manufacture of both polysaccharide and conjugate vaccines. Many quality parameters for final vaccines can be initially assessed by analysis of bulk monovalent polysaccharides or by using critical in-process tests supporting the manufacturing process. Important quality parameters for purified polysaccharide include identity, purity, composition, and molecular size, and depend on the type and extent of further processing. The purification process is validated to consistently produce compliant material.

The purity of the polysaccharides depends on the purification steps, including harvest methods, clarification, and downstream purification processes. For purification, a combination of precipitation, filtration, and chromatographic procedures can be used, depending on the chemical nature of the polysaccharide. The final purification step can consist of buffer exchange and filtration followed by storage of purified polysaccharide (frozen), or additional precipitation and washing of the precipitate with solvent before drying, followed by storage. Drying of polysaccharides can be performed in dessicators and can include several steps of grinding or fluffing and return to the dessicators for further drying. Manufacturers should take care during these steps because mechanical handling of the polysaccharide can reduce its molecular size. The purified polysaccharide is stored at a suitable temperature in conditions that avoid the uptake of moisture. Lyophilization of polysaccharides is also possible. The stability of the polysaccharide under specified storage conditions should be demonstrated; this may include assessment of the optimal moisture content of the dried material.

Differentiating which tests should be used for polysaccharide release and which are better suited to in-process testing to ensure process consistency depends on the process and how the polysaccharide will be further processed. Final decisions about process parameters typically take place after discussions with regulatory authorities.

@2024 USPC

## Dry Weight

Because dry weight is used both to calculate the results of certain tests with reference to the dried substance and to calculate amounts for subsequent processes, volatile matter, including water, in the purified polysaccharide is determined by a combination of suitable methods including the following:

- thermogravimetry (see *Loss on Drying* ⟨731⟩)
- Karl Fischer (water only: see *Water Determination* ⟨921⟩)
- residual solvents determined by gas chromatography (see *Residual Solvents* ⟨467⟩ and *Chromatography* ⟨621⟩) and by nuclear magnetic resonance (NMR) spectroscopy (see *Nuclear Magnetic Resonance Spectroscopy* ⟨761⟩) or colorimetric methods.

## Polysaccharide Identity

The manufacturer is required to confirm the identity of the active component present in the purified polysaccharide. If other polysaccharides are produced at the same manufacturing site, the method should be validated to show that it distinguishes the desired polysaccharide from all other polysaccharides produced in that facility (see 21 CFR 610.14). The identity is determined by a prespecified combination of suitable methods such as:

- Immunological test methods: These methods require access to highly specific antisera that are able to distinguish between closely related polysaccharide antigens. Commonly used formats for this purpose are immunoprecipitation, immunoelectrophoresis, and enzyme-linked immunosorbent assays (ELISA). The (serological) specificity of the antiserum should be demonstrated by the absence of cross-reactivity with heterologous polysaccharides manufactured in the same facility. More information regarding these methods can be found in *Immunological Test Methods—General Considerations* ⟨1102⟩, *Immunological Test Methods—Enzyme–Linked Immunosorbent Assay (ELISA)* ⟨1103⟩, and *Immunological Test Methods—Immunoblot Analysis* ⟨1104⟩.
- NMR spectroscopy (see ⟨761⟩): NMR methods require access either to authentic samples of the polysaccharide or to reference spectra. Comparison is made visually in terms of the positions, relative intensities, and multiplicities of significant resonances, or by use of other objective methods.
- Polysaccharide identity can also be assessed by use of a matrix of compositional assays, usually with colorimetric or chromatographic readouts, that define factors such as the amounts of different sugar types (e.g., amino sugars, uronic acids, or methyl pentoses depending on the polysaccharide), the amount of substituents (e.g., *O*-acetyl groups), and the content of nitrogen and phosphorus.

## Polysaccharide Purity and Quantity

### COLORIMETRIC ASSAYS

Historically, polysaccharide content compared to dry weight (purity) was estimated using a range of colorimetric assays for functional groups specific to the polysaccharide antigen. Because the reference standard is typically a pure monosaccharide or similar model compound, and because assays were typically determined before most structures were known, component quantification may not parallel true stoichiometry. Thus, manufacturers should develop correlations among alternative approaches. Purity can be calculated based on the method employed and the salt form present. *Table 1* lists colorimetric tests that may be appropriate to determine the composition of a particular polysaccharide within a vaccine. The response factors for the sugar units in the polysaccharide may differ from those of a pure monosaccharide reference standard. Manufacturers should address these concerns during method validation.

**Table 1. Colorimetric Assays for Polysaccharide Composition and Quantity**

[a] The hestrin assay is appropriate for compositional analysis and identity, but because the degree of *O*-acetylation can vary between polysaccharide batches it is not normally a suitable assay for polysaccharide quantitation.

### HYDROLYSIS AND COMPOSITION ANALYSIS BY CHROMATOGRAPHY

Acid or base hydrolysis depolymerizes polysaccharides into oligosaccharides, monosaccharides, or smaller fragments that are polysaccharide-specific for the optimized hydrolysis conditions employed. Aggressive hydrolysis conditions can destroy some components of the polysaccharide. These fragments can be quantified directly by use of, for example, high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) or conductivity detection for ions (HPAEC-CD), or by reversed phase high-performance liquid chromatography (HPLC) of fluorophore-labeled sugars. Alternatively, the hydrolysate can be derivatized and analyzed by gas chromatography with flame ionization (GC-FID) or mass spectrometric detection (GC-MS). Suitable polysaccharide reference materials or monosaccharides are required, and the hydrolysis conditions are product-specific. *Table 2* summarizes the type of hydrolysis applied, the analytical methods, and the analytes that have been quantified for different polysaccharides.

**Table 2. Chromatographic Methods for Compositional Analysis and Quantification of Vaccine Polysaccharides[a]**

| PS Antigen | Acid Hydrolysis and HPAEC | Acid Hydrolysis, Fluorophore Labeling, and HPLC | HF Hydrolysis and HPAEC | Base Hydrolysis and HPAEC | Meth - anolysis and GC or HPAEC |
|---|---|---|---|---|---|
| PRP | Ribitol | — | Phosphate | PRP monomer | — |

| MenY | Glc, Neu5Ac | Neu5Ac | — | *O*-acetyl | — |
| MenW135 | Gal, Neu5Ac | Neu5Ac | — | *O*-acetyl | — |
| Pneumo (Serotype Specific) | Alditols, methylpentoses, hexoses, hexosamines, uronic acids, Pyruvate | — | Phosphate | *O*-acetyl | Alditols, methylpentoses, hexoses, hexosamines, uronic acids |
| Vi | — | — | — | *O*-acetyl Vi monomer fragment | — |

[a] PS = polysaccharide; HF = hydrofluoric acid; PRP = polyribosylribitol phosphate; MenA = Meningococcus group A; MenC = Meningococcus group C; MenY = Meningococcus group Y; MenW135 = Meningococcus group W135; Pneumo = Pneumococcus; Man = mannose; Neu = neuraminic acid; Ac = acetyl; Glc = glucosamine; Gal = galactose.

### CAPILLARY ELECTROPHORESIS

Capillary zone electrophoresis has been used for the identification and quantification of meningococcal polysaccharides without depolymerization.

### IMMUNOCHEMICAL ASSAYS

Immunochemical assays such as immunonephelometry or ELISA require access to specific antisera that must be calibrated to reference materials. The response may be modified by the matrix or size of the polysaccharide.

### NMR SPECTROSCOPY

The relative intensities of characteristic resonances can confirm the proportions of different sugar residue types and substituents such as *N*- or *O*-acetyl or pyruvate that are present in the polysaccharide. Quantification can be achieved by comparison of these intensities to that of an added internal standard (see ⟨761⟩).

Regarding phosphorus determination, one should remember that a number of bacterial polysaccharides contain phosphodiester linkages. The polysaccharide may be quantified based on its phosphorus content by colorimetric assays or instrumental approaches such as inductively coupled plasma–optical emission (ICP-OES) or ICP-mass spectrometry (ICP-MS).

### COUNTERIONS

If the percentage purity of polysaccharide bulks (compared to dry weight) is part of their release program, the amount and type of counterion present must be considered and can be determined by, for example, ICP-MS. This is normally an in-process control step.

## Polysaccharide Molecular Size Distribution

The molecular size distribution is generally evaluated by liquid chromatography using soft gel–filtration procedures or size exclusion–high-performance liquid chromatography (SEC-HPLC) equipped with in-line refractive index (RI). The results are reported as the distribution coefficient ($K_D$) determined from the main peak of the elution curve or as the percentage of material that elutes before a defined $K_D$ cut-off value. The absolute molecular weight of the polysaccharide and its hydrodynamic (gyration) radius can be determined by coupling static light scattering and RI detectors to the SEC-HPLC column, and measuring

@2024 USPC

the RI increment (*dn*/*dc*) using reference polysaccharides. Requirements based on molecular weight can be expressed in terms similar to those based on molecular size, and related either to peak values or to the proportion that elutes before a defined cut-off value.

### Level of Protein Contamination

The residual protein content of the polysaccharide should be determined by an appropriate assay and should be shown to be below the approved specification. These specifications typically vary by polysaccharide and serotype. Method validation should assess the need for sample pretreatment before protein determination and specific interference by the polysaccharide in the protein assay. Further, method validation should demonstrate that the assay sensitivity is appropriate for the specification. *Biotechnology-Derived Articles—Total Protein Assay* ⟨1057⟩ contains information regarding these assays. Methods that are typically applied to polysaccharides include colorimetric assays (e.g., Lowry, Biuret, bicinchonic acid, or Bradford assays) and UV absorbance.

### Level of Nucleic Acid Contamination

The nucleic acid content of the purified polysaccharide should be determined and should be shown to meet specifications, which are typically less than 1% w/w. *Nucleic Acid–Based Techniques—Approaches for Detecting Trace Nucleic Acids (Residual DNA Testing)* ⟨1130⟩ provides additional information about these methods.

### Quantification of Process- and Product-Related Impurities

Depending on in-process testing or release requirements, chromatographic and spectroscopic methods can be used to quantify residuals from the fermentation and isolation/purification steps. These residuals may include antifoaming agents, phenol, cetyltrimethyl ammonium bromide, ethanol, and other residual solvents. Other impurities should also be quantified using appropriate tests, including:

- bacterial endotoxins (see *Bacterial Endotoxins Test* ⟨85⟩)
- pyrogens (see *Pyrogen Test* ⟨151⟩)
- sterility (see *Sterility Tests* ⟨71⟩), if required
- bioburden (see *Microbiological Examination of Nonsterile Products: Microbial Enumeration Tests* ⟨61⟩), where appropriate.

As an in-process control, the proportion of pneumococcal C polysaccharide in pneumococcal capsular polysaccharides can be determined by a combination of $^{1}H$ and $^{31}P$ NMR spectroscopy or by HPAEC-PAD analysis of ribitol. Alternatively, it can be derived from the compositional analysis.

### Stability-Indicating Tests

The polysaccharide may lose integrity because of gradual hydrolysis, resulting in a reduced molecular size, and this degradation can be monitored by size exclusion chromatography or by high-performance size exclusion chromatography (HPSEC) with static light scattering detectors for molecular weight. Loss of *O*-acetyl groups can be monitored by HPLC methods. Both the loss or migration of *O*-acetyl groups and the integrity of phosphate-containing polysaccharides can be tracked by NMR spectroscopy. Immunochemical methods can also be used to monitor polysaccharide integrity but should be validated for that purpose.

## KEY QUALITY PARAMETERS FOR BULK FORMULATED POLYSACCHARIDE VACCINE

The bulk formulated polysaccharide vaccine refers to a solution that contains a blend of appropriate amounts of the required monovalent bulk polysaccharides, as well as any buffer salts, excipients, adjuvants, and antimicrobial preservatives present in the vaccine product. Typically, the vaccine is sterilized, usually by filtration, and is ready for filling in the final dosage forms.

### Antimicrobial Preservative

If an antimicrobial preservative is present and is not assayed at a later stage, its concentration can be assayed at this stage using an appropriate validated chemical, physicochemical, chromatographic, or spectroscopic assay. While the specification will depend on the regulatory agency, typically the amount of preservative should not exceed 120% of the expected value, and the manufacturer must demonstrate that the preservative is effective at that concentration (see *Antimicrobial Effectiveness Testing* ⟨51⟩).

### Sterility

At this stage, if the expectation is that the material is sterile, then sterility should be demonstrated using an appropriate validated assay such as one of those described in ⟨71⟩. For other manufacturing processes, measurement of some combination of bioburden, endotoxin count, or pyrogenicity may be sufficient.

Official

https://pharmacopeia.com/

### Polysaccharide Quantity

To ensure correct dilution of the bulk before final filling, and unless other control mechanisms are in place, determination of the content of individual serotypes or total polysaccharide content may be required using appropriate validated physicochemical or immunochemical methods as defined in the bulk polysaccharide section.

### pH, Osmolarity/Isotonicity, and Excipients

The final format of a vaccine may be liquid or lyophilized. If the format in this stage does not change during the final fill and is not analyzed later then manufacturers should assay this bulk material for:

- pH (see *pH* ⟨791⟩)
- possibly osmolarity or isotonicity (see *Osmolality and Osmolarity* ⟨785⟩). If approved by a regulatory agency, routine osmolarity testing may be omitted if the manufacturer demonstrated consistency in development and clinical lots.
- excipient content, if present.

## KEY QUALITY PARAMETERS FOR POLYSACCHARIDE VACCINES: FINAL FILLS

In accordance with 21 CFR 610.1, "No lot of any licensed product shall be released by the manufacturer prior to the completion of tests for conformity with standards applicable to such product. Each applicable test shall be made on each lot after completion of all processes of manufacture which may affect compliance with the standard to which the test applies. The results of all tests performed shall be considered in determining whether or not the test results meet the test objective, except that a test result may be disregarded when it is established that the test is invalid due to causes unrelated to the product." Test methods should be appropriately verified and validated.

### Description and Solubility

Liquid vaccines are typically clear colorless liquids that are essentially free from visible particles. Lyophilized products are typically white or cream-colored powders or pellets that are freely soluble in water and yield clear colorless liquids that are free from visible particles.

### Polysaccharide Identity

The manufacturer should demonstrate that all the expected polysaccharides are present in the final fill. The test may be immunochemical, physicochemical, or chemical. Regulation 21 CFR 610.14 requires that the identity test should distinguish the product from other products handled in the same facility. In some cases specific quality attributes of the polysaccharide relating to identity, such as *O*-acetyl content, may also be specified, and should be assayed at this final fill stage if not assessed at an earlier stage. Often polysaccharide identity and quantity can be confirmed and determined by the same assay.

### Polysaccharide Quantity

The content of each polysaccharide present in the final lot should be determined by a suitable validated immunochemical or physicochemical method. Typically, Vi and pneumococcal polysaccharide vaccines contain 25 µg of each serotype in a single human dose, whereas meningococcal polysaccharide vaccines contain 50 µg of each serogroup in a single human dose. When immunochemical methods are used, the antisera should be specific for each polysaccharide in the vaccine, including, in the case of the pneumococcal serotypes, immunologically cross-reactive species. Specifications are established on a case-by-case basis, but typically the content of each polysaccharide in the vaccine should be either between 70% and 130% or between 80% and 120% of the label claim.

### Polysaccharide Structural Integrity and Molecular Size

In the absence of suitable validation data showing that no changes occur during filling and storage, the structural integrity and molecular size of the individual polysaccharide components should be assessed as far as is possible following the final fill. Depending on the nature of the polysaccharide and the complexity of the vaccine, the integrity of individual serotypes or serogroups can be established by a combination of immunochemical stability-indicating measurements (e.g., ELISA, rate nephelometry, or physicochemical methods), by size or molecular weight determination alone or in combination with serotype-specific assays, or by quantification of specific groups such as *O*-acetyl groups that have been shown to be critical for immunogenicity. Together with the serotype-specific quantification, these assays act as a surrogate for a potency assay.

### pH

The pH of the final fill should be determined for liquid products or for redissolved lyophilized products according to ⟨791⟩ and should meet the requirements of the relevant licensing authority. This attribute should be included in stability-testing programs.

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M7149_01_01
@2024 USPC

### Antimicrobial Preservative

Where applicable, the amount of antimicrobial preservative should be determined by a suitable validated approach. Typically, the value should not exceed 120% of the quantity stated on the label. The approved lower limit should not be lower than the minimum amount shown to be effective throughout the product's shelf life.

### Process Impurities

Unless the product has been tested at an earlier manufacturing stage, and depending on the manufacturing process used, process impurities or residuals such as phenol or formaldehyde should be tested by appropriate validated assays. For more information about allowable process impurities, see *Vaccines for Human Use—Bacterial Vaccines* ⟨1238⟩.

### Sterility

The sterility of each lot should be ensured according to procedures described in ⟨71⟩ and 21 CFR 610.12. The product should comply with the requirements of the tests.

### Pyrogens or Bacterial Endotoxin

Depending on regulatory requirements, the product's endotoxin content or pyrogenicity should be determined and should be shown to meet the relevant specifications. Methods for endotoxin testing are found in ⟨85⟩. Methods for pyrogen testing are found in ⟨151⟩.

### Osmolarity and/or Isotonicity, Excipients, and Moisture Content

If the vaccine is a liquid preparation, the pH and osmolarity/isotonicity of each final lot should be tested and shown to be within the pre-approved specifications. For a lyophilized preparation, analysts should measure the pH after reconstitution with the appropriate diluent.

Excipient functional category (sometimes referred to as *functionality*) is a broad, qualitative, and descriptive term for the purpose or role an excipient serves in a formulation. Of greater importance, however, are the quantitative performance requirements (i.e., critical material attributes) of excipients that must be evaluated and controlled to ensure consistent performance throughout the product life cycle. Manufacturers should anticipate lot-to-lot and supplier-to-supplier variability in excipient properties and should have in place appropriate controls if needed to ensure consistent excipient performance (refer to *Excipient Performance* ⟨1059⟩ for guidance).

Regarding moisture content in lyophilized products, as specified in 21 CFR 610.13 each lot of dried product must be tested for residual moisture and must meet and not exceed established limits as specified by an approved method (see also ⟨731⟩ and ⟨921⟩).

### Diluent for Lyophilized Products

Data should be provided to support diluent sterility (see ⟨71⟩) and to ensure that adventitious microbial contamination does not occur under the reconstitution conditions (i.e., diluents should not introduce contamination) or during storage conditions as described in the package insert. If an antimicrobial preservative is used (as is the case normally only in multidose products), testing according to ⟨51⟩ is recommended to demonstrate acceptability. Testing may not be required on all lots once process control and consistency have been established.

### General Safety

Depending on regulatory requirements, a general safety test may be necessary as set out in 21 CFR 610.11(g), and the product should meet the specifications.

## KEY QUALITY PARAMETERS FOR CARRIER PROTEIN

A number of protein carriers have been used in preclinical and clinical evaluation of conjugate vaccines. Proteins such as diphtheria and tetanus toxoids, which derive from the respective toxins after chemical detoxification with formaldehyde, initially were selected as carriers because of the safety track record accumulated with tetanus and diphtheria vaccination, and these proteins are used today as carriers for meningococcal, Hib, and pneumococcal vaccines in a number of countries worldwide. CRM197, a nontoxic mutant of diphtheria toxin, is also used as a carrier for licensed Hib, pneumococcal, and meningococcal conjugate vaccines and for other vaccines being developed. An outer membrane protein complex (OMPC) of serogroup B meningococcus is the carrier for a licensed Hib conjugate vaccine. An Hib-related protein, Protein D, is the carrier for most of the polysaccharides included in one licensed conjugated pneumococcal vaccine.

### Key Quality Parameters for Carrier Protein

Five carrier proteins currently are used for conjugate vaccines approved for use by various regulatory authorities: Diphtheria Toxoid, Tetanus Toxoid, CRM197, *Haemophilus* Protein D, and OMPC. When the carrier protein is a component of an approved

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M7149_01_01
@2024 USPC

vaccine like diphtheria and tetanus toxoids, the first key quality parameters are those defined by the release tests on the concentrated bulks for these components. Other quality parameters include the level of oligomerization (monomer vs. multimeric forms). For carrier proteins that are not licensed as stand-alone vaccines, the list of key quality attributes should at least include identity, sterility or bioburden (depending on the manufacturing process), endotoxins, and purity. In some specific cases, additional quality attributes may require measurement.

#### CARRIER PROTEIN IDENTITY

The identity of the carrier proteins can be assessed by suitable methods that can be divided into two categories:

- Immunochemical methods: immunoprecipitation (flocculation, radial immunodiffusion, and nephelometry), immunoelectrophoretic methods (rocket immunoelectrophoresis), and immunoenzymatic methods (immunoblots and ELISA)
- Standard physicochemical methods used for other purified proteins: mass spectrometry, peptide mapping, and molecular mass determination.

Using these methods, a sample preparation is compared to a reference preparation to demonstrate consistency. The tests listed here may not be appropriate for toxoid proteins.

#### STERILITY OR BIOBURDEN

Sterility and bioburden are determined according to procedures described in ⟨71⟩ and ⟨61⟩, respectively, and 21 CFR 610.12.

#### ENDOTOXINS

To ensure an acceptable level of endotoxin in the final product, manufacturers can determine the endotoxin content of the carrier protein according to ⟨85⟩ and thus can show that endotoxin levels are within acceptable limits. For some products, rabbit pyrogenicity testing ( ⟨151⟩) may be a more relevant test.

## Diphtheria Toxoid

#### ANTIGENIC PURITY

Depending on the manufacturing process diphtheria toxoid preparation can show different degrees of purity. Typically, antigenic purity for diphtheria toxoid as determined by the flocculation test should be at least 1500 Lf (limit of flocculation) units/mg of protein.

#### MONOMER, DIMER, OR AGGREGATE CONTENT

Diphtheria toxin is characterized by the presence of dimeric and multimeric aggregation forms that are also present in the corresponding detoxified preparations. Regarding this parameter, analysts can monitor the manufacturing consistency of diphtheria toxoid by determining the content of monomers vs. dimers and other aggregates using a suitable method such as SEC-HPLC coupled with a static light scattering detector. In some cases, because of the low purity of the preparation the HPLC profile may result in a broad peak that cannot be resolved into the contribution of the individual species.

## Tetanus Toxoid

#### ANTIGENIC PURITY

Typically, the antigenic purity of tetanus toxoid as determined by the flocculation test should be at least 1500 Lf units/mg of protein.

#### MONOMER, DIMER, OR AGGREGATE CONTENT

The detoxification process for tetanus toxin results in oligomerization to an extent that depends on the process conditions. Similar to diphtheria toxoid, the physicochemical consistency of tetanus toxoid can be monitored by the determination of monomeric vs. dimeric forms and other aggregates using suitable methods like SEC-HPLC coupled with static light scattering detection. Other methods like ultracentrifuge analysis can be applied but may be less suitable for routine testing.

## CRM197

CRM197 protein is a nontoxigenic diphtheria toxin isolated from the supernatant of cultures of *Corynebacterium diphtheriae* C7(β197)$^{tox-}$ and purified by a sequence of chromatographic and diafiltration steps. A guideline for production and control of bacterial proteins used in vaccine manufacturing is given in ⟨1238⟩. Recombinant CRM197 should meet requirements for nonrecombinant material, although additional characterization appropriate for recombinant proteins may be required.

#### PURITY

The purity of CRM197 batches should be determined via suitable methods, e.g., HPLC (see ⟨621⟩), sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE; see *Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis* ⟨1056⟩), or

DOI: https://doi.org/10.31003/USPNF_M7149_01_01
@2024 USPC

*Capillary Electrophoresis* ⟨1053⟩. Typical expectations are that the purity of CRM197 should be at least 90% and often greater than 95%.

DEGREE OF NICKING

CRM197 contains an exposed loop of three arginine residues that is clipped by proteases present in the culture medium, resulting in a so-called nicked form. The manufacturing process should demonstrably be able to regularly produce CRM197 with a consistently low degree of nicking. In the presence of a reducing agent like dithiothreitol, the nicked form breaks down into two distinct polypeptides called fragments A and B that can be easily detected by SDS-PAGE, which accordingly is a suitable method to determine the degree of nicking. In a validated process testing may be needed as an in-process control.

### *Haemophilus* Protein D

*Haemophilus* Protein D is obtained as a recombinant protein from *E. coli* fermentation that, after extraction from the cells, is purified by a series of chromatographic and diafiltration steps and finally is sterile filtered. Routine release tests for protein D include identity, purity, sterility, protein content, and endotoxin content. Host cell proteins and host cell DNA should also be tested unless process validation has shown consistent clearance.

PURITY

Purity should be monitored with an appropriate test such as HPLC, SDS-PAGE, or capillary electrophoresis (CE).

### Outer Membrane Protein Complex

The OMPC of *Neisseria meningitidis* group B is derived from meningococcal serogroup B bacterial cells by extraction with buffer-containing detergent. Analysts can monitor manufacturing consistency by determining the OMPC composition with SDS-PAGE or another suitable method.

ENDOTOXIN CONTENT OR PYROGENICITY

To ensure an acceptable level of endotoxin in the final product, analysts can determine the endotoxin content of the carrier protein and can show that it falls within acceptable limits according to ⟨85⟩. Alternatively, OMPC preparations should pass the rabbit pyrogenicity test following injection into rabbits at, typically, 0.25 µg/kg of body mass (see ⟨151⟩).

MENINGOCOCCAL OMPC REQUIREMENTS—PURITY AND LIPOPOLYSACCHARIDE CONTENT

The composition of meningococcal OMPC carrier should be monitored for consistency by SDS-PAGE or by another suitable method. Typically, the lipopolysaccharide (LPS) content should not exceed 8% by weight. Suitable methods for LPS determination include HPLC, colorimetric analyses, SDS-PAGE, and GC-MS.

## KEY QUALITY PARAMETERS FOR ACTIVATED INTERMEDIATES

Different chemical strategies can be applied to the synthesis of glycoconjugate vaccines. Two main approaches have traditionally been employed for glycoconjugate vaccines preparation: one is based on random chemical activation along the chain of the native or slightly size-reduced polysaccharide, followed by conjugation; the other is based on selective activation of end groups of oligosaccharides generated by controlled fragmentation of the native polysaccharide and subsequently coupling to the protein carrier. Depending on the conjugation chemistry, a chemical spacer can be used to facilitate the coupling of the protein to the saccharide antigens, and, in some cases, prior derivatization of the protein carriers is also required. In some cases the activated or derivatized polysaccharide or oligosaccharide is isolated and represents an intermediate of the glycoconjugate vaccine manufacturing process. In order to ensure a reproducible product by means of consistent application of the appropriate conjugation stoichiometry, manufacturers should use appropriate methods to determine the degree of activation or derivatization of the poly- or oligosaccharide and of the carrier protein.

### Degree of Activation of Activated Polysaccharide

If appropriate, different activation or derivatization strategies can be applied to poly- or oligosaccharides in order to make them suitable for covalent coupling to the carrier protein. In some cases the hydroxyl groups of the polysaccharide first are reacted with cyanogen bromide or CDAP or carbonyldiimidazole to form active esters. These active intermediates then can be reacted *in situ* with adipic acid dihydrazide or other bifunctional amines to introduce an amino linker. Some bacterial polysaccharides possess carboxyl or phosphate groups that might be used for introduction of an amino linker using a carbodiimide-mediated chemistry. Subsequent coupling to the carboxyl groups of the carrier protein to obtain the desired glycoconjugate can be performed using, for example, a soluble carbodiimide-mediated chemistry. Alternatively, the amino linker incorporated into the polysaccharide structure can be further derivatized to obtain a bromo-acyl or a maleimido function that is amenable to coupling with a thiol group that is present or previously was incorporated into the carrier protein.

In some other cases aldehyde groups can be introduced into the polysaccharide structure by reaction of vicinal hydroxyl groups with the oxidizing reagent sodium metaperiodate ($NaIO_4$). Depending on the polysaccharide structure, the $NaIO_4$

DOI: https://doi.org/10.31003/USPNF_M7149_01_01
@2024 USPC

treatment can also be used for simultaneous controlled depolymerization and aldehyde group generation. The poly- or oligosaccharides-containing aldehyde groups then can be covalently coupled to lysine residues and the *N*-terminal amino groups of the carrier protein by reductive amination in the presence of sodium cyanoborohydride ($NaBH_3CN$) or other reducing agents that are selective for Schiff bases.

Some manufacturing strategies are based on the controlled hydrolysis of the native polysaccharides to produce oligosaccharides that can be specifically derivatized by a sequence of steps that lead to the introduction of an active ester function at their reducing ends. The desired conjugate is then obtained by reaction of the activated oligosaccharides with the lysine residues and *N*-terminal amino groups of the carrier protein.

To ensure a consistent conjugation stoichiometry, and therefore a consistent manufacturing process, manufacturers should determine the level of derivatization or activation of the poly- or oligosaccharide intermediates. Appropriate methods for determination of the newly introduced chemical functions into the saccharide structures should be in place and could include, for example, colorimetric or other suitable methods. In cases where the activated polysaccharide is conjugated without isolation, consistency in the degree of polysaccharide activation may also be demonstrated as part of process validation or reflected by characteristics of the final conjugate bulk.

The calculation of the degree of poly- or oligosaccharide derivatization may require determination of the total saccharide quantity that can be achieved by applying, for example, HPAEC-PAD, colorimetric assays, or other suitable methods. In a validated process where production consistency has been established, and depending on the conjugation chemistry used and the results of clinical trials, testing may be used as an in-process control. Residual unconjugated linker that could interfere with subsequent steps should be controlled via measurement or process validation.

### Molecular Sizing of Activated, Derivatized, or Processed Polysaccharide

The molecular size and degree of polymerization of the poly- or oligosaccharide intermediates depends on the particular manufacturing process and should be measured because these attributes can affect the consistency of the conjugation process. Suitable tests should be applied to intermediate pools that are selected on the basis of the different manufacturing processes. Examples of suitable methods for profiling molecular sizes and determining the degree of polymerization of poly- and oligosaccharides are: SEC coupled with UV, RI, or static light scattering detectors; colorimetric assays based on total and end group determination; HPAEC-PAD; or NMR spectroscopy. In a validated process, testing can be used as an in-process control.

### Degree of Activation of Activated Carrier Protein

As mentioned above, some manufacturing procedures for glycoconjugate vaccines may also require activation of the protein carrier. This process step introduces into the protein side chains additional functional groups that react with the poly- or oligosaccharide intermediates activated with the proper functional group. In general, such functional groups are introduced by derivatization of protein amino acid side chains like glutamic or aspartic acid with a bifunctional reagent (e.g., adipic acid dihydrazide or hydrazine) so that a highly nucleophilic hydrazide group becomes available for coupling with the polysaccharide. In other manufacturing strategies, the lysine side chains of the carrier protein can be derivatized to introduce different reactive groups (e.g., bromo-acyl, thiol, or maleimido groups). Appropriate methods for determination of the newly formed chemical functions introduced into the carrier proteins should be in place and may include spectrophotometric assays and mass spectrometry. The calculation of the degree of activation or derivatization of the carrier protein may also require the determination of the total protein quantity (e.g., by colorimetric assays or other appropriate methods). In a validated process where production consistency has been established, and depending on the conjugation chemistry used and the results of clinical trials, testing may be used as an in-process control. Depending on the conjugation chemistry used (i.e., immediate conjugation after activation), consistency in degree of carrier protein activation may also be demonstrated as part of process validation or reflected by characteristics of the final conjugate bulk.

### Carrier Protein Monomer Content

In some cases the procedures for protein carrier activation or derivatization may result in a certain degree of covalent aggregation of the carrier itself, and this should be monitored with appropriate tests like SEC-HPLC coupled with static light scattering detection, SDS-PAGE, matrix-assisted laser desorption–ionization mass spectrometry, or other suitable tests.

## KEY QUALITY PARAMETERS FOR MONOVALENT BULK CONJUGATE (DRUG SUBSTANCE)

### Conjugation

Conjugation of the polysaccharide antigen to the carrier protein or protein complex is the critical component of the manufacturing process for conjugate vaccines. A general overview of a conjugation process is presented in ⟨1238⟩. In addition to developing a description of critical processing equipment, reagents, and processing steps, manufacturers should provide the rationale for the conjugation chemistry selected and the purification steps, if any, used to remove unwanted reaction components. Clearance of product-related impurities (e.g., unconjugated polysaccharide or unconjugated carrier protein) should be monitored and controlled.

Depending on the nature of the manufacturing process, the monovalent conjugate bulks can be considered to be the drug substance or can be considered a process intermediate.

During conjugation, the reactive functional groups present on the polysaccharide antigen are reacted with the functional groups located on the carrier protein or carrier complex to form stable, covalent bonds. Many different types of chemistries are used, including reductive amination, thio-alkylation, or CDAP chemistry. The choice of chemical method should be based on

@2024 USPC

the availability of functional groups, either naturally occurring or introduced via an activation or side chain loading process, and the ability to control the manufacturing process to produce a consistent and stable product.

Although the conjugation process may be conceptually straightforward, the process should be well controlled. The process typically consists of mixing the activated polysaccharide with the selected carrier and allowing the components to react. Depending on the nature of the chemical reaction, an additional chemical reactant may be needed to complete the reaction or stabilize the conjugate product. For example, in the case of reductive amination, it may be necessary to add a reducing agent to convert the linkage from a relatively unstable Schiff base to a more stable secondary amine. Chemical deactivation or capping of residual reactive groups may also be required. Finally, residual levels of unreacted components such as free protein, free polysaccharide, chemical reagents, and byproducts should be removed from the process via validation or should be monitored by testing. Regulatory authorities may request stability evaluation of these intermediates because the data may support stability predictions for multivalent vaccines for which data collection is more difficult.

To define and control the conjugation process, the manufacturer should establish targets for process parameters and tolerances for all critical process steps where possible, including extent of activation, charge ratios for each reaction component, reaction time, reaction temperature, reaction pH, and mixing conditions. Additionally, tolerances for the purity of each of the reaction components should be established, including the polysaccharide, carrier protein, and any chemical components as noted above.

The common key quality attributes for monovalent conjugates, the rationale for monitoring these parameters, and suitable test methods are described below.

## Polysaccharide Identity

Polysaccharide identity confirms that the correct antigen was used during the manufacturing process and that no critical epitope was lost during conjugation. Polysaccharide identity should be confirmed using a suitable immunological or chemical method. Examples of immunological methods include ELISA, immunoblot analysis, and rate nephelometry. The specificity of the test method must be ensured by selection of appropriate reagents. Alternatively, the identity of the polysaccharide can be confirmed using a chemical or physical method such as HPLC, HPAEC-PAD, GC, or NMR if acceptable specificity can be demonstrated and it can be shown that the carrier protein does not substantially interfere with the identification of the polysaccharide.

## Carrier Protein Identity

Depending on the nature of the manufacturing process and the manufacturing controls, it may be necessary to confirm the identity of the carrier protein, e.g., during a manufacturing process for a multivalent product in which different antigens are conjugated to different carrier proteins within the same facility. Carrier protein identification can also be performed using an immunological method such as ELISA or, if possible, an appropriate chemical method such as peptide mapping (see *Biotechnology-Derived Articles—Peptide Mapping* ⟨1055⟩). If appropriate, the carrier identity can be evaluated in the same assay that is used for the identity of polysaccharide.

## Polysaccharide Quantity

Polysaccharide quantity or concentration must be confirmed for all lots of monovalent conjugate because it is directly related to the product dose. Polysaccharide yield can also be a useful marker for process consistency. A variety of methods are available and suitable for use in determining the polysaccharide concentration. These include colorimetric methods such as the phenol–sulfuric acid, orcinol, and anthrone–sulfuric acid assays and monosaccharide analysis following hydrolysis by HPAEC-PAD, HPLC with fluorescence detection (HPLC-FD), or GC. Immunological methods that may be suitable include ELISA or rate nephelometry. The suitability of these methods depends on the availability of appropriate reagents. The choice of method should be made on the basis of precision and accuracy. Interference from the carrier protein must be avoided. Additionally, the chemistry of the polysaccharide antigen should be considered when analysts select the method. For example, the phenol–sulfuric acid assay may not be suitable for use if the antigen is composed largely of amino sugars or sialic acid. Suitable methods for polysaccharide quantification are listed in previous sections of this chapter.

## Carrier Protein Quantity

The concentration of the carrier protein must be confirmed for all lots of monovalent conjugate. Conjugate vaccines are typically formulated based on the polysaccharide concentration, not the carrier protein concentration. However, the concentration of the carrier protein is needed to determine the polysaccharide–protein ratio, a key indicator of process consistency.

Analysts should select a test method that is specific for the carrier protein and does not suffer from interference from the polysaccharide components. Suitable methods may include amino acid analysis (see *Biotechnology-Derived Articles—Amino Acid Analysis* ⟨1052⟩), colorimetric protein tests such as the bicinchoninic acid assay or UV absorbance (see ⟨1057⟩ for both types of methods), or the protein-specific output from HPSEC with static light scattering, RI, or UV detection.

## Polysaccharide–Protein Ratio

As noted in *Carrier Protein Quantity,* the polysaccharide–protein ratio may be an indicator of process consistency. Therefore, tolerances should be established for two of the three parameters: polysaccharide concentration, protein concentration, and polysaccharide–protein ratio. It is not necessary to establish limits for all three parameters because the polysaccharide–protein

https://pharmacopeia.com/

DOI: https://doi.org/10.31003/USPNF_M7149_01_01
@2024 USPC

ratio is typically calculated from the measured polysaccharide and carrier protein concentrations. Because the downstream processing and dilutions usually are based on the amount of polysaccharide present in the monovalent bulks, the limit for the polysaccharide content can be based on the minimum concentration required for downstream processing.

## Molecular Size Distribution or Integrity or Proof of Covalency

The molecular size of the conjugate is a key indicator of process consistency. Unusually small conjugates may indicate incomplete conjugation whereas unusually large conjugates may indicate aggregation and may result in a loss of yield during downstream filtration steps. The average molecular size and the size distribution should be measured using appropriate sizing methods such as SEC, HPSEC, HPSEC with static light scattering or RI detection, or analytical ultracentrifugation. The choice of the method should be made on the basis of the expected size of the conjugate and the availability of a chromophore for detection.

## Proportion of Free (or Unconjugated) Polysaccharide

The proportion of unconjugated polysaccharide must be monitored for each lot of monovalent conjugate because of the possibility that the presence of a large amount of unconjugated polysaccharide may suppress the immune response to the antigen. Additionally, the presence of free polysaccharide is a key indicator of process consistency and is an indirect measure of covalent attachment to the carrier. Measurement of the proportion of unconjugated polysaccharide can be used as a stability-indicating test if appropriately validated.

To measure the level of unconjugated polysaccharide, analysts must separate the unconjugated polysaccharide from the conjugated polysaccharide. This can be achieved chromatographically, or by chemical precipitation of the conjugate with acid or detergents, aluminum adsorption, capillary electrophoresis, gel filtration, centrifugal ultrafiltration, solid-phase extraction, or immunoprecipitation. The amount of free polysaccharide then can be quantitated using the method that was used to quantitate the total polysaccharide level, if that method is sufficiently sensitive, by UV detection if a chromophore is present, or by immunological or appropriate physicochemical methods.

The level of unconjugated polysaccharide must be measured at release and during stability testing because deconjugation is a potential degradation mechanism.

## Proportion of Unconjugated Carrier Protein

The level of unconjugated carrier protein must be monitored for each lot of monovalent conjugate because this level is a key marker of process consistency and is an indirect measure of covalency. To measure the amount of unconjugated protein, the unconjugated protein must be separated from the conjugate. This can be done chromatographically or by electrophoresis (slab or capillary). Once it is separated, the amount of unconjugated protein can be monitored by UV or by a colorimetric method (see ⟨1057⟩). Method selection should be based on sensitivity, precision, and specificity for unconjugated protein.

## Unreacted Functional Groups

During the conjugation process, reactive functional groups on the polysaccharide react with functional groups on the carrier protein. However, the reaction is typically not driven to completion, and a process of capping of remaining reactive groups may be required, depending on the nature of the residual reactive groups, the conjugation chemistry used, and manufacturing process optimization. The method chosen to cap reactive groups depends on the conjugation chemistry employed. Even so, some reactive groups may still remain on the conjugate even after the reaction is quenched by reduction, or after remaining reactive groups have been chemically capped. Safety concerns, if any, depend on the nature of the reactive groups and the level of reactive groups that remain. The level of residual reactive groups should be monitored as a measure of process consistency unless process validation has shown that unreacted functional groups detectable at this stage are removed during subsequent manufacturing processes. Additionally, the presence of residual reactive groups may affect product stability during storage.

The test method used to evaluate residual reactive groups depends on the activation chemistry that is used and the nature of the polysaccharide antigen. Appropriate methods may include gas chromatography, HPLC with fluorescence, or UV detection following hydrolysis.

## Residual Reagents

Consistency in the amount of residual reagents from the conjugation chemistry can be demonstrated during process development, and the process can be validated for their clearance. This validation includes not only unconjugated polysaccharide and protein but also buffers, salts, small-molecule reaction components, and byproducts generated during conjugation. Provided that consistent levels of residual solvents are recovered, such testing may serve as an in-process control.

## Sterility or Bioburden

Depending on the manufacturing process, the monovalent conjugate bulks should be tested for bioburden or sterility. If the monovalent conjugate bulks are subjected to additional process steps with no process holds, in some cases it may be appropriate to perform the sterility or bioburden test at a downstream step.

Official

https://pharmacopeia.com/

### Bacterial Endotoxins

The monovalent conjugate bulks must be tested for bacterial endotoxins. If the monovalent conjugate bulks are subjected to additional process steps with no process holds, in some cases it may be appropriate to perform the endotoxin test at a downstream step.

## FORMULATED AND ADJUVANTED (IF APPROPRIATE) CONJUGATE BULKS

Monovalent conjugate bulks can be individually adsorbed and formulated as monovalent bulks before mixing during preparation of the final vaccine.

### Adjuvant Content

If an adjuvant has been added to the conjugate bulk, its content should be determined by an appropriate method. If aluminum is used as an adjuvant, typical maximum values are 0.85 mg of aluminum per dose, although higher limits up to 1.25 mg of aluminum per dose may be accepted if justified, and lower limits may apply according to governing agency requirements.

### Polysaccharide Content

Assessment of polysaccharide content can be required but is often difficult at this stage because of the presence of adjuvants or excipients. Several methods are available and are suitable for use in determining the polysaccharide concentration. These include colorimetric methods such as the phenol–sulfuric acid, orcinol, and anthrone–sulfuric acid assays; and post-hydrolysis monosaccharide analysis by HPAEC-PAD, HPLC-FD, or GC. Suitable immunological methods include ELISA or rate nephelometry. If possible, the same method must be used for both this step and the conjugate bulk step. The choice of method should be based on precision, accuracy, and specificity. Interference from the matrix must be avoided. Additionally, the chemistry of the polysaccharide antigen should also be considered when analysts select the method.

### Free (or Unconjugated) Polysaccharide

Free polysaccharide content must be measured as a release test for monovalent formulated bulk if the free polysaccharide cannot be accurately or precisely measured in the final product. For most applications, polysaccharide testing is a marker of consistency; i.e., it is monitored for each bulk in order to establish production consistency. The test may be omitted when manufacturing consistency has been demonstrated, or the test can be used as an in-process control. If free polysaccharide could be adsorbed on adjuvant, a desorption step using, for example, phosphate buffer, may be required. The unconjugated polysaccharide must be separated from adsorbed and nonadsorbed conjugated polysaccharide. Adsorbed conjugate can be removed by centrifugation, and nonadsorbed conjugate can be eliminated chromatographically; by chemical precipitation of the conjugate with acid or detergent precipitation or aluminum adsorption; by immunochemical precipitation with anti–carrier antibodies; by capillary electrophoresis; or by gel or membrane filtration or ultrafiltration. The amount of free polysaccharide then can be quantitated using the same method that was used to quantitate the total polysaccharide level if the latter is sufficiently sensitive and accurate. Quantitative tests for polysaccharide include colorimetric methods such as the phenol–sulfuric acid, orcinol, and anthrone–sulfuric acid assays; and monosaccharide analysis following hydrolysis by HPAEC-PAD, HPLC-FD, or GC. Suitable immunological methods include ELISA or rate nephelometry.

Results should be expressed as the percentage of unconjugated polysaccharide vs. the total content experimentally determined, or, if this value cannot be determined experimentally, it may be possible to calculate it from a theoretical value.

The level of unconjugated polysaccharide must be measured during stability studies because deconjugation is a potential degradation mechanism.

### Level of Adsorption to Adjuvant

The level of adsorption in monovalent formulated bulks must be performed as a release test if it cannot be performed on the final product. If it is not a release test then the adsorption test is a marker of consistency, and the test is performed on each bulk in order to establish production consistency. After consistent production has been demonstrated, the test can be omitted.

After product centrifugation, nonadsorbed conjugate is quantified in the supernatant. The adsorbed conjugate then is quantified by a suitable validated method, which can be the same test used for the total conjugate content. If the physical or chemical method used for the quantification is not specific for the conjugated form of the saccharide, the amount of free polysaccharide is subtracted from the total polysaccharide in order to determine the quantity of adsorbed conjugate. Otherwise an immunologically specific method can be used (e.g., ELISA). Results can be expressed as the percentage of nonadsorbed conjugate vs. the total content experimentally determined. If it is not possible to determine the amount of nonadsorbed conjugate experimentally then it may be possible to calculate it from a theoretical value. The level of adsorption to adjuvant must be measured during stability testing.

### Sterility

The sterility of each lot should be measured according to procedures described in ⟨71⟩ and 21 CFR 610.12.

https://nhathuocngocanh.com/

# KEY QUALITY PARAMETERS FOR CONJUGATE VACCINE DRUG PRODUCT

## Description and Solubility

Each container in each final fill or drug product should be inspected visually (manually or with automatic inspection systems), and containers that show abnormalities such as improper sealing, lack of integrity, or turbidity should be discarded. Similarly, the presence of clumping or particles may indicate a product failure.

## Polysaccharide Identity

Polysaccharide identity tests confirm that the correct antigen was used during the manufacturing process. Polysaccharide identity should be confirmed using a suitable immunological or physicochemical method, e.g., ELISA, immunoblots, or rate nephelometry. The specificity of the test method must be ensured by use of appropriate reagents. Acceptable specificity must be demonstrated, and tests must show that the carrier protein does not substantially interfere with the identification of the polysaccharide. Assays based on hydrolysis and chromatographic identification of saccharide components (e.g., HPAEC) after polysaccharide hydrolysis may be acceptable.

## Polysaccharide Quantity

Typically, monovalent conjugate vaccines contain 10 µg of saccharide, and multivalent vaccines contain between 1 and 10 µg of each serotype or serogroup per single human dose. Assessment of the content of polysaccharide may be difficult because of the presence of adjuvant or excipients, especially when multiple components are present. The amount of each polysaccharide may be required in order to calculate the free polysaccharide content and the proportion of unadsorbed conjugate, or this information may be used during processing of the vaccine's final formulation. Polysaccharide quantity or concentration must be confirmed for all types of monovalent conjugates because it is directly related to the product dose. A variety of methods are available and suitable for use in determining the polysaccharide concentration [see discussion of polysaccharide quantitation in the *Key Quality Parameters for Monovalent Bulk Conjugate (Drug Substance)* section above].

## Carrier Protein Identity (if Appropriate)

Depending on the nature of the manufacturing process and the manufacturing controls, if the identity of the carrier protein has not been confirmed at an earlier stage, it may be necessary to do so before product release. For example, an identity test for the carrier protein could be necessary during the manufacturing process for a multivalent product for which different antigens are conjugated to different carrier proteins within the same facility. Carrier protein can be identified using an immunological method such as an immunoblot or ELISA, or using an appropriate chemical method such as peptide mapping. If appropriate, the carrier's identity can be evaluated in the same assay used to identify the polysaccharide.

## Molecular Size (if Feasible or Appropriate)

If the molecular size distribution has not been established for the individual monovalent bulk conjugates used in the drug product formulation, the molecular size distribution of the conjugates must be determined in the final fill or drug product. The molecular size of the conjugate is a key indicator of process consistency. The average molecular size and the size distribution should be measured using appropriate sizing methods such as SEC, HPSEC, HPSEC with static light scattering or RI detection, analytical ultracentrifugation, or dynamic light scattering. The choice of the method should be based on the expected size of the conjugate and the availability of a chromophore or fluorophore for detection. In the case of molecular size distribution determinations at the final fill or in drug products composed of multivalent polysaccharides, serotype-specific detection methods may be required for the individual monovalent conjugates. Molecular size is a sensitive indicator of conjugate stability, and, where possible, it should be measured during stability studies.

## Proportion of Free (or Unconjugated) Polysaccharide

To measure the level of unconjugated polysaccharide, analysts must separate the unconjugated polysaccharide from the adsorbed and nonadsorbed conjugated polysaccharide and interfering substances. If unconjugated polysaccharide may be adsorbed to adjuvant, prior desorption with, for example, phosphate buffer is required. Methods for separation and measurement of conjugated and unconjugated polysaccharide are described above in *Formulated and Adjuvanted Conjugate Bulks.* The level of unconjugated polysaccharide is a stability-indicating measurement because deconjugation is a potential degradation mechanism and should be measured during stability studies. However, assessing the level of unconjugated polysaccharide and the stability of complex multivalent products is technically demanding, and alternative approaches to assessing antigen integrity include molecular size, *O*-acetyl content, or immunological measurement. Specific assays may provide partial but overlapping information and should be matched to the product. Free saccharide data obtained for individual monovalent conjugates may also prove valuable and predictive.

## pH, Osmolarity/Isotonicity, and Excipients

If the vaccine is a liquid preparation, the pH and osmolarity/isotonicity of each final lot should be tested and shown to be within the pre-approved specifications. For a lyophilized preparation, the pH should be measured after reconstitution with the

Official

https://pharmacopeia.com/

appropriate diluent. Residual moisture in lyophilized products should be determined. See comments above regarding excipient functionality.

## Adjuvant Quantities (if Appropriate)

If an adjuvant has been added to the conjugate bulk, its content should be determined by an appropriate method. If aluminum compounds (such as aluminum hydroxide or hydrated aluminum phosphate) are used as adjuvants, the amount of aluminum should not exceed 1.25 mg per single human dose or as otherwise required by the governing agency (see also 21 CFR 610.15).

## Antimicrobial Preservative (if Appropriate)

During product development manufacturers should consider the stability of the chosen preservative and possible interactions between the vaccine components and the preservative. If a preservative has been added to the vaccine, the content of preservative should be determined by an appropriate method (see *Antimicrobial Agents—Content* ⟨341⟩). The amount of preservative in the vaccine dose should be shown neither to have any deleterious effect on the antigen nor to impair the safety of the product in humans. If present, the amount must be NLT the minimum amount shown to be effective and typically should be NMT 120% of the amount stated on the label.

## Moisture Content (Lyophilized Products)

If the vaccine is freeze-dried, the average moisture content should be determined by an appropriate method. Values should be within limits established during the product's stability studies. Typically, the average residual moisture content should be NMT 2.5%, and no vial should be found to have a residual moisture content of 3% or greater.

## Sterility

The sterility of each lot should be determined according to procedures described in ⟨71⟩ and 21 CFR 610.12.

## Pyrogens and Endotoxins

Endotoxin (see ⟨85⟩) content or pyrogenic activity (see ⟨151⟩) should be within approved product specifications.

## Diluent for Reconstitution of Lyophilized Vaccines

Manufacturers should generate data that show that adventitious microbial contamination does not grow under the reconstitution conditions (e.g., with diluents that will be used for reconstitution) or under specified storage conditions. A preservative is not normally required for single-dose vials when the product will be used soon after reconstitution, but multidose vials do require preservatives. Testing in alignment with ⟨51⟩ is recommended to demonstrate acceptability, but testing may not be required routinely after process control and consistency have been established.

## General Safety or Abnormal Toxicity

The general safety or abnormal toxicity for vaccines should be established by appropriate evaluation and should be consistent with levels found to be acceptable in vaccine lots that were used in clinical trials.

## INTRODUCTION

Vaccines have been used for centuries to immunize individuals against pathogenic organisms with the goal of preventing the associated diseases. Vaccines are biological products that contain antigens capable of inducing a specific and active acquired immune response in the body. Antigens present in vaccines are processed by specialized cells in the body's immune system, resulting in the development of blood proteins known as antibodies (i.e., humoral immunity), specialized lymphocytes (i.e., cell-mediated immunity), or both. Therefore, immune responses may be antibody mediated, cell mediated, or both. Antigens are ▲the components responsible▲ (USP 1-May-2021) for vaccine function and generally consist of a portion of the pathogenic organism, ▲such as an inactivated or▲ (USP 1-May-2021) attenuated form of the whole microorganism, ▲or are produced recombinantly from a non-infectious organism engineered to express antigens from a pathogenic species or recombinant protein expressed in genetically engineered cell line. In the case of vaccines derived from recombinant technology, the antigen is expressed in a host cell of an unrelated microorganism and then used for vaccine manufacture.▲ (USP 1-May-2021) In the case of

DNA-based vaccines (currently under development), the vaccine would contain nucleotide sequences (genetic material) that encode microbial antigens.

▲▲ (USP 1-May-2021) A list of vaccines currently licensed in the US is posted ▲on the FDA website (see *Appendix*). There are▲ (USP 1-May-2021) various types ▲of vaccines, which can be classified▲ (USP 1-May-2021) depending on their design and the processes involved in their manufacture ▲(see *Table 1*).▲ (USP 1-May-2021) Vaccines for human use may contain whole killed or attenuated organisms (e.g., bacteria or viruses) or antigens derived from portions of a pathogen (either by partitioning and purification or derived using recombinant technology, ▲or they may be engineered to be expressed by non-infectious viruses.▲ (USP 1-May-2021) Some polysaccharide vaccines are conjugated to a carrier in order to enhance their immune response.

**▲Table 1. Bacterial and Viral Vaccines**

| Bacterial Vaccines | Viral Vaccines |
|---|---|
| Carbohydrate subunit vaccines[a] | Recombinant virus-like particles (VLPs)[b] |
| Purified polysaccharide vaccines | Isolated (virus-derived) viral proteins[a] |
| Glycoconjugate vaccines | Recombinant (monomeric) viral proteins[b] |
| Protein subunit vaccines | — |
| Toxoid vaccines | — |
| Isolated bacterial proteins | — |
| Recombinant bacterial proteins[b] | — |
| Bacterially derived protein-containing lipid vesicles[c] | — |
| Inactivated bacterial vaccines[d] | Inactivated viral vaccines[d] |
| Live attenuated bacterial vaccines | Recombinant chimeric viral vaccines |
| — | Live attenuated viral vaccines[e]▲ (USP 1-May-2021) |

[a] Subunit vaccines are extracts from inactivated/killed viruses or bacteria and generally undergo some degree of purification.
[b] Recombinant protein viral and bacterial vaccines are derived from host cells that have been transformed with expression vectors that carry genes that encode antigenic material from infectious agents. The expression cells are grown in bioreactors to produce the recombinant antigenic material.
[c] Protein-containing vesicles are semi-purified native bacterial membrane fragments or artificial liposomes containing specific semi-purified native bacterial proteins or recombinantly expressed antigenic bacterial proteins. Processing and semi-purification renders the preparations non-viable while retaining their immunogenicity.
[d] Inactivated bacterial and viral vaccines are produced by growing cells of disease-causing bacteria or viruses in cell substrates and subsequently inactivating them to prevent replication in the recipient. These preparations may or may not be partially or completely purified.
[e] Live attenuated bacterial or viral vaccines are weakened (attenuated) forms of a pathogen. They contain antigens that are similar to disease-causing microbes. They may be derived from the pathogen itself, or from a different organism that contains antigens that cross-react with the virulent microbe (e.g., vaccinia and variola).

In addition to antigen(s), vaccines may contain ▲▲ (USP 1-May-2021) other components, such as adjuvants that enhance the immune response to the vaccine antigen, preservatives to prevent bacterial or fungal contamination of multiple-dose vials, or other excipients needed for pharmaceutical manufacturing or vaccine stabilization. Residual components from the manufacturing process also may be present in vaccine preparations. Examples of these categories are listed in *Table 2*.

Different vaccine antigens are often combined in one final formulation in order to elicit immunity against multiple diseases and to reduce the number of separate administrations needed to achieve immunity to the various vaccine antigens.

Despite the multiple forms vaccines may take, several common features characterize the manufacture and testing of vaccines. This chapter focuses on commonalities throughout the manufacturing process, from raw material qualification to final release tests.

## Regulations and Standards

Vaccines are regulated by the US FDA as biological products. The general requirements are listed in national laws and international guidances. For the US, national requirements are codified in 21 Code of Federal Regulations (CFR) §200 and 21 CFR §600, with additional recommendations available in the FDA's *Points to Consider* and guidance documents ▲(see *Appendix*).▲ (USP 1-May-2021) [International guidances are available from the International Council for Harmonisation (ICH) ▲(see *Appendix*)▲ (USP 1-May-2021) and the World Health Organization.] New methodologies are continually being developed and validated and will be included in the *USP* as they become available. Reference standards are available from USP and the FDA.

***Change to read:***

## OVERALL MANUFACTURING PLAN

When considering the overall plan for manufacturing a vaccine, manufacturers need to consider the following factors:

- Physical facilities ▲and design, qualification, and maintenance of utilities and equipment▲ (USP 1-May-2021)
- Raw materials and process aids
- ▲▲ (USP 1-May-2021)Manufacturing process▲▲ (USP 1-May-2021)
  - Initial process (production of virus/bacteria and recombinant materials)
  - Downstream processes (purification or chemical modification, if applicable)
- Antigen modifications such as conjugation or toxoiding
- Storage of process intermediates and final bulk
- In-process and final product testing regimens and control schemes
- Addition of adjuvants, if applicable
- Formulation and filling
- Container–closure system
- Stability program that supports the ▲expiry▲ (USP 1-May-2021) dating ▲▲ (USP 1-May-2021) of the product

Quality systems are needed to support the following manufacturing process development: specifications for raw materials, process ▲controls and process▲ (USP 1-May-2021) intermediates, and final product ▲quality, stability, and shelf-life studies; analytical development and validation;▲ (USP 1-May-2021) change control; ▲facility, utility, and equipment qualification; cleaning, maintenance, and potential change-over protocols;▲ (USP 1-May-2021) and failure investigations and complaints. All of these elements are important in the life cycle of the vaccine product.

The overall goal of a comprehensive manufacturing program is to consistently ▲and continuously▲ (USP 1-May-2021) produce a vaccine that is safe and effective. Concurrently with clinical development of the vaccine, the manufacturing process is refined, ▲the process is validated for consistency,▲ (USP 1-May-2021) and the ▲test▲ (USP 1-May-2021) methods are validated for ▲their intended use.▲ (USP 1-May-2021) This includes systems to control changes to the process or inputs. Manufacturers should expect that changes will be required during the vaccine's manufacturing life cycle, and manufacturers necessarily will use data from development and routine manufacturing to assess the process as well as proposed changes. The manufacturers should adopt systems that continually evaluate all aspects of manufacturing to identify unanticipated changes in vaccine quality and to assess them as quickly as possible.

## Manufacturing Facilities and Systems

Manufacturers should ▲document the▲ (USP 1-May-2021) general layout of the manufacturing facilities, including diagrams that show the following: flow of raw materials and process inputs; movement of product, intermediates, waste streams, and personnel; and air flows and pressurization levels. These diagrams assist in minimizing the risk of potential product contamination from various sources. These sources can include cross-contamination from other products, contamination from different batches of the same product, and extraneous contamination from microorganisms ▲or foreign material.▲ (USP 1-May-2021)

Official

https://pharmacopeia.cn/v29240/

Evaluation of the flow diagrams can assist with strategies for the development of engineering controls, personnel procedures, and monitoring systems to enable compliance with ▲current▲ (USP 1-May-2021) good manufacturing practices (▲cGMPs).▲ (USP 1-May-2021) Analysis of potential risks may also provide insights about what information should be recorded in batch documentation to facilitate consistent manufacture and failure investigations. Together, physical facilities, ▲utilities, equipment,▲ (USP 1-May-2021) procedures, personnel, training, and quality systems make up the GMP environment in which a vaccine will be produced.

## Manufacturing Process

The manufacturing process includes process inputs such as raw materials and processing aids and unit operations comprising both the initial and downstream processing steps. A process flow map for the manufacturing process is useful and assists in validation of the manufacturing process. This map shows all unit operations, the inputs to each operation, and the outputs to subsequent manufacturing steps. Analytical testing done at relevant steps and the specifications required to proceed to the next stage of processing may be added to the map. A process map also supports a processing space to facilitate a rugged process (i.e., one based on suitable characterization studies to establish boundaries within which manufacturing can occur to promote unchanged safety and efficacy outcomes).

The process flow map should include all steps from making the seed/cell bank ▲▲ (USP 1-May-2021) to formulation, filling, ▲and packaging▲ (USP 1-May-2021) of the final product. The validation strategy should include the steps that require validation, along with identification of the process space, associated critical process parameters (CPPs), and critical quality attributes (CQAs). The CPPs are those that directly affect the core quality attributes needed to successfully manufacture a batch of product. Some manufacturers identify other processing parameters that are important for processing but do not affect CQAs. These important but noncritical factors help identify the process development space, can contribute to the development of a rugged process, ▲and▲ (USP 1-May-2021) can be useful when the company assesses processing deviations. The concepts of quality by design and exploration of the process space are relatively new to the biologics/vaccine industry but are becoming considerations for the overall development-planning process).

## Manufacturing Surveillance

Manufacturing surveillance is the continual observation of how the process and the resulting product are performing. This section is not exhaustive; rather, the points raised here outline the types of considerations recommended for a manufacturer during the development of a vaccine. Manufacturing surveillance includes the following:

- Periodic review of the performance of the manufacturing process
- Analytical assays
- Stability programs
- ▲Facility evaluation through environmental monitoring▲ (USP 1-May-2021)
- Product complaints
- Adverse event reports
- Product failure investigations
- Atypical or deviation events

Taken as a whole, these activities allow a manufacturer to assess the state of the process and product and to evaluate which, if any, operations need to be modified. These same systems also provide a surveillance matrix to evaluate changes. In any of these programs, it is also valuable to develop additional characterization assays that are not used for process intermediate or product release purposes but may be used for further evaluation when additional information is needed or desired. These additional assays for characterization are often based on different underlying analytical procedures to provide different ways to evaluate materials.

Routine surveillance processes are increasingly implemented to attempt to detect changes in processes before any CQAs are adversely affected. Not all vaccine processes can be characterized to the same extent or level (e.g., a live virus vaccine vs. a recombinant protein vaccine), and statistical tools are often used to determine alert or action levels in surveillance programs. Exceeding these levels requires the manufacturer to evaluate the situation but does not necessarily signal product failure.

GMP manufacturing entails facility, ▲utilities, and equipment▲ (USP 1-May-2021) design; process development; quality systems; and manufacturing surveillance. Together, these systems help the manufacturer to control the production of a vaccine. As noted, many types of vaccines are marketed, and each has its unique features and therefore requires different plans for each of the steps mentioned in this section.

***Delete the following:***

## ▲SEED LOT SYSTEMS

Seed lots are the stocks of specific strains of bacteria, viruses, or biotechnology-engineered cells used to express vaccine antigens. All seed lots should be documented in terms of their isolation, derivation (or construction, in the case of recombinant vector or engineered cells), and passage history. The purpose of a seed-lot system, which typically includes master and working stock seeds, and associated master and working cell banks, is to help ensure the consistency of vaccine manufacturing. The use of master and working seed lots provides a method to limit the replication of the seed and to minimize the possibility of genetic variation.

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M914_02_01

A master seed lot is a physically homogeneous preparation derived from an original seed processed at one time and passaged for a limited number of times. The master seed lot is characterized for its biological, biochemical and genetic characteristics, and to ensure its purity, its freedom from adventitious agents, and its clinical ability to produce an effective vaccine.

Cultures from the working seed lot should have the same characteristics as the master seed lot from which they are derived. For influenza vaccines, which may be reformulated with new virus antigens each year, certified seed lots can be obtained from national regulatory agencies.

A working seed lot is derived from the master seed within a limited number of passages. The working seed is tested to ensure its purity, freedom from adventitious agents, and biochemical properties. The working seed is used for production of vaccine without intervening passages.

## Bacterial Vaccine Seed Lot System

In the bacterial seed lot system, a master seed is subcultured to produce a working seed one passage beyond the master seed. An aliquot of the working seed is then expanded to produce a vaccine lot. The strain(s) used for the master seed lots are identified by historical records that include information about their origin. Information about the bacterial seed lot system should include source, passage history, and raw materials to which it was exposed, with specific emphasis on raw materials of ruminant origin. Seeds should be stored at an appropriate temperature in more than one location within a facility or at a distant site in order to decrease catastrophic risk.

Identity tests may include inoculation onto suitable biochemical media, Gram stains, genotype, and serological identification with suitable specific antisera. Special tests may be added, for example, to show culture viability but also lack of virulence.

Purity of the bacterial strains used for seed lots is verified by methods of suitable sensitivity to ensure that no adventitious agents are present. These purity tests often are performed in the presence of the seed under conditions where growth is inhibited by the presence or the absence of specific nutrients. Streaking can also be used to show that the cultured seed is a pure culture.

## Viral Vaccine Seed Lot System

The derivation and passage history of viral seeds should be recorded in detail. Any manipulation of the viral phenotype (e.g., cold adaptation, development of temperature sensitivity, or attenuation of virulence) or intentional genetic manipulations (e.g., reassortment or recombination) should be documented.

These viral seeds are commonly differentiated into a master viral seed and working viral seeds or working viral stock. Viral seeds should be stored at cryogenic temperatures to promote stability and in more than one location within a facility or at a distant site to decrease catastrophic risk. Manufacturers should assess the following characteristics of the viral seed stock:

- Growth characteristics on the intended production cell substrate,
- Tissue tropism;
- Genetic markers;
- Identity (for recombinant vectors);
- Viability during storage,
- Genetic stability through production;
- Attenuation properties;
- Purity;
- Absence of adventitious agents. If attenuation or derivation is achieved by passage through different species, the viral seed should be assessed for absence of adventitious agents common to those species.

The master viral seed should be extensively characterized to demonstrate the stability of genotype and phenotype for a number of passages beyond the level used in production. Generally, during assessment of genetic stability, a master seed undergoes a minimum of five passes beyond the passage that will produce the final vaccine.

Tests should be performed for identity (e.g., sequencing the entire virus or a portion of it), adventitious agents, viral phenotype, genetic stability, and, if applicable, agents that might be present in the seed as a result of its passage history. Viral phenotype can be assessed further for tissue tropism, attenuation properties, and temperature sensitivity. Not all of these tests may be necessary for every viral seed strain.

In some cases the viral seeds may have a broad host range and therefore may require neutralization of the vaccine virus before they are tested for adventitious agent(s). If possible, testing for adventitious agents should be done without neutralization in order to avoid an antiserum that may inadvertently neutralize an adventitious agent present in the seed. Sometimes it is not possible to effectively neutralize a viral seed, and in such cases alternative strategies can be used. For example, the test can be performed in a cell substrate that does not permit replication by the vaccine virus. However, such a substitution of the substrate cell may compromise the test's sensitivity for detection of other adventitious agents. Therefore, the tests may be supplemented with use of polymerase chain reaction (PCR) assays.

Assessment of neurovirulence may be appropriate if the virus is known to be neurotropic. Manufacturers should consult with regulators about appropriate animal models, methods, and scoring systems for this assessment before they initiate such studies. For viruses that are neurovirulent or may revert to neurovirulence (e.g., polioviruses), it may be necessary to assess neurovirulence beyond the master seed.

If the master viral seed is well characterized, the working viral seed may not require extensive characterization. For example, it may not be necessary to repeat testing for all the relevant viruses from the derivation history.

## Systems for Biotechnology-Engineered Vaccines

For a vaccine produced via a biotechnology-engineered cell-expression system, a master seed lot or a master cell bank will be established during product development. The seed lot or cell banks should be homogenous, which is often accomplished

by limiting dilutions. The seed lot or cell bank system should be characterized in a manner analogous to that used for the cell substrate discussed in the next section, and additional tests can be used to demonstrate the genetic stability of the expression system.▲ (USP 1-May-2021)

***Change to read:***

## ▲RAW MATERIALS,▲ (USP 1-MAY-2021) FERMENTATION, AND CELL CULTURE MEDIA

▲Raw materials can directly affect the identity, strength, purity, and quality of vaccines. A consistent manufacturing process critically depends on the use of consistent raw materials (e.g., during seed banking, propagation, harvest, purification, and formulation). Accurate records of the composition and source of the culture medium used in seed banking and routine fermentation should be maintained, and the release criteria for raw materials or components should also be documented.▲ (USP 1-May-2021)

A medium is the material in which an organism is grown and amplified in quantity to produce mass material for vaccine production. Its composition is diverse and depends on the cell types that the medium supports, ranging from well-defined chemical media to chemically undefined media that contain natural components such as sera from animal origin (see *Bovine Serum* ⟨1024⟩). ▲Raw materials for bacterial growth media typically consist of both well-defined chemical entities (e.g., amino acids, carbohydrates, vitamins, minerals) and more complex components (e.g., protein hydrolysates, yeast extracts, peptones). Manufacturers should consider the source of each of these raw materials to ensure that they come from reliable vendors who adhere to cGMP quality standards and can assure a long-term supply. Manufacturers should communicate with raw material vendors in order to avoid any changes in the sourcing or manufacture of components and to avoid supply shortages. Without such communications, the consistency of the propagation processes and the supply of the vaccine can be adversely affected. Consistent raw materials are particularly critical for more complex fermentation components such as fetal calf serum, yeast extracts, or peptones, for which changes may be difficult to detect but are likely to have a direct effect on fermentation. In general, the use of animal-derived raw materials should be minimized because they pose additional risks and are more prone to variability. The section below, *Materials of Animal Origin*, describes additional considerations specific to animal-origin raw materials.

The use of antibiotics should be minimal or should be avoided to ensure that no unwanted antibiotics are included in the drug product unless they are intentionally used in manufacturing (e.g., as selective markers).

As manufacturers scale up fermentation to pilot production (i.e., within 10-fold of final manufacturing scale), they should also ensure, to the extent possible, the availability of multiple sources for all raw materials. This will ensure that supply or business instabilities at one vendor do not become the limiting factor in vaccine manufacture.

Specific requirements relating to bacterial vaccines are covered in *Vaccines for Human Use—Bacterial Vaccines* ⟨1238⟩, and aspects specific to virus-derived and recombinant viral vaccines are covered in *Vaccines for Human Use—Viral Vaccines* ⟨1239⟩.▲ (USP 1-May-2021)

***Add the following:***

## ▲MATERIALS OF ANIMAL ORIGIN

Some raw materials and reagents, such as gelatin, calf serum (see ⟨1024⟩), or trypsin for vaccine manufacturing raise concerns regarding the potential presence of adventitious agents. Gelatin or processed gelatin also is used as a vaccine stabilizer. The gelatin source may be either bovine or porcine. Although the conditions of manufacturing gelatin are harsh (i.e., the product is subjected to extremes of heat and pH), there remains a concern with bovine sources about the presence of the transmissible spongiform encephalopathy (TSE) agent, because this agent is known to resist such conditions. Therefore, if gelatin added to a vaccine or used in manufacturing is from a bovine source, the material should have the appropriate documentation certifying that it comes from a country or region that is in compliance with TSE guidance for industry. In case such a certification cannot be provided, tests should be performed on the raw material to demonstrate that it is TSE-free. If additives from animal sources are added to the culture medium, they should be certified to be free from contaminants and adventitious agents, or raw materials should be sourced from countries acceptable to the FDA. Vendors/manufacturers should provide information about the identity and source of additives and should test for adventitious agents. Additionally, manufacturers should test these materials when possible to minimize the risks of contamination with adventitious agents, such as those that cause bovine spongiform encephalopathy or TSE. Reduction of serum components [e.g., bovine serum albumin (BSA)] should be considered in processing.▲ (USP 1-May-2021)

***Add the following:***

## ▲SEED LOT SYSTEMS AND CELL BANKING

Cell banking is described in detail in *Cell Banking* ⟨1042⟩. Aspects specific to bacterial vaccines are included in ⟨1238⟩, and aspects related to viral vaccines (such as virus seed stocks) are described in ⟨1239⟩.▲ (USP 1-May-2021)

## PROPAGATION AND HARVEST

The propagation and harvest phases follow the manufacturing process from the initiation of cell growth in the working cell bank to the separation of the crude drug substance. In addition, in these manufacturing process steps, raw materials, media, and solutions should be qualified for their intended use. Batch numbers should be clearly assigned as needed, and the relationship between component harvests and batches of individual drug substances should be recorded clearly.

▲Propagation and harvest for bacterial vaccines are described in detail in ⟨1238⟩ and in specific product class chapters. Propagation and harvest for viral vaccines are described in detail in ⟨1239⟩.▲ (USP 1-May-2021)

***Add the following:***

## ▲VACCINES PRODUCED BY RECOMBINANT TECHNOLOGY

The production of antigen, either monomeric or in self-assembling aggregates such as virus-like particles, is increasingly being performed using recombinant technology in a heterologous production cell line. In general, the requirements for the production of these products follow the requirements for other recombinant protein products.▲ (USP 1-May-2021)

***Change to read:***

## PURIFICATION

The objective of the purification steps is to remove as much as possible of the impurities in the initial harvest and to maximize the purity of the final vaccine product. Process residuals may consist of materials from the culture medium and/or cellular components. Purification procedures should be optimized and validated. When applicable, viral clearance steps (viral removal or inactivation) should be included and validated using relevant model viruses. Special considerations are observed depending on the types of vaccines and production system used.

▲Information specific to the purification of bacterial vaccines is presented in ⟨1238⟩, material specific to bacterial polysaccharide and glycoconjugate vaccines is presented in *Vaccines for Human Use—Polysaccharide and Glycoconjugate Vaccines* ⟨1234⟩, and information specific to viral vaccines is presented in ⟨1239⟩.▲ (USP 1-May-2021)

### Biotechnology-Engineered Cells

Of ▲particular▲ (USP 1-May-2021) concern in the purification of recombinant-derived vaccine components, ▲including virus-like protein vaccines,▲ (USP 1-May-2021) is the issue of residual host cell components that could produce an adverse immunogenic response in patients. This response could be exacerbated by the presence of vaccine adjuvants.

▲▲ (USP 1-May-2021)

***Change to read:***

## INTERMEDIATES

Intermediates are defined here as the unformulated active (immunogenic) drug substances that are ▲further▲ (USP 1-May-2021) processed before final formulation and can be stored ▲▲ (USP 1-May-2021) before further processing. Those intermediates ▲that will▲ (USP 1-May-2021) be stored should be included in a formal stability program ▲to assess maximum storage times.▲ (USP 1-May-2021) Examples of intermediates include bulk polysaccharides, purified recombinant proteins (concentrates), ▲toxoids, purified and inactivated virus harvests, and polysaccharide activation and carrier-protein conjugation intermediates.▲ (USP 1-May-2021)

### Production of Intermediates

Intermediates are manufactured from starting materials by one or a combination of different processes (e.g., fermentation, cultivation, isolation, or synthesis). Subsequent steps of the procedure involve preparation, characterization, and purification, eventually resulting in the drug substance ▲intermediate.▲ (USP 1-May-2021) Quality systems documents are adopted for ▲process development, in-process controls, and▲ (USP 1-May-2021) production and all applicable information should be recorded in a controlled document (i.e., a batch record). When applicable, stability studies ▲should be available▲ (USP 1-May-2021) and release tests should be performed before proceeding to the next ▲processing▲ (USP 1-May-2021) steps (see below).

### Tests for Intermediates

The quality attributes of the intermediate are commonly tested in conjunction with further ▲batch▲ (USP 1-May-2021) processing. Characterization beyond release testing should be considered. Characterization methods can use appropriately qualified procedures. Depending on the individual vaccine, some tests are routinely performed before the intermediates are converted to the final bulk.

If intermediates need to be stored and/or subsequently shipped to a different location for further processing, the stability of these materials should be demonstrated. Stability tests can be a combination of both physicochemical analysis and biological assays.

***Add the following:***

## ▲FILTERED BULK OR DRUG SUBSTANCE

The final step in the manufacturing of antigen intermediates is the preparation of filtered bulk or drug substance. It is acceptable to have a low-bioburden drug substance, provided that sterile filtration is performed prior to use of this material to prepare formulated bulk. Preparation of low-bioburden drug substance involves filtration using 0.22-µm sterilizing grade filter membranes. For some antigens, which are not amenable to filtration, the process of manufacturing should be an aspectic process demonstrated through the use of media-fill tests. According to the FDA guideline (see *Appendix*) and industry standards, filters used for the final filtration to prepare sterile filtered bulk should be validated to reproducibly remove microorganisms from a carrier solution containing bioburden of a high concentration of at least $10^7$ colony forming units (cfu)/$cm^2$ of effective filter area (EFA). Thus, the retention capacity of a validated sterilizing-grade filter with an EFA of A ($cm^2$) is at least A × $10^7$ cfu. However, the currently used 0.22-µm sterile filter membranes can withhold much higher microbial challenges (unpublished company results for 0.22-µm polyvinylidene fluoride membranes demonstrated that a bacterial challenge concentration as high as $10^9$ cfu/$cm^2$ can be validated).▲ (USP 1-May-2021)

***Change to read:***

## FINAL BULK ▲(FORMULATED BULK)▲ (USP 1-MAY-2021)

Final bulk is the ▲formulated▲ (USP 1-May-2021) drug product that contains the drug substance(s), excipients, and other ingredients at the desired concentrations and is ready for filling into individual ▲dosage containers from which the vaccine would be administered.▲ (USP 1-May-2021)

### Production of Final Bulk

Appropriately controlled amounts of all ingredients are blended to uniformity to produce the final bulk. The processing may include one or more steps such as buffer exchange and addition of diluents, bulking agents, stabilizing excipients, adjuvants, and preservatives. Final bulk may be prepared aseptically or processing may include a sterilization step.

### Tests for Final Bulk

The quality attributes of the final bulk should be tested. Appropriate testing should be performed with respect to identity, purity, potency, sterility (see *Sterility Tests* ⟨71⟩), and antimicrobial effectiveness (see *Antimicrobial Effectiveness Testing* ⟨51⟩). Tests demonstrating safety ▲and potency,▲ (USP 1-May-2021) if applicable, are performed.▲▲ (USP 1-May-2021)

Testing is required for specific process-related and product-related impurities, depending on the vaccines being manufactured. In addition, tests are required for the bulking agent, stabilizing excipients, adjuvants, and/or preservatives, if used. All the testing should be done according to respective standard operating procedures (SOPs), and all tests should have specifications (or provisional specifications, where applicable).

### Stability Test for Final Bulk

If final bulks are stored and/or subsequently shipped to a different location for further processing, the stability of these materials should be demonstrated. Stability tests can be a combination of both physicochemical analysis and biological assays. Implementation of a stability program is required for formal stability studies, and the studies should be executed according to a protocol that contains detailed information about the types of tests, including specifications, ▲storage condition,▲ (USP 1-May-2021) testing intervals, and data and analysis.

***Change to read:***

## FINAL CONTAINER

A final container of vaccine contains the active ingredient(s) [i.e., antigen(s)] as well as additional components, such as stabilizers, adjuvants, ▲and/▲ (USP 1-May-2021)or antimicrobial preservatives. They also may include residual materials from the manufacturing process.

### Excipients and Other Additives

In addition to specific antigens, vaccines often include excipients and other additives that are intentionally added to the vaccine by the manufacturer for a specific purpose. These include adjuvants, antimicrobial preservatives, and stabilizers. Vaccines also contain manufacturing residuals, which are trace amounts of various components used during manufacturing. Thus, the

Official

https://pharmacopeia.cn/v29240/

combinations of these components comprise and define the complete vaccine product. Manufacturers must adhere to regulations governing permissible limits of such components, as indicated in the product's license.

## ADJUVANTS

Adjuvants are agents incorporated into vaccine formulations to enhance and increase the immune responses generated by the vaccine antigens. Specifically, they can increase the amount of antibody produced, direct the immune response (Th1 or Th2), increase the duration of antibody presence (persistence), or produce a combination of these effects.

Aluminum compounds have long been the most widely used adjuvants worldwide. Two methods traditionally have been used for combining aluminum adjuvant to antigen to form aluminum-adsorbed vaccines. The first involves the addition of the antigen solution to preformed aluminum precipitate. The second involves the addition of an antigen to aluminum in solution and the addition of a compound that will coprecipitate the aluminum salt and the antigen in situ. Solutions of aluminum potassium sulfate, known as alum or aluminum chloride, have been used together with phosphate salts as precipitating agents. A number of aluminum adjuvant formulations are used in vaccines.

Tests for aluminum are based on metal detection tests described in *Aluminum* ⟨206⟩. Regulations ▲[see 21 CFR §610.15(a), *Ingredients, preservatives, diluents, adjuvants*]▲ (USP 1-May-2021) limit the amount of aluminum permitted in a dose of vaccine.

▲Other adjuvants have recently been used in vaccine products licensed in the US, including squalene and monophosphoryl lipid A (MPLA) (in combination with an aluminum-based adjuvant). MPL is quantified either through degradation to fatty acid methyl esters and quantification by gas chromatography, or through quantification of the glucosamine content. Squalene is quantitated by HPLC. Squalene adjuvants should be characterized for both the mean particle size and the number of large particles. The surfactants (e.g., sorbitan trioleate, Tween 80) used to formulate the squalene adjuvant can also be quantitated using HPLC. Specific tests to monitor the stability of bulk adjuvant should be developed.▲ (USP 1-May-2021)

Note that adjuvants are not licensed by themselves; they do not constitute a product. Rather, a vaccine consisting of specific antigen(s) and an adjuvant are licensed together as a drug product.

## ANTIMICROBIAL PRESERVATIVES

In the case of multiple-dose containers, antimicrobial preservatives are added to inhibit the growth of microorganisms that may be introduced from repeated puncture of multidose vials. With certain exceptions, a preservative is required to be present in vaccines marketed in multidose containers [21 CFR §610.15(a)]. Exceptions include yellow-fever vaccine; measles, mumps, and rubella ▲vaccine;▲ (USP 1-May-2021) and dried vaccines when the accompanying diluent contains a preservative.

The microbial preservatives currently used in vaccines are thimerosal, 2-phenoxyethanol, benzethonium chloride, and phenol. These agents must pass the appropriate antimicrobial effectiveness test, as described in ⟨51⟩. Antimicrobial test challenges should be conducted as part of the normal formal stability program, including at the expiration date. Various tests for preservatives can be found in *Antimicrobial Agents—Content* ⟨341⟩.

## STABILIZERS

The primary purpose of stabilizers is to protect certain vaccines from adverse conditions such as heat or to serve as a cryopreservative during the lyophilization process, usually during the freezing step. The particular materials chosen for this purpose include sugars (e.g., sucrose or lactose), amino acids [e.g., glycine or glutamic acid (monosodium salt)], glycerol, and proteins [e.g., human serum albumin (HSA) or gelatin]. Materials should be customized to a specific vaccine formulation and selected with patient safety in mind.

When a protein is chosen as a stabilizer, two main safety concerns arise. One stems from the source of the protein: animal or human origin raises the possibility of the presence of an adventitious agent. The second concern is the possibility of an allergic reaction in persons sensitized to that protein. This should be evaluated as part of the clinical program during vaccine development. At present, two proteins are used as stabilizers for vaccines: HSA and gelatin. The FDA requires that any serum-derived albumin used in manufacturing be US-licensed HSA. FDA guidance further recommends that a statement indicating the source and related risks appear in the "Warnings" section of the labeling for HSA-containing products.

▲In case such a certification cannot be provided, tests should be performed on the raw material to demonstrate that it is TSE-free.▲ (USP 1-May-2021)

## MANUFACTURING RESIDUALS

Vaccines may contain residual amounts of any of the materials used in the manufacturing process. These materials are termed manufacturing residuals. As a general principle, it is not possible to remove a particular substance completely, nor is it possible to conclusively demonstrate that a particular substance has been completely removed. Therefore the goal is to reduce these substances to an undetectable level, using a sensitive and validated analytical methodology. Some products are tested for pyrogenic substances as a manufacturing residual (see *Pyrogen Test* ⟨151⟩); and, if the product is freeze-dried, it should be tested for residual moisture (see *Loss on Drying* ⟨731⟩). Residual levels of manufacturing materials, including inactivating agents if applicable, should be justified. The release specifications of these components are required as part of the approved license ▲and can be validated out as manufacturing experience increases.▲ (USP 1-May-2021)

## CELL-DERIVED RESIDUALS

Live attenuated bacterial vaccines are not usually subject to a high degree of post-expansion purification. However, killed bacterial component vaccines typically undergo significant purification to reduce cell-derived residuals. Common cellular components to be reduced are proteins, nucleic acids, and polysaccharides. Assays for these components are routinely conducted, if appropriate, to ensure purity. A common residual in bacterial vaccines made from gram-negative bacteria is

DOI: https://doi.org/10.31003/USPNF_M914_02_01
@2024 USPC

lipopolysaccharide (LPS), commonly known as endotoxin. Endotoxin testing is performed during the manufacturing process for any gram-negative bacterial vaccine. In the case of gram-positive bacterial vaccines, the endotoxin testing should be conducted to ensure that no contaminants from gram-negative bacterial growth are present. Also, there must be a release specification for this residual. Two tests are currently used to detect LPS in biological products, the *Limulus* amebocyte lysate (LAL) test (see *Bacterial Endotoxins Test* ⟨85⟩) and the rabbit pyrogen test (see ⟨151⟩). The *Limulus* lysate that is used to test for bacterial endotoxin in FDA-regulated products is itself a US-licensed product. The rabbit pyrogenicity test requires the use of animals and is more difficult to perform; therefore, it is not employed to the ▲same▲ (USP 1-May-2021) extent as the LAL test.▲▲ (USP 1-May-2021)

Viral vaccine manufacturing requires cell substrates to produce the viruses, which are then taken through purification processes. Generally, killed viral vaccines are more highly purified than live attenuated ones. Depending on the method used to manufacture the vaccine, manufacturers work with the FDA to develop prudent specifications for the final vaccine. Animal-derived host cells have been used extensively in vaccine manufacturing, particularly for viral vaccines. For example, influenza and yellow fever vaccines are produced in egg allantoic fluid and chicken embryos, respectively. Mumps, measles, and some rabies vaccines are produced in chick embryo cells. The labels of these products must state that residual chicken proteins may be present in the final vaccine, and the label may indicate how much is present. Further, the label also urges practitioner caution when vaccinating a person with a known hypersensitivity to eggs.

▲Some▲ (USP 1-May-2021) hepatitis B vaccines are based on recombinant DNA-derived proteins expressed in yeast cultures. In ▲these▲ (USP 1-May-2021) cases, the labels notify health care professionals that yeast protein may be present in the vaccine and recommend that suitable precautions be exercised. In the case of live viral vaccines, considerations may be given to the reduction of cellular residual materials (e.g., host DNA, proteins). ▲▲ (USP 1-May-2021)

### ANTIBIOTIC RESIDUALS

Some antibiotics (but not penicillin) can be used in minimal amounts in the manufacturing process for viral vaccines, according to 21 CFR §610.15(c). Those that have been used include gentamicin, streptomycin, neomycin, and polymyxin B. There is no requirement for tests of residual levels of these antibiotics in the final vaccine. However, according to 21 CFR §610.61(m), the calculated amount expected to remain as a residual in the final vaccine, based on the amount added and the dilution factor in the manufacturing process, must be stated on the product label.

### INACTIVATING CHEMICAL AGENTS

Several chemical agents have been used to inactivate bacteria and viruses or to detoxify toxins in vaccine production processes. Formaldehyde and β-propiolactone are the most commonly used inactivating agents. Other less often used inactivating agents include glutaraldehyde and hydrogen peroxide. As a manufacturing residual, the inactivating agent should be removed from the final product as thoroughly as possible. The upper limit for formaldehyde is generally 0.02%, equivalent to 0.1 mg per 0.5-mL vaccine dose. The limit for β-propiolactone should be below the limit of detection.

***Change to read:***

## EVALUATING THE STABILITY OF VACCINES

The stability of vaccine products depends on the nature of the vaccine antigen, the product formulation, ▲the container–closure system,▲ (USP 1-May-2021) and the control of vaccine storage prior to use.

Vaccine products are evaluated using programs that include real-time long-term storage under prescribed conditions. The use of extreme temperatures ▲or other factors▲ (USP 1-May-2021) to potentially accelerate degradation may help manufacturers understand the stability of the product.

Vaccine products, like all pharmaceutical products, should be evaluated to define suitable conditions for storage (21 CFR §610.50 and §610.53). General principles of stability testing for biological products are described in *Quality of Biotechnological Products: Stability Testing of Biotechnological/Biological Products* ⟨1049⟩. Typically, these concerns are focused on the final vaccine product, but evaluations are also needed for bulk intermediates to justify the conditions under which they are held. In both cases, manufacturers define in advance the conditions to which the product will be exposed (e.g., temperature, light, and humidity) and the time range during which the product will be exposed to those conditions. Stability studies should evaluate all storage conditions to which the product or intermediate is likely to be exposed during production, handling, shipping, and storage so that appropriate time limits can be placed on the exposure to those conditions.

The primary criteria for defining the storage conditions for these intermediates and the final products are generally focused on acceptable maintenance of potency; however, as discussed below, there often are other attributes that need to be considered.

Evaluation of the stability of vaccine products has three general purposes. First, the products are shown to maintain an acceptable analytical profile throughout manufacture and use to preserve safety and effectiveness. Second, stability studies across several product batches provide an effective way to characterize the inherent properties of the product. This in turn leads to the third use, demonstrating manufacturing consistency in the product. ▲Higher-temperature stability studies are usually performed to generate data in support of excursions and investigations and are not expected to be performed on every batch that is placed on stability.▲ (USP 1-May-2021)

### Stability Protocols

The overall experimental plan for evaluating the stability profile of a given set of product or intermediate batches typically specifically defines the conditions under which the samples will be stored, why these conditions are relevant, the length of time

Official

https://nhathuocngocanh.com/

the samples will be stored at each condition, when samples will be tested during this time course, and the analytical measurements at each time point. Additionally, these stability protocols itemize the analytical procedures to be used. For stability studies that occur early in product development, the studies may be conducted to confirm the suitability of the product formulation and/or storage conditions. Later in development, stability studies are typically conducted to provide data supporting the product ▲expiry dating▲ (USP 1-May-2021) or intermediate hold time, to provide more elaborate product characterization, and to evaluate manufacturing consistency. These latter studies define the product end–expiry specifications that allow definitions of acceptable and unacceptable product. Unacceptable product is defined as product that is no longer acceptable for use in clinical studies or for commercial use (e.g., because of degradation or loss of potency). Stability studies should be conducted over a duration sufficient to determine the point of loss of acceptable potency or other relevant parameters.

## Analytical Measurements

Manufacturers should consider the rigor of the analytical method(s) used to evaluate the stability of complex products and improve their understanding of the parameters that are critical to immunogenicity (including stability-indicator parameters). Selection of the stability-indicator parameters varies with the unique characteristics of each vaccine.

The primary parameter that reflects stability for most vaccines is the potency assay (see *Potency Tests* below). This assay can take many forms, depending on individual vaccines (e.g., an infectivity assay for a live virus vaccine or a measure of the ▲quantity▲ (USP 1-May-2021) of conjugated ▲saccharide in a glycoconjugate▲ (USP 1-May-2021) vaccine). The potency assay is generally the key analytical result predicting whether a vaccine will remain suitable for use and whether it will produce the expected clinical response. Other analytical measurements can provide important supplemental data, particularly those that have a clear link to the potency of the product. Examples include the degradation profile, dissociation of a carrier protein from conjugated vaccines, and dissociation of an adjuvant from an antigen complex. Additionally, other common assays typically are performed as part of the stability study and may address physical or chemical changes in the product that may or may not affect its potency (e.g., general safety, degree of aggregation, pH, moisture, container, preservative, and enclosure).

## Formal Evaluation of Stability Data and Product Expiry Dating

Vaccines must remain within potency specifications at the expiration date, provided that the product was stored under the normal conditions specified. Manufacturers should conduct stability studies to determine those storage conditions and that ▲expiry dating▲ (USP 1-May-2021) to demonstrate that the product remains within the potency specifications. Manufacturers should conduct stability studies on a continuing basis. If a major manufacturing process changes, additional stability studies should be conducted to verify that there is no adverse impact on the stability profile. ▲▲ (USP 1-May-2021) An accelerated study involving temperatures both higher and lower than routine can evaluate the impact of temperature excursions on products. A similar evaluation should be done for product intermediates to establish how long a given intermediate can be held under defined conditions before it is processed further or discarded.

# NOMENCLATURE

There are no uniform systems for naming new vaccines. 21 CFR §299 describes the cooperation of the FDA and the US Adopted Names Council (USAN) in naming drugs, including vaccines. USAN is a private organization sponsored by the American Medical Association, USP, and the American Pharmacists Association. Section 262 in Title 42 of the Public Health Service Act requires that each package of the biological product be plainly marked with the proper name (name designated in the license 21 CFR §600.3) of the biological product contained in the package.

***Add the following:***

# ▲CONTAINER

The final container for the drug product is typically a vial with a rubber stopper and seal, or a prefilled syringe with a glass barrel and rubber plunger. Adsorption of the drug product on the container is prevented by selecting appropriate liquid formulation components, which may include proteins or mild non-ionic detergents; they also prevent virus aggregation and promote a more consistent product. Plastic containers have been introduced recently. Stopper and plunger components are typically butyl rubber compounds, which can be polytetrafluoroethylene- or silicone-coated to minimize vaccine adsorption, leaching of extractable components, or both. Sterilization methods should be characterized to ensure that they do not alter the container material properties with respect to vaccine interactions; for example, moisture absorbed during steam sterilization may add moisture over time to lyophilized vaccines, and ionizing radiation may alter the surface chemistry of polymer compounds. All containers and product-contact components should meet USP Class VI extractables testing (see *The Biocompatibility of Materials Used in Drug Containers, Medical Devices, and Implants* ⟨1031⟩) for the formulation chemistry and sterilization methods of interest and be compliant to relevant biocompatibility testing according to the risk of the intended use.▲ (USP 1-May-2021)

***Change to read:***

## LABELING

Vaccine product labeling is regulated in compliance with 21 CFR §201 and §610. Requirements are set for container labeling and package labeling.

### Container Label

Provisions are made for the following labels:

- Full label
- Partial label
- No label on the container itself when the containers cannot support a label that includes all required information; such products should be placed in a package that does include all required information

The label should be affixed to the container in a manner that allows visual inspection of the contents for the full length or circumference of the container. If no package exists, the container bears all of the information required for the package label.

The full container label normally contains the following:

- Proper name of the product
- Name, address, and license number of the manufacturer
- Lot number or other lot identification
- Expiration date
- Recommended individual dose, for multiple-dose containers
- The phrase “Rx only” for prescription biologicals
- ▲Storage conditions
- Instructions related to resuspension or shaking, if appropriate▲ (USP 1-May-2021)
- Any applicable cautionary statements.

### Package Label

In addition to the information required on the container label, the package label should describe the following:

- Any preservative used and its concentration, or the words “no preservative” if no preservative is used and its absence is a safety factor
- Number of containers, if more than one; or amount of product in the container, expressed as number of doses, volume, units of potency, weight, and equivalent volume (for dried product to be reconstituted); or a combination of the above to provide an accurate description of the contents, as applicable
- Recommended storage temperature
- The words “shake well”, “do not freeze”, or the equivalent, as well as other instructions when indicated by the character of the product
- Recommended individual dose, for multiple-dose containers;
- Recommended route of administration, or reference to such directions in an enclosed circular
- Presence of known sensitizing substances;
- Type of antibiotics added during manufacture and the amount calculated to remain in the final product
- Inactive ingredients, when they constitute a safety factor or are referenced to an enclosed circular
- Adjuvant, if present
- Source of the product, when this may be a factor in safe administration
- Identity of each microorganism used in manufacture and, if applicable, the production medium and the method of inactivation or reference to an enclosed circular
- Minimum potency in terms of official standard of potency, or the words “no US standard of potency”.

### Prescribing Information

Detailed information about a vaccine appears in its prescribing information, commonly called the package insert. Increasingly, vaccines are distributed with patient package inserts written in lay language. Prescribing information (21 CFR §201.56 and §201.57) includes the following:

- Highlights of prescribing information
- Product names, other required information
- Boxed warning
- Recent major changes
    - Indications and usage
    - Dosage and administration
    - Dosage forms and strengths
    - Contraindications

## LOT RELEASE TESTING

### General Principles

▲Drug product is defined in 21 CFR §210.3(b)(4) as "a finished dosage form, for example, tablet, capsule, solution, etc., that contains an active drug ingredient generally, but not necessarily, in association with inactive ingredients. The term also includes a finished dosage form that does not contain an active ingredient but is intended to be used as placebo." In compliance with 21 CFR §600, *Biological products: general*, and in particular, 21 CFR §601.2, *Applications for biologics licenses; procedures for filing*, the manufacturer "shall submit data derived from nonclinical laboratory and clinical studies which demonstrate that the manufactured product meets prescribed requirements of safety, purity, and potency…" Documentation of the vaccine drug product includes the following: components used in manufacture; composition of the drug product; specification for each component; manufacturing and packaging procedure and in-process controls for the drug product; and specifications necessary to ensure identity, strength, quality, purity, and potency in accordance with 21 CFR §211, *Current good manufacturing practice for finished pharmaceuticals*.▲ (USP 1-May-2021)

Manufacturers perform all appropriate tests for the licensed specifications for the product, according to 21 CFR §610.1 and §610.2. ▲Some tests that are performed on the final bulk need not be repeated on filled vials (e.g., when one final bulk is used to fill multiple batches of filled vials).▲ (USP 1-May-2021) Samples of each licensed lot and protocols ▲for vaccines▲ (USP 1-May-2021) containing ▲all appropriate tests from▲ (USP 1-May-2021) the manufacturers' test results are submitted to the FDA ▲for review, testing, or both.▲ (USP 1-May-2021) After the FDA evaluates the protocol to ensure that the product specifications are met, and after satisfactory confirmatory testing, the FDA approves the release of the lot if all tests meet the standards of safety, purity, and potency established for the particular vaccine product. After approval is granted, the manufacturer distributes and markets ▲that lot of product. The lot release protocol for each vaccine includes the specific potency test, as well as common tests, such as the visual inspection of final vials, and safety, sterility, and purity testing for each lot.▲ (USP 1-May-2021)

Guidelines are available regarding alternatives to lot release and a surveillance system. All of these variations are subject to the regulations in 21 CFR §610.2 that allow the FDA to require that samples of any lot of licensed product (e.g., vaccine), together with the protocols showing results of applicable tests, be sent to the FDA.

### Common Tests

The tests common to all lots of all products include tests for potency, general safety, sterility, purity, identity, and constituent materials. The manufacturer completes these tests for conformity with standards applicable to each product. The results of all tests are considered, except when a test has been invalidated as a result of causes unrelated to the product (21 CFR §610.1).

#### POTENCY TESTS (VACCINE-SPECIFIC)

The basic definition and requirements for vaccine potency and potency assays are provided in 21 CFR §600.3 and §610.10. A vaccine potency assay should indicate the therapeutic activity of the drug product as indicated by appropriate laboratory tests or by adequately developed and controlled clinical data. Potency may be expressed in terms of units by reference to a standard ▲("relative potency").▲ (USP 1-May-2021) Product potency tests vary with vaccine product types (e.g., viral, bacterial, live attenuated, inactivated, or polysaccharide). As a result, potency assays for vaccines ▲are based on a wide range of analytical approaches.▲ (USP 1-May-2021) In vitro potency tests for live virus may include plaque formation assays, endpoint dilution assays [e.g., the tissue culture infective dose ($TCID_{50}$)], virus neutralization assays, or quantitative polymerase chain reaction (PCR) assays. Quantitative colony formation assays are used for live attenuated bacterial vaccines. Animal challenge tests for immunogenicity assays of potency, such as those for diphtheria and tetanus (US Department of Health, Education, and Welfare, 1953; see ▲*Appendix*),▲ (USP 1-May-2021) or rabies and anthrax show in vivo response. ▲Antigen quantification▲ (USP 1-May-2021) assays use enzyme-linked immunosorbent assays (ELISA; e.g., with hepatitis A) or rate nephelometry and rocket immunoelectrophoresis (e.g., with pneumococcal polysaccharides). The potency tests for bacterial vaccines, such as the meningococcal polysaccharides, pneumococcal polysaccharides, or *Haemophilus b* protein conjugate vaccines use chemical and physical chemical assays. In the case of pure polysaccharide vaccines, the concentration or quantity of the vaccine component (polysaccharide) and its quality (e.g., size) have been shown to be indicative of the human immune response.

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M914_02_01
@2024 USPC

Assay precision and reproducibility vary with the different methodologies that are used in potency assays, ranging from the high accuracy and precision of chemical tests at one end of the spectrum to bioassays at the other end. *Design and Analysis of Biological Assays* ⟨111⟩ provides guidance for bioassays and applies to vaccine potency assays. Other tests should be validated as described in *Validation of Compendial Procedures* ⟨1225⟩.

### RELEASE TESTS

Official release of vaccines by the vaccine regulatory authority may be based on either the bulk or the final container. It is highly desirable to perform potency tests on the final container. However, under certain circumstances this may not be practical or even possible ▲(e.g., for some combination or multivalent vaccines);▲ (USP 1-May-2021) thus, a case-by-case approach ▲is sometimes▲ (USP 1-May-2021) required. The choice of whether to test the bulk or the final container derives from a number of considerations, such as the quantity of vaccine available for tests at the different manufacturing stages. For certain vaccines, both bulk and final container receive official release.▲▲ (USP 1-May-2021)

### GENERAL SAFETY

For biological products that are intended for administration to humans, manufacturers perform a general safety test in order to detect any extraneous toxic contaminants. Procedures and exceptions are specified in 21 CFR §610.11.

### STERILITY

A sterility test of each lot of each product is conducted according to procedures described in ⟨71⟩ and 21 CFR §610.12 for ▲▲ (USP 1-May-2021) bulk and▲/or▲ (USP 1-May-2021) final container material▲, as appropriate.▲ (USP 1-May-2021)

### BACTERIAL ENDOTOXINS

Each lot of final containers of a vaccine intended for use by injection is tested for bacterial endotoxins ▲when appropriate,▲ (USP 1-May-2021) as indicated in ⟨85⟩.

### PURITY

Vaccines need to be ▲as▲ (USP 1-May-2021) free of extraneous material ▲as possible.▲ (USP 1-May-2021) Approved vaccine license applications indicate extraneous materials that are unavoidable in the manufacturing process for a specific product. The application may indicate test results and allowable limits for such materials, according to procedures described in 21 CFR §610.13.

### RESIDUAL MOISTURE

Each lot of dried product is tested for residual moisture [see 21 CFR §610.13 (a), ⟨731⟩, and FDA's *Guideline for the Determination of Residual Moisture in Dried Biological Products* (see ▲*Appendix*)].▲ (USP 1-May-2021)

### PYROGENS

Each lot of final containers of a vaccine intended for use by injection is tested for pyrogenic substances, as indicated in ⟨151⟩ ▲as appropriate,▲ (USP 1-May-2021) and 21 CFR §610.13(b).

### IDENTITY

The contents of a final container of each filling of each lot are tested for identity after labeling is completed. Identity is established by the physical or chemical characteristics of the vaccine, inspection by macroscopic or microscopic methods, specific cultural tests, or in vivo or in vitro immunological tests. In large part, identity tests are performed to distinguish the subject vaccine from other materials manufactured at the same site (21 CFR §610.14).

### CONSTITUENT MATERIALS

Ingredients, preservatives, diluents, adjuvants, extraneous protein, cell culture-produced vaccines, and antibiotics are tested according to 21 CFR §610.15.

## Permissible Combinations

Formulations that combine several vaccines must be licensed as combinations (21 CFR §610.17). The potency of each vaccine in the combination is individually tested and must meet the specifications in the context of the final combined product; other appropriate quality tests also apply. For vaccines that are physically combined in clinical locations just before administration to a patient, prescribing information should describe specific procedures to follow in those settings.

## Quality

In general, quality control systems for vaccine manufacture are identical to those routinely employed for the production of other pharmaceuticals. These include raw material testing and release, manufacturing, process-control documentation, and

Official

https://pharmacopeia.cn/

DOI: https://doi.org/10.31003/USPNF_M914_02_01
@2024 USPC

aseptic processing. Manufacturers formally assign responsibility to designated staff for maintaining the continued safety, purity, and potency of the product and for ensuring compliance with applicable product and establishment standards, along with compliance with cGMPs. Analysts use reference standards and validated methods to determine active ingredients, residuals, and impurities. Manufacturers determine product safety in a variety of ways that may include the use of experimental animals, procedures to demonstrate product sterility, and tests to ensure product potency. The complexity of the quality control systems for vaccines lies in the variety of methods used to produce and control production. Lot release testing proceeds according to 21 CFR §610.2 and involves evaluating lots for safety, purity, and potency before release. Manufacturers follow FDA and applicable international standards for testing and validation. The basic considerations for validation are included in ⟨1225⟩, in addition to guidance documents issued by the FDA and the ICH (see ▲*Appendix*).▲ (USP 1-May-2021)

## Alternative Tests

Modification of test methods or manufacturing processes as licensed may be permitted if the regulatory authority can be assured that the modifications cause no reduction in the safety, purity, potency, and effectiveness of the biological product. It may be necessary for the manufacturer to file the proposed changes prior to implementation (21 CFR §601.12 and 21 CFR §610.9).

***Add the following:***

## ▲RETENTION SAMPLES AND OTHER REQUIREMENTS

Retention samples are held by the manufacturer for at least 6 months after the expiration date. An adequate quantity of material from each lot of each product is held for examination and testing for safety and potency (see 21 CFR §600.13).

Records are maintained concurrently with each step in the manufacture and distribution of the product such that at any time successive steps of manufacture and distribution may be traced (see 21 CFR §600.12).

For storage conditions, see 21 CFR §610.50 and §610.53.

For shelf life/expiry date, see 21 CFR §610.50 and §610.53.▲ (USP 1-May-2021)

***Change to read:***

## GLOSSARY

**Acceptance criteria:** The product specifications and acceptance or rejection criteria, with an associated sampling plan, necessary for making a decision to accept or reject a lot or batch (or any other convenient subgroups of manufactured units).

**▲Adjuvant:** A component added to a vaccine which, although not pharmacologically active in its own right, enhances or modifies the patient's response to the vaccine immunogens.▲ (USP 1-May-2021)

**Adventitious agent:** A microorganism (e.g., bacteria, fungi, mycoplasma, spiroplasma, mycobacteria, rickettsia, viruses, protozoa, parasites, TSE agent) that is inadvertently introduced into the production of a biological product.

**▲Ancillary raw material:** Ancillary raw materials are components or reagents used during the manufacture of vaccines and biologicals that exert an effect on the product but are not intended to be part of the final product.▲ (USP 1-May-2021)

**Batch:** A specific quantity of a drug or other material intended to have uniform character and quality, within specified limits, and produced according to a single manufacturing order during the same cycle of manufacture.

**Biological product:** Any virus, therapeutic serum, toxin, antitoxin, or analogous product applicable to the prevention, treatment or cure of diseases or injuries of man.

▲▲ (USP 1-May-2021)

**Characterization:** Determination of the properties of a substance.

**Component:** Any ingredient intended for use in the manufacture of a drug product, including those that may not appear in such drug product.

**Container** (also final container)**:** The immediate unit, bottle, vial, ampule, tube, or other receptacle containing the product as distributed for sale, barter, or exchange.

**Control:** Having responsibility for maintaining the continued safety, purity, and potency of the product and for compliance with applicable product and establishment standards, and for compliance with current GMPs.

**Control cells:** Cells that are split off from the production culture and maintained in parallel under the same conditions and using the same reagents (e.g., culture medium) to perform quality control tests on cells that have not been exposed to the vaccine virus (which may interfere with some tests).

**▲Expiry dating:**▲ (USP 1-May-2021) The period beyond which the product cannot be expected beyond reasonable doubt to yield its specific results.

▲▲ (USP 1-May-2021)

**Drug product:** A finished dosage form (e.g., solution, suspension) that contains an active drug ingredient generally in association with inactive ingredients ▲in the final container–closure.▲ (USP 1-May-2021)

**▲Excipient:** Excipients are substances other than the active pharmaceutical ingredients (API) that are appropriately evaluated for safety and enable the drug substance to be delivered to the patient in the right form and supports the way and place of action without being active themselves.▲ (USP 1-May-2021)

**Expiration date:** The calendar month and year, and where applicable, the day and hour, that the ▲expiry dating▲ (USP 1-May-2021) ends.

**Filling:** A group of final containers, identical in all respects, that have been filled with the same product from the same bulk lot without any change that will affect the integrity of the filling assembly.

**Final bulk:** The stage of vaccine production directly prior to filling of individual vials.

**Free of and freedom from:** For a substance to be considered free of a contaminant, an assay must demonstrate that a defined quantity of the substance is negative for that contaminant to a defined level of sensitivity. The level of assay sensitivity is defined by the choice of assay and can be determined experimentally using standardized reagents. Alternatively, a validated process that is known to remove a contaminant to a defined level may be used to demonstrate freedom from that contaminant.

**Harvest:** Collection of material at the end of vaccine virus propagation in cell culture, from which vaccine will be prepared. This material may be the culture supernatant, the cells themselves (often in disrupted form), or some combination thereof.

**Inactive ingredient:** Any component other than an active ingredient ▲or an adjuvant.▲ (USP 1-May-2021)

**In-process material:** Any material fabricated, compounded, blended, or derived by chemical reaction that is produced for, and used in, the preparation of the drug product.

**Intermediates:** Unformulated active ingredients that are processed before final formulation and can be stored ▲▲ (USP 1-May-2021) before further processing.

**Label:** Any written, printed, or graphic matter on the container or package or any such matter clearly visible through the immediate carton, receptacle, or wrapper.

▲▲ (USP 1-May-2021)

**Lot:** A batch, or a specific identified portion of a batch, having uniform character and quality within specified limits; or, in the case of a drug product produced by continuous process, a specific identified amount produced in a unit of time or quantity in a manner that assures its having uniform character and quality within specified limits.

**Lot number, control number, or batch number:** Any distinctive combination of letters, numbers, or symbols, or any combination thereof, from which the complete history of the manufacture, processing, packing, holding, and distribution of a batch or lot of drug product or other material can be determined.

**Manufacture:** All steps in the propagation or manufacture and preparation of products including, but not limited to, filling, testing, labeling, packaging, quality control, and storage by the manufacturer.

**Manufacturer:** Any legal person or entity engaged in the manufacture of a product subject to license under the Public Health Service (PHS) Act. Also includes any legal person or entity who is an applicant for a license where the applicant assumes responsibility for compliance with the applicable product and establishment standards.

▲▲ (USP 1-May-2021)

**Master virus seed:** A viral seed of a selected vaccine virus from which all future vaccine production will be derived, either directly or via working virus seeds.

▲▲ (USP 1-May-2021)

**Package:** The immediate carton, receptacle, or wrapper, including all labeling matter therein and thereon, and the contents of the one or more enclosed containers. If no package is used, the container will be deemed to be the package.

▲▲ (USP 1-May-2021)

**Potency:** The therapeutic activity of the drug product as indicated by appropriate laboratory tests or by adequately developed and controlled clinical data. Potency may be expressed in terms of units by reference to a standard.

▲▲ (USP 1-May-2021)

**Process:** A manufacturing step performed on the product itself that may affect its safety, purity, or potency, in contrast to manufacturing steps that do not intrinsically affect the safety, purity, or potency of the product.

**Proper name:** The name, designated in the license, to be used on each package of the product.

**Purity:** Relative freedom from extraneous matter in the finished product, whether or not harmful to the recipient or deleterious to the product. Purity includes, but is not limited to, relative freedom from residual moisture or other volatile substances and pyrogenic substances.

**Qualification:** Determination of the suitability of a material for manufacturing based on its characterization.

▲**Residual impurity:** Residual impurities are unwanted chemicals or biologicals present in traces in the final product and arise from a normal manufacturing process. They have no therapeutic value and are potentially harmful. Therefore, they need to be controlled during the manufacturing process.▲ (USP 1-May-2021)

**Safety:** The relative freedom from harmful effect to persons affected, directly or indirectly, by a product when prudently administered, taking into consideration the character of the product in relation to the condition of the recipient at the time.

**Specification:** The quality standard (i.e., tests, analytical procedures, acceptance criteria) provided in an approved application to confirm the quality of products, intermediates, raw materials, reagents, components, in-process materials, container–closure systems, and other materials used in the production of a product.

**Standards:** Specifications and procedures applicable to an establishment or to the manufacture or release of products, which are prescribed in this chapter or established in the biologics license application and designed to ensure the continued safety, purity, and potency of such products.

**Sterility:** Freedom from viable contaminating microorganisms, as determined by tests prescribed by the FDA.

▲▲ (USP 1-May-2021)

**Unacceptable product:** Product that is no longer acceptable for use in clinical studies or for commercial use (e.g., because of degradation or loss of potency).

**Validation:** The performance characteristics of an analytical procedure, based on the demonstration that the procedure is suitable for its intended purpose or use. Validation of a process is the determination of the extent to which a process meets the requirements for the various performance characteristics and the demonstration that the process uniformly performs to defined characteristics. Validation is generally performed in accordance with ⟨1225⟩ and the relevant ICH guidelines.

**Viral clearance:** The combination of the physical removal of viral particles and the reduction of viral infectivity through inactivation.

**Virus seed or viral seed:** A live viral preparation of uniform composition (not necessarily clonal) derived from a single culture process, aliquoted into appropriate storage containers, and stored under appropriate conditions.

▲▲ (USP 1-May-2021)

**Working virus seed:** A viral seed derived by propagation of virus from the master virus seed under defined conditions and used to initiate production cell cultures lot-by-lot.

## INTRODUCTION[1]

Solutes may differ in both the extent and the rate at which they dissolve in a solvent. Solubility is the capacity of the solvent to dissolve a solute whereas dissolution rate is how quickly the solubility limit is reached. Equilibrium solubility is the concentration limit, at thermodynamic equilibrium, to which a solute may be uniformly dissolved into a solvent when excess solid is present. The apparent solubility may be either higher or lower than the equilibrium solubility due to transient supersaturation or incomplete dissolution due to insufficient time to reach equilibrium. Equilibrium can be defined as sufficiently converged when it no longer changes significantly during a certain time frame. Solubility may be stated in units of concentration such as molality, molarity, mole fraction, mole ratio, weight/volume, or weight/weight.

Solubility can be expressed in absolute as well as relative terms. One method of describing the absolute solubility is the descriptive solubility defined in *General Notices, 5.30 Description and Solubility*. Relative measures of the solubility are important for predicting the drug delivery characteristics of a dosage form and characterizing a drug as either high solubility or low solubility in the biopharmaceutics classification system (BCS) (*1*).

Accurate determination of the solubility of pharmaceutical materials is important for understanding both quality control and drug delivery issues for pharmaceutical formulations. The apparent solubility (see the *Glossary*) of a material is affected by the physicochemical properties of the material (e.g., surface area, particle size, crystal form), the properties of the solubility media (e.g., pH, polarity, surface tension, added surfactants, co-solvents, salts), and the control of the solubility measurement parameters (e.g., temperature, time, agitation method). Additionally, the apparent solubility may be comprised of the intrinsic solubility of the uncharged moiety, the solubility of the ionized compound, and the effect of solubilizers and multiple crystal forms or salt forms. Control of these experimental factors during solubility measurements is key to obtaining accurate, reliable values for the equilibrium solubility of a material.

This chapter will begin with a discussion of the concepts and equations that are relevant to solubility measurements. Understanding these relationships is fundamental to accurate evaluation of solubility. This will be followed by a brief description of typical experimental methods used to assess solubility of pharmaceutical materials. Finally, the use of solubility measurements to obtain biorelevant solubility (for human products) and species-dependent solubility (for veterinary products) will be discussed.

[1] The terms used in this chapter are defined in the *Glossary*.

# BACKGROUND

## Thermodynamic Equilibrium and Solubility

Dissolution of a crystalline solid solute can be modeled by the two-step process of melting the crystal into a pure liquid solute followed by mixing the liquid solute into the solvent. The Gibbs free energy of mixing determines whether, and to what extent, two compounds mix to form a homogeneous phase.

$$\Delta G_{mix} = \Delta H_{mix} - T\Delta S_{mix}$$

$\Delta G_{mix}$ = Gibbs free energy of mixing
$\Delta H_{mix}$ = enthalpy of mixing; indicates if the mixing is an endothermic or exothermic process
$T$ = temperature in degrees Kelvin
$\Delta S_{mix}$ = change in entropy (disorder) that results from mixing

If the change in the Gibbs free energy is negative, the mixing will be thermodynamically favored. When equilibrium is reached, $\Delta G$ will be equal to zero. The enthalpy of mixing is due to the breaking of cohesive interactions (solute–solute, solvent–solvent) and the creation of adhesive interactions (solute–solvent). In other words:

$$\Delta H_{mix} = H_{UU} + H_{VV} - H_{UV}$$

$\Delta H_{mix}$ = enthalpy of mixing
$U$ = solute
$V$ = solvent

This enthalpy change is also equivalent to the work done by removing a volume of pure solvent and a volume of pure solute and exchanging them. The enthalpy change is equal to the newly created interfacial surface energy according to:

$$\Delta H_{mix} = \gamma_{UV}A_U = \sum_i \gamma_{iV}A_i$$

$\gamma_{UV}$ = solute-solvent interfacial surface tension
$A_U$ = interfacial surface area
$\gamma_{iV}$ = group-solvent interfacial surface tension for group $i$
$A_i$ = surface area of group $i$

This equation also shows how the total surface energy can be broken into $i$ smaller groups each with its own surface area, $A_i$, and corresponding group-water interfacial tension $\gamma_{iV}$.

For an ideal system, $\Delta H_{mix}$ is zero because the interactions between the ideal solute and ideal solvent are identical. The entropy of mixing for an ideal solution always increases as a result of mixing and is given by:

$$\Delta S_{mix}^{ideal} = R(X_U \ln X_U + X_V \ln X_V)$$

which under dilute conditions can be simplified to:

$$\Delta S_{mix}^{ideal} = R \ln X_U$$

For an ideal system under dilute conditions when a crystalline solid is in equilibrium with a saturated solution of the same solute:

$$\Delta G_U^{ideal} = -T\Delta S_U^{ideal} = -RT \ln X_U$$

$$\ln X_U = \frac{\Delta G_m}{RT}$$

$R$ = gas constant
$X_U$ = concentration of the solute expressed as a mole fraction
$\Delta G_m$ = the free energy change from melting the crystalline solid

Which illustrates how the solubility of the substance can be correlated with the melting point. For a real solution, the solute may also affect (reduce) the disorder in the solvent by inducing structure to the solvent. Therefore, for a real solution, this yields:

$$\Delta G_{mix}^{real} = \sum_i \gamma_{iV}A_i - T(\sum_i h_i A_i + \Delta S_{mix}^{ideal})$$

$h_i$ = entropic effect on solvent of group $i$ with area $A_i$

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M2248_03_01
@2024 USPC

This model allows the total solute surface area ($A_U$) to be broken into smaller pieces ($\sum_{Ai}$) and the contribution of these groups to the enthalpic and entropic contributions to the free energy can be estimated.

## Methods of Estimating Aqueous Solubility

Yalkowsky demonstrated (*2*,*3*) that a relatively simple general solubility equation (GSE) may be used to empirically estimate the intrinsic solubility of compounds in water.

$$\log S_0 = 0.5 - 0.01(MP - 25) - \log K_{OW}$$

$S_0$ = intrinsic solubility (of the unionized molecule)
$MP$ = melting point of the crystalline solid (in degrees Celsius)
$K_{OW}$ = octanol–water partition coefficient; the temperature of the water is 25°

The GSE indicates that the aqueous solubility will be reduced for compounds with a higher melting point and compounds with a higher tendency to partition into an oil phase (octanol). The logarithm of the octanol–water partition in the GSE accounts for the difference between an ideal solution and an aqueous solution due to the enthalpy of mixing (*3*). The GSE can also be used to predict the solubility of ionizable compounds by combining it with the Henderson–Hasselbalch equation if the p$K_a$ is known (see *Effect of pH*).

Use of GSE requires the measurement of the melting point and partition coefficient (and p$K_a$ for ionizable compounds). There are several computer programs that will support the estimation of the partition coefficient and the p$K_a$ for compounds based on structure (*4*), but this is not the case for melting points. Efforts to develop computational methods to predict aqueous solubilities have relied on training sets of molecules to search for correlations with properties that can be more easily predicted from the structure (e.g., molecular weight, solvent-accessible surface area, number of rotatable bonds, etc.) (*5*). The success of these computational approaches is often limited to molecules that are similar to the training set. These calculational methods are adequate for providing assistance in prescreening synthetic candidates, but are not sufficiently accurate to substitute for experimental solubility.

## Factors that Affect Solubility and Solubility Measurements

### EFFECT OF pH

The solubility of ionizable acids and bases is pH dependent because the charged species have a higher affinity for the aqueous environment than the neutral form. The total solubility of the ionizable acid or base is the sum of the intrinsic solubility and the amount of ionized solute present at that pH. The Henderson–Hasselbalch equation relates the increase in the solubility to the pH of the solution relative to the p$K_a$ (acidic) or p$K_a$ (basic) of the ionizable acid or base.

$$\mathrm{pH} = \mathrm{p}K_a + \log\frac{[A^-]}{[HA]};\ S_{tot} = S_0\left(1 + 10^{\left(\mathrm{pH} - \mathrm{p}K_a\right)}\right)$$

p$K_a$ = –log($K_a$)
$K_a$ = acid dissociation constant
$[A^-]$ = molar concentration of the acid's conjugate base
$[HA]$ = molar concentration of the undissociated weak acid
$S_{tot}$ = total solubility of weak acid
$S_0$ = intrinsic solubility of uncharged moiety

$$\mathrm{pH} = \mathrm{p}K_a + \log\frac{[B]}{\left[BH^+\right]};\ S_{tot} = S_0\left(1 + 10^{\left(\mathrm{p}K_a - \mathrm{pH}\right)}\right)$$

p$K_a$ = –log($K_a$)
$K_a$ = base dissociation constant
$[B]$ = molar concentration of the base's conjugate base
$[BH^+]$ = molar concentration of the dissociated base
$S_{tot}$ = total solubility of weak base
$S_0$ = intrinsic solubility of uncharged moiety

The Henderson–Hasselbalch equation helps explain the increase in solubility at the first p$K_a$, but is not useful for modeling the behavior of polyprotic acids over a pH range incorporating additional p$K_a$ values. Because ionizable molecules can differ in the number and type of ionizable groups, it is important to explore solubility across a range of pH values. *Figure 1* illustrates this pH dependence of the solubility for a molecule with two ionization constants of 5.6 and 11.7. The molecule is charged below pH 5.6 and above 11.7 and is neutral between these two pH values. Where the molecule is unionized, the solubility is equal to the intrinsic solubility. For the ionized molecule, the solubility increases on a log scale as the pH changes. The formation of a salt may limit the solubility at a low or high pH (see *Figure 1*). If the acid used to adjust the pH contributes the counter-ion for the salt, the common-ion effect will further suppress the solubility as the counter-ion concentration is increased (see *Figure*

@2024 USPC

*1*). If the salt is dissolved at higher pH, the salt may supersaturate the solution initially, but will eventually precipitate as whatever solid form has lower solubility at that pH (*6*).

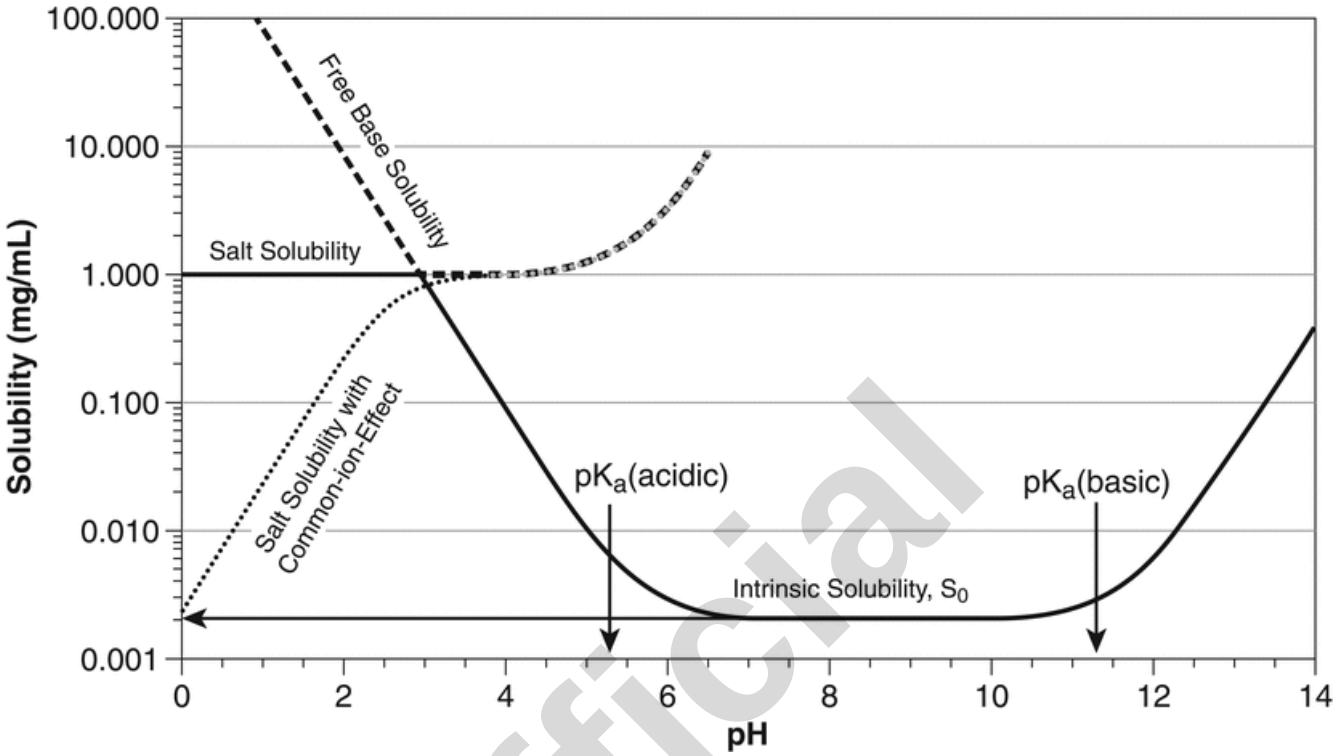

Figure 1. Effect of pH on solubility for an ionizable compound. When the molecule is unionized, the solubility is equal to the intrinsic solubility. For the ionized molecule, the solubility increases on a log scale as the pH changes. The salt solubility limits the solubility at a low pH. If the acid used to adjust the pH contributes the counter-ion for the salt, the common-ion effect will further suppress the solubility as the counter-ion concentration is increased (apparent at pH <2 in the figure).

## EFFECT OF SALTS AND COUNTER-IONS

Ionizable compounds can also form salts with an oppositely charged counter-ion (*6*). In a solution, in the presence of the charged counter-ion, the solubility product describes this equilibrium reaction as follows:

For the salt dissolution, $A_nB_m(s) \rightarrow nA^+(aq) + mB^-(aq)$
solubility product, $K_{sp} = [A^+]^n[B^-]^m$

The maximum solubility of the salt in a solution is also illustrated in *Figure 1*. As a result of the formation of the salt, the actual solubility of the charged molecule is seen to plateau (at a pH below the p$K_a$ of the drug in this example) instead of continuing to increase as predicted by the Henderson–Hasselbalch equation. Because the solubility product, $K_{sp}$, is a constant, the solubility of the ionizable moiety may drop even further if the acid being used to adjust the pH increases the concentration of the oppositely charged counter-ion. The reduction in the solubility of the charged molecule as the counter-ion concentration is increased is referred to as the common-ion effect (*6*). This is frequently seen when hydrochloric acid (HCl) is used to reduce the pH, and the solubility of the chloride salt is reduced due to increasing chloride concentration (e.g., at pH <2). Although not illustrated in *Figure 1*, salts may also limit the solubility on the basic side of the plot (e.g., a sodium salt of an acid moiety), and the common-ion effect may similarly affect the solubility at a high pH when the compound used to adjust the pH has a common-ion (e.g., sodium hydroxide).

## EFFECT OF CO-SOLVENTS

Water is often a poor solvent for many pharmaceutical ingredients, but water is miscible with other solvents that may provide good solubility for these substances (e.g., ethanol, propylene glycol, polyethylene glycol, etc.). According to the log-linear model (*2*), the log *S* of the solute can generally be linearly interpolated between two miscible co-solvents. This relationship is illustrated in *Figure 2*. When this solubility plot is switched to a linear scale, it becomes evident that even low concentrations of the poor solvent (typically water) in the co-solvent mixture can dramatically reduce the solubility for the solute. For this reason, solutions containing co-solvents are particularly prone to precipitation when diluted due to the significant change in solubility. [NOTE—This simple model, as depicted in *Figure 2*, assumes that maximum solubility occurs at 100% of the good solvent and this may not be the case for all co-solvent systems.]

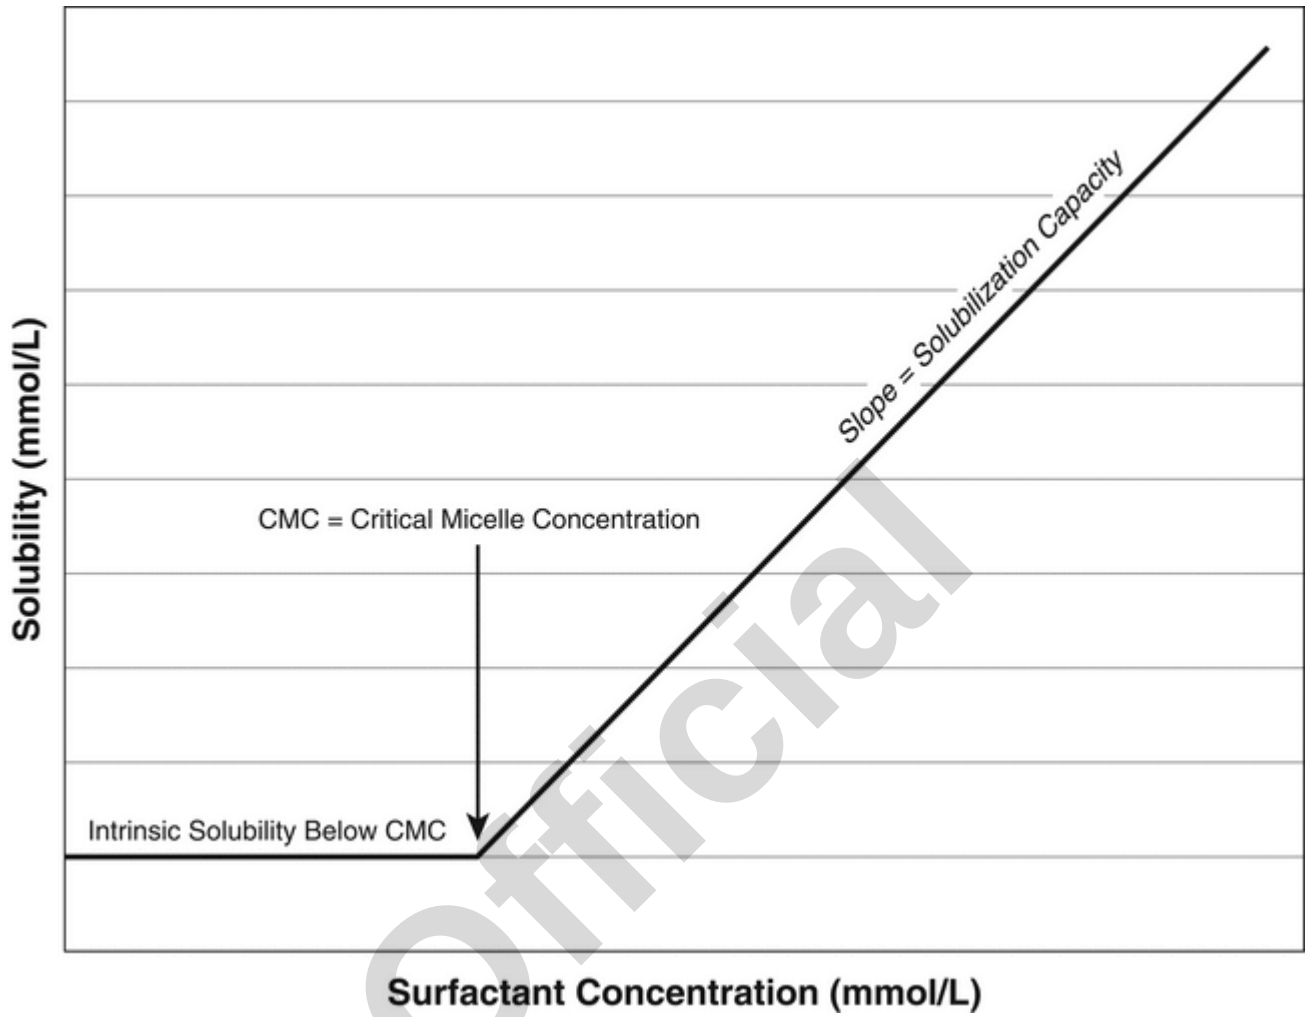
Figure 2. Illustration of the log-linear model of Yalkowsky and co-workers (*2*). The log of solubility appears to be linear as a function of the co-solvent fraction. When plotted on a linear scale, it is apparent that the solubility drops exponentially as the poor solvent is added to the better solvent.

## EFFECT OF SURFACTANTS

Surfactants are amphiphiles, which are characterized by polar and nonpolar regions. When placed in water, a surfactant prefers to reside at the air-water interface and orients its polar region in water and its nonpolar region to the less polar interface (air). When the air-water interface is saturated with adsorbed surfactant, additional surfactant molecules aggregate into a spherical micelle with a polar surface and a nonpolar core. This point when micelles form is known as the critical micelle concentration (CMC). Above the CMC, the number of micelles in a solution increases linearly as the concentration of surfactant increases. If a pharmaceutical material is able to partition into the micelle, its solubility will increase linearly as the number of micelles increases (see *Figure 3*). The CMC for surfactants is dependent on several factors including temperature, ionic strength, and pH. As an example, the CMC for sodium lauryl sulfate is 6 mM, and the CMC for polysorbate 80 is 0.012 mM, in pure water at 25°. The solubilization of a molecule by a surfactant can be evaluated based on two descriptors: the molar solubilization capacity, and the micelle-water partition coefficient. The micelle-water partition coefficient is the ratio of drug concentration in the micelle to the drug concentration in water for a particular surfactant concentration (*7*).

https://pharmacopeia.cn/v29240/



Official

Figure 3. Solubility enhancement by surfactants. Solubilization requires the formulation of micelles. Below the CMC, added surfactant results in monomers of surfactant dissolved in the solvent and no solubility enhancement occurs. Above the CMC, the solubility increases linearly. The slope of this linear increase indicates the solubilization capacity of the micelles.

As illustrated in *Figure 3*, the solubility in the presence of surfactants is the additive combination of the amount dissolved in the aqueous phase plus the amount solubilized by the micelles. The micelles will be larger than the solute and will diffuse more slowly than the solute. Drug delivery in the presence of micelles will be due to the absorption of the free drug in solution as well as drug delivery by micelle-mediated transport (*5*,*6*). Therefore, solubilization by surfactants may not result in an enhancement in drug delivery that is directly proportional to the increase in aqueous solubility (*5*,*6*).

## EFFECT OF COMPLEXING AGENTS

Complexing agents may form intermolecular complexes with low-solubility materials and enhance the solubility. Aqueous solubility of nonpolar molecules in the presence of complexing agents is improved as the nonpolar molecules and the nonpolar region of the complexing agent are sequestered out of water. When this occurs, the aqueous solution can accommodate more of the nonpolar molecules. Regardless of the ratio of ligand to solute in these complexes (e.g., 1:1, 2:1, 3:1, etc.), the solubility enhancement is expected to increase as the concentration of the complexing agent increases (*8*). This is very similar to solubilization by surfactants except there will not be a minimum concentration of the complexing agent required. Complexes with high stability constants may bind solutes strongly enough to enhance aqueous stability. Cyclodextrins are often used to enhance solubility by forming complexes with drug substances.

## EFFECT OF SURFACE AREA (DISSOLUTION RATE)

The Noyes–Whitney equation (as expressed by Nernst and Brunner) states:

$$\text{Rate} = \frac{\partial C}{\partial t} = \frac{DA\left(C_S - C\right)}{h}$$

$C$ = concentration of the solute in the solvent at time, $t$

https://pharmacopeia.cn/v29240/

$D$ = diffusivity of the solute
$A$ = surface area of the solute particles
$C_S$ = saturated solubility of the solute
$h$ = thickness of the diffusion layer

In unstirred solutions, the diffusion layer thickness, *h,* may be large and is primarily affected by the diffusivity of the solute; however, good mixing may significantly reduce the diffusion layer thickness. For small particles in well-mixed solutions, the diffusion layer thickness, *h*, was found (*9*) to be proportional to the square root of the particle radius. This equation indicates that the smaller particles will have greater surface area and will dissolve more quickly. In order to reach the equilibrium solubility as quickly as possible, the surface area should be kept as high as possible (i.e., smaller particles) and the diffusion layer thickness kept as small as possible (i.e., good mixing) (*9*).

For spherical particles, the surface area, *A*, can be expressed as a function of the total mass, *M*:

$$\text{For spherical particles, } A = \frac{6M}{\rho d}$$

$\rho$ = density
$d$ = particle diameter

The dissolution rate of a material will not affect the equilibrium solubility, but will affect how quickly this equilibrium is achieved.

$$\text{Rate} = \frac{\partial C}{\partial t} = \frac{6DM}{\rho dh}(C_S - C)$$

### EFFECT OF SURFACE ENERGY

The surface energy of the particle may affect the solubility. According to the Kelvin equation, smaller particles have higher solubility than larger particles due to the effect of the surface energy on the total Gibbs free energy of the system. Typically, this effect on solubility only becomes significant for particles smaller than 1 micron. The Kelvin equation quantifies this as:

$$\ln\frac{S}{S_0} = \frac{4\gamma V_m}{RTd}$$

$S$ = apparent solubility
$S_0$ = solubility of an infinitely large particle
$\gamma$ = surface energy of the solute
$V_m$ = molecular volume of the solute
$R$ = gas constant
$T$ = temperature
$d$ = diameter of the particle

The solubility difference between smaller and larger particles leads to so-called Ostwald ripening in polydisperse suspensions. The small particles dissolve and result in a solution that is supersaturated relative to the solubility of the larger particles. This leads to recrystallization on the surface of the larger particles. The larger particles grow in size while the smaller particles dissolve resulting in an increase in the mean particle size of the suspension (*10*).

## EXPERIMENTAL METHODS

## Methods for Determination of Equilibrium Solubility

### SATURATION SHAKE-FLASK METHOD

The shake-flask method is based on the phase solubility technique that was developed 40 years ago and is still considered by most to be the most reliable and widely used method for solubility measurement today (*11–18*). The shake-flask method should be used when equilibrium solubility needs to be determined. Other methods may be used to evaluate apparent solubility, but are not considered suitable for evaluation of true equilibrium solubility.

The solubility medium selected for solubility measurements should be selected to be relevant to the application with efforts made to control the surfactant type and concentration, the ionic strength of the buffer, and the types of counter-ions present in the buffer. When the results are intended to predict absorption or bioavailability, it is recommended that one of the biorelevant media solutions be used (see *Solubility Measurements in Biorelevant Media*). When the results are intended to support the development of dissolution tests, it is recommended that the dissolution medium be used. For research purposes, when the pH dependence of the compound is being evaluated, a buffer that allows control of ionic strength and counter-ion types over a wide pH range is recommended (e.g., Britton–Robinson or Sörensen buffers). For solubility measurements that will be used for BCS classification, USP-recommended buffers should be used (*19*).

**Sample preparation:** The test substance is typically prepared by adding an excess of solid to the solubility medium, which is in a stoppered flask or vial. The amount of medium in the flask or vial does not need to be measured accurately. It is recommended that the solid be added to the solubility medium at about 1–2 mg/mL in excess of the estimated solubility. (For

@2024 USPC

low-solubility compounds, a concentration of 1–2 mg/mL may be sufficient.) The surface area of the solid may be increased by grinding (e.g., in a mortar and pestle) of the sample prior to addition to the medium or by sonication of the sample after addition to the medium. [**CAUTION**—It is advised to use caution when employing high-energy methods to increase the surface area because it may alter the solid form of the solute.] It is recommended that sample preparation be performed in triplicate to provide at least 3 solubility results for each test condition.

**Equilibration of solution:** To facilitate dissolution of the solid, the suspension should be actively mixed or agitated. As a good initial time of incubation, 24 h is recommended; however, the suitability of the selected equilibration time must be verified. The temperature of the suspension should be well controlled during this dissolution phase (±0.5°). Following the dissolution phase, it is recommended that the excess solid be allowed to sediment completely. Sedimentation and decantation is recommended as the safest method for separation of the solid from the saturated solution. For non-clarifying colloid solutions, centrifugation can be used. Sampling of the supernatant should avoid incorporating any undissolved solid, as this will significantly affect the solubility result. The transfer pipet needs to be pretreated with sample solution before use, so that surface adsorption is not altering the transferred solution. If filtration cannot be avoided, then it is essential that the proper filter type is selected. For polar, ionized species, hydrophobic type filters (nylon) are recommended; while for unionized species the hydrophilic type filters [e.g., polyvinylidene difluoride (PVDF) or polyethersulfone (PES)] are recommended. The filtration should be done after sedimentation, and not directly after agitation. Presaturation of the filter is necessary (i.e., the initial portions of filtrate should be discarded). The temperature of the suspension during the sedimentation and centrifugation steps must also be well controlled (±0.5°) and be equivalent to the temperature at which solubilization occurred.

Saturation (equilibrium) has been reached when multiple samples, assayed after different equilibration time periods, yield equivalent results (e.g., change by less than 5% over 24 h, or less than 0.2%/h). To confirm that the apparent solubility is the equilibrium solubility, it is recommended that the same suspension be re-equilibrated via the same procedure (e.g., mix for an additional 24 h).

**Analysis of solution:** The requirements for the analytical method used to quantitate the concentration of the solute and the level of analytical validation required should be commensurate with the intended use of the solubility data. In general, the method should be linear and specific. The supernatant solution may need to be diluted before analysis to be within the linearity of the analytical method and to avoid possible precipitation. The solution may be analyzed by UV-Vis spectrometry or by liquid chromatography methods to determine the soluble concentration. The advantage of HPLC is that it can detect instability by resolving drug-related impurities (*13*,*20*).

It is recommended that the excess solid in the suspension be analyzed at the end of the solubility measurement to verify that the solid form has not changed. In cases where the solid form has changed, it is likely that the new solid form has a lower solubility than the initial solid form and that the observed solubility is due to the new lower-solubility form; however, this should be evaluated on a case-by-case basis. Powder X-ray diffraction (PXRD), Raman or near infrared (NIR) spectrometry, or evaluation of the melting point by differential scanning calorimetry (DSC) are examples of techniques that can be used to evaluate the solid form. Solutes that are unstable (either chemically or physically) during the equilibration time are not suitable for equilibrium solubility measurements by the shake-flask method. For example, amorphous drugs that will convert to lower solubility salts or polymorphs should be analyzed using one of the apparent solubility methods.

**Reporting of solubility results:** If a non-standard composition for the media is used in the solubility determination, the details of the composition should be reported. The ionic strength of the media used in the solubility determination should be calculated and reported with the solubility result. The pH of the supernatant solution should be recorded (at the temperature of the solubility measurement) when the sample is withdrawn for analysis. When using well-defined, standard media, it is recommended that the pH of the media not be adjusted to compensate for alteration of the pH by the dissolving species; rather, the solubility value should be reported at the pH value and temperature observed at the end of the equilibration step (*12*,*18*). If the pH of the media is significantly affected by the dissolving species and solubility at a particular pH is desirable, it is recommended to perform an additional solubility measurement in a higher buffer-capacity medium. Report the mean temperature and the precision of temperature control during the equilibration.

The precision of the reported equilibrium solubility should reflect the level of agreement between the measurements rather than the precision of the solubility analysis. Standard deviations in the measured solubility (based on averaging 3 or more independent samples) should be included.

***Change to read:***

## METHODS FOR DETERMINATION OF APPARENT SOLUBILITY

### Intrinsic Determination (Rotating Disk)

The measurement of intrinsic dissolution is described more fully in ▲*Intrinsic Dissolution Testing Procedures for Rotating Disk and Stationary Disk* ⟨1087⟩▲ (CN 1-Dec-2020). This measurement technique may also be used to assess the solubility.

To apply this method to the measurement of solubility, the dissolution experiment must be continued to the point that the rate of dissolution is insignificant (e.g., less than 5%/24 h or less than 0.2%/h).

All the requirements discussed for the shake flask method in *Analysis of solution* and *Reporting of solubility results* will also apply to measurements using the intrinsic dissolution apparatus.

### Potentiometric Titration

The potentiometric acid–base titration for solubility measurements is based on a characteristic shift in the middle of the titration curve that is caused by precipitation (*21*). For the titration, accurate volumes of a standardized acid or base are added to a solution containing an ionizable substance and a salt, for example, 0.15 M potassium chloride (KCl), which is included to increase the accuracy of the measurements. Sparging (a technique that involves bubbling a chemically inert gas such as

nitrogen, argon, or helium through a liquid) with argon prevents carbon dioxide ($CO_2$) from the atmosphere from influencing the pH value. A glass electrode is used to monitor the pH value continuously. The potentiometric titration curve is obtained by plotting the pH value against the consumed volume of acid/base (*21*).

### Turbidimetry

Turbidimetry involves the dissolution of a compound in an organic solvent, for example, dimethyl sulfoxide (DMSO). The resulting solution is added to a buffer solution in intervals adequate to characterize changes in turbidity. Further aliquots of the solution are added after the first detection of turbidity by light scattering. Subsequently, the volume added can be plotted against the turbidity. The solubility is then estimated by back-extrapolation to the point where precipitation began. This method can be used to measure as many as 50–300 samples per day. When using solvents such as DMSO, drawbacks include the increase in solubility of the drug substance for the short duration of the experiment, which leads to a kinetic rather than thermodynamic solubility, the formation of a supersaturated solution, and the undefined crystalline form of the precipitated solid (unless it is removed from the suspension and characterized).

### Physical Assessment of Solubility

For compounds with extremely high solubility, as well as for biologics and other molecules that lack chromophores or are not easy to quantitate in solution, a physical assessment of solubility may be used to assess apparent solubility. In this case, the principle of measurement is the loss of solid material to the solution phase. Equilibrium may be assessed by both the stability of the weight loss as well as the stability of the change in the physical properties of the resulting solution (e.g., refractive index, density, osmolality, etc.). Because the physical assessment of solubility does not involve a specific or stability-indicating assay, it is recommended that some attempt be made to verify the stability and purity of the solute. Also, evaporation of the solvent should be carefully monitored and controlled during the solubility measurement performed by this method.

## SOLUBILITY MEASUREMENTS IN BIORELEVANT MEDIA (*22–26*)

The use of simple aqueous buffers to evaluate the aqueous solubility of a drug substance as a function of pH may underestimate the bioavailability (*22*,*23*). The media recipes presented here are examples that may be used to evaluate the solubility in simulated human, canine, and bovine (ruminant) fluids to make improved estimates of bioavailability.

The temperature of the solubility medium should be controlled at ±0.5° during biorelevant solubility measurements. Biorelevant solubility measurements should follow the shake-flask method, including solubility measurements at multiple time points to confirm that equilibrium has been achieved. The salt form of a drug added to the solubility medium may significantly affect the composition of the medium (i.e., ionic strength, pH, etc.). Therefore, the solubility of a salt and a free base of the same drug should not be assumed to be equivalent unless proven through independent measurements starting with the different crystalline solids.

### Human Fasted-State Simulated Gastric Fluid (FaSSGF) (*24*)

The pH is 1.6 at 37°. See *Table 1* for the media composition.

**Table 1**

| Ingredient | Concentration (mM) | Concentration (g/L) |
|---|---|---|
| Hydrochloric acid | ~31.3 (q.s. to pH 1.6) | ~1.14 (q.s. to pH 1.6) |
| Sodium chloride | 34.2 | 2.00 |
| Sodium taurocholate | 0.08 | 0.047 |
| Lecithin | 0.02 | 0.015 |
| Pepsin | — | 0.1 |

### Human Fed-State Simulated Gastric Fluid (FeSSGF) (*24*)

The pH is 5 at 37°. See *Table 2* for the media composition.

**Table 2**

| Ingredient | Concentration (mM) | Concentration (g/L) |
|---|---|---|
| Hydrochloric acid | (q.s. to pH 5) | (q.s. to pH 5) |
| Sodium hydroxide | (q.s. to pH 5) | (q.s. to pH 5) |
| Sodium chloride | 237.0 | 13.85 |

## Canine Fasted-State Simulated Gastric Fluid (FaSSGFc pH 1.2–2.5) (*26*)

Canine gastric pH can vary substantially. Due to interstudy variations in the canine gastric pH estimates, solubility should be evaluated over a range of 1.2–6.5. The pH of this fluid is adjusted by altering the amount of hydrochloric acid so that pH values in the range of 1.2–2.5 may be achieved. The pH is 1.2–2.5 at 37°. See *Table 7* for the media composition.

**Table 7**

| Ingredient | Concentration (mM) | Concentration (mg/mL) |
|---|---|---|
| Hydrochloric acid | ~3.6–82 (q.s. to pH 1.2–2.5) | ~0.13–3 (q.s. to pH 1.2–2.5) |
| Sodium chloride | 14.5 | 0.847 |
| Sodium taurocholate | 0.10 | 0.055 |
| Sodium taurodeoxycholate | 0.10 | 0.054 |
| Lecithin | 0.025 | 0.019 |
| Lysolecithin | 0.025 | 0.012 |
| Sodium oleate | 0.025 | 0.0076 |

## Canine Fasted-State Simulated Gastric Fluid (FaSSGFc pH 2.5–6.5) (*26*)

Canine gastric pH can vary substantially. Due to interstudy variations in the canine gastric pH estimates, solubility should be evaluated over a range of 1.2–6.5. The pH of this fluid is adjusted by altering the amount of sodium hydroxide so that pH values in the range of 2.5–6.5 may be achieved. The pH is 2.5–6.5 at 37°. See *Table 8* for the media composition.

**Table 8**

| Ingredient | Concentration (mM) | Concentration (g/L) |
|---|---|---|
| Maleic acid | 21.68 | 2.516 |
| Sodium hydroxide | ~14.5–40 (q.s. to pH 2.5–6.5) | ~0.58–1.6 (q.s. to pH 2.5–6.5) |
| Sodium chloride | 18.81 | 1.099 |
| Sodium taurocholate | 0.10 | 0.055 |
| Sodium taurodeoxycholate | 0.10 | 0.054 |

Official

## Canine Fasted-State Simulated Intestinal Fluid (FaSSIFc) (*26*)

The pH is 7.5 at 37°. See *Table 9* for the media composition.

**Table 9**

| Ingredient | Concentration (mM) | Concentration (mg/mL) |
|---|---|---|
| Sodium dihydrogen phosphate, monohydrate | 28.65 | 3.953 |
| Sodium hydroxide | 21.66 | 0.866 |
| Sodium chloride | 59.63 | 3.485 |
| Sodium taurocholate | 5.0 | 2.8 |
| Sodium taurodeoxycholate | 5.0 | 2.7 |
| Lecithin | 1.25 | 0.96 |
| Lysolecithin | 1.25 | 0.62 |
| Sodium oleate | 1.25 | 0.38 |

## Bovine Simulated Ruminal Fluids (*27–29*)

The media defined here are suitable to represent bovine as well as other ruminant species. The normal pH of a healthy reticulo-rumen is in the 5.5–6.8 range. High-grain diets typically result in a lower ruminal pH (~5.5), whereas high-forage diets result in a higher ruminal pH (~6.8).

In the abomasum (true stomach), the pH is about 2–3 and is similar to conditions observed in monogastrics and humans. To represent the abomasum, one may use 0.01 M hydrochloric acid (pH 2), 0.0033 M hydrochloric acid (pH 2.5), or 0.001 M hydrochloric acid (pH 3). Intestinal pH in ruminants is similar to that observed in monogastrics and humans. The pH at the pylorus is about 3.0 and increases to about 7.5 in the ileum. To represent the bovine intestinal fluids, one may use one of the simulated intestinal fluids defined for human or canine above.

The temperature is set for 39°. [NOTE—The pH of media should be confirmed at 39°.] See *Table 10* for the media composition.

**Table 10**

| Ingredient | High-Grain Diet Simulated Rumen | High-Forage Diet Simulated Rumen |

| Manganese chloride tetrahydrate | 10.0 |
| Iron (III) chloride hexahydrate | 8.0 |

## GLOSSARY

[NOTE—The following definitions are provided to clarify the use of these terms in the context of this chapter. These definitions are not intended to supersede or contradict definitions found elsewhere in the *USP–NF*.]

**Apparent solubility:** The empirically determined solubility of a solute in a solvent system where insufficient time is allowed for the system to approach equilibrium or where equilibrium cannot be verified. The apparent solubility may be either higher or lower than the equilibrium solubility due to transient supersaturation or incomplete dissolution and insufficient time to reach equilibrium.

**Aqueous solubility:** Solubility in a medium that is primarily comprised of water but may also contain solubilization enhancement from co-solvents, surfactants, complexing agents, pH, or other co-solutes. The term "aqueous solubility" is very general and should not be confused with the water solubility. The aqueous solubility is significantly affected by the composition of the aqueous medium.

**Dissolution:** The non-equilibrium process of approaching the solubility limit at thermodynamic equilibrium (i.e., the solute and solvent forming a uniformly mixed solution). The dissolution rate will affect the time required to reach equilibrium and may affect the apparent solubility, but will not affect the final equilibrium solubility.

**Equilibrium solubility:** The concentration limit, at thermodynamic equilibrium, that a solute can dissolve into a saturated solution when excess solid is present. Equilibrium can be defined as sufficiently converged when it no longer changes significantly during a certain time frame.

**Intrinsic solubility:** The solubility of the uncharged (neutral) moiety. Intrinsic solubility can only be accurately measured in pH ranges where the distribution of species is dominated by the uncharged molecule. For some compounds, it may be impossible to directly measure the intrinsic solubility and it must be determined by fitting the solubility data as a function of pH.

**Solubility:** The extent to which a solute may be uniformly dissolved into a solvent. This may be referred to as equilibrium (saturated) solubility to differentiate it from apparent solubility. Solubility may be stated in units of concentration such as molality, mole fraction, mole ratio, weight/volume, and weight/weight.

Official

https://pharmacopeia.cn/v29240/

**Water solubility:** Solubility in pure water. Measurements of solubility in pure water are problematic due to poor control of pH and ionic strength.

# ⟨1237⟩ VIROLOGY TEST METHODS

## INTRODUCTION

This chapter describes virology test methods applicable to the development of biological product drugs, such as recombinant proteins, subunit vaccines, therapeutic monoclonal antibodies, and growth hormones. Several topics are excluded from the scope of this chapter:

- Blood- and plasma-derived products as well as whole blood and plasma products used directly in transplantation or infusion. However, the basic principles, strategies, and testing methods for ensuring virus-free products are applicable.
- Methodologies for the safety testing of live viral vaccines.
- Specific methods for viral clearance studies, which are described in the *USP* general information chapter *Viral Safety Evaluation of Biotechnology Products Derived from Cell Lines of Human or Animal Origin* ⟨1050⟩.

Virology test methods have historically been employed in the clinical settings of disease diagnosis, intervention, and containment; but the development of biological (biologics and biotechnology-derived) products and therapies for human or animal use has created the need for sensitive viral detection assays for use in the GMP production and testing of biological products. This need is not limited to the production of viral vaccines, but also applies to the development and manufacture of recombinant proteins, cell and gene therapies, and other products.

Sensitive virology test methods for quality control of biological products are necessary for several reasons. The production of biological products often requires a variety of raw materials and processing reagents of animal origin that have varying potential for introducing viral contaminants. The production of biological products may allow the replication of adventitious agents during processing, and therefore these materials must be prescreened to avoid the opportunity for contamination of the product. Another point to consider regarding screening these materials is that the product may not be compatible with processing methods used to eliminate or inactivate these adventitious agents. Because of the nature of the biological products, the production process needs to include appropriate testing regimens that monitor the possible introduction of adventitious agents and/or viral agents into the systems used. For these reasons, sensitive viral detection methods are required not only for the release testing of biological drug products, but also during the intermediate stages of processing, process development, and routine manufacture. Important stages for consideration include the development of cell substrates and banks, raw materials of animal origin, process intermediates, and critical excipients when derived from animal tissues. This strategy should be augmented with viral clearance and inactivation studies whenever possible.

For products intended to contain live viruses (e.g., infectious oncolytic viruses and live viral vector products used for gene therapy), the cell- and animal-based infectivity methods discussed in this chapter may be useful only following neutralization of the specific viral entity contained in the product for any product that is intended to contain live viruses (e.g., infectious oncolytic viruses and live viral vector products used for gene therapy). Alternatively, selection of appropriate indicator cell lines or animal models in which the specific viral entity is known not to replicate can be considered. It should also be expected that assay systems based on detection of viral particles or viral components will indicate the presence of the viral entity itself in such products, but may not indicate the viability of the virus. The remainder of the chapter is divided into three sections discussing assays for the three topics: (1) *Detection of Viable Viruses,* (2) *Detection of Viral Components,* and (3) *Detection of Antibodies to Viral Antigens.* The chapter covers the classic virology methods that are still routinely used, as well as modern molecular and immunological approaches. The methods described in these sections may possess different sensitivities to diverse viruses; they are therefore intended to complement each other to provide a science-based foundation for the detection of adventitious viruses. Multiple methods may be used in complementary fashion to improve the pathogen safety margin of a product. Identification of viruses detected in cell-based assays on the basis of cytopathic effects often depends on the use of molecular and immunological analyses; these analyses are therefore relevant both to viral detection and to subsequent viral identification. The chapter provides an overview of the detection and analysis of the most important groups of viruses as well as the most commonly used techniques. Tests specific to individual vaccines or biological products are excluded, because they are expected to be included in monographs for such products.

Methods that are well established with little variation in practice are described in more detail, whereas methods that are more flexible are described in general terms, both in the performance of the tests and in considerations for acceptance. Relevant regulatory references are given in the *Appendix.* Relevant USP general chapters should be consulted with regard to bioassay design, data analysis, interpretation, and assay validation.

## DETECTION OF VIABLE VIRUSES

Infectious virus particles contaminating biologics and biotechnology-derived products are of great safety concern, because they have the potential for causing serious, possibly life-threatening, infections in the patients treated. This is particularly true if the patients are immunocompromised. Although complete assurance of viral safety for finished biological products can never be realized, a significant safety margin can be established through viral detection methods applied to unprocessed bulk and raw materials before purification in combination with purification processes that demonstrate the ability to inactivate or remove potential viral contaminants present at levels too low to detect. (See *Viral Safety Evaluation of Biotechnology Products Derived from Cell Lines of Human or Animal Origin* ⟨1050⟩ for information on viral clearance and inactivation methods.) For cell and gene therapy products that lack extensive purification steps, final products may be directly tested for the presence of relevant contaminating viruses. This section describes two broad systems for the detection of infectious virus: cell culture–based infectivity assays and in vivo infectivity assays. These systems may possess complementary sensitivities for viruses, and as a result, both methods may be used as limit tests for cell bank and raw material characterization and for lot release testing of biologics and biotechnology-derived products. Considerations for optimizing sample preparation for these tests are discussed, followed

https://mhathaway.org/search/

by a description of the more commonly employed detection assays. Finally, to ensure the reliability of experimental results, quality control issues in general and detection limit estimation in particular are discussed.

## Sample Selection of and Preparation for Cell- and Animal-Based Virus Detection Assays

The requirements for selection, preparation, and storage of test samples for viral detection methods (cell- and animal-based) are dictated by the lability of the viruses being detected. The ability of a virus to remain infectious in the absence of a host cell is highly variable. Virus infectivity also may differ in sensitivity to repeated freezing and thawing cycles.

Sample preparation typically involves storage of test samples at low temperatures (ideally –60° or below) as soon as practicable upon collection. When intended for use in a viral screening assay, aliquots of samples should be prepared to avoid multiple freezing and thawing. Samples intended for viral infectivity assays are typically shipped with sufficient dry ice to last several days more than the expected time required for transit. When received at the testing laboratory, the sample should be examined to verify that it is still frozen, and appropriate documentation should be completed. For any storage or hold condition, the impact of the condition on viral viability should be empirically assessed and sufficient cold chain management ensured.

Typical sample types for viral detection assays are described below.

### CELL LYSATES

Test samples derived from cell substrates (master and working cell banks, end-of-production cell samples) are prepared in a manner that allows sampling of both the cells (for cell-associated viruses) and the conditioned medium (for virus shed into the medium). To achieve this, a culture of the cells is sampled. A cell suspension of ~$10^7$ cells per mL in conditioned medium is prepared and frozen (ideally at –60° or below). Because this medium does not contain cryopreservative, the majority of the cells will lyse upon thawing of the sample, releasing the cell-associated virus. Low-speed centrifugation will remove larger cellular debris and yield a supernatant that may be inoculated directly onto detector cells in cell-based viral infectivity assays. A similar sample is prepared for in vivo viral adventitious agent testing. In this case, however, the test sample is thawed and injected without clarification into the various animal systems via the various described routes.

### BIOTECHNOLOGY BULK HARVEST (UNPROCESSED BULK HARVEST) SAMPLES

Routine lot testing of bulk harvest samples is mandatory for most types of biologics (see *Viral Safety Evaluation of Biotechnology Products Derived from Cell Lines of Human or Animal Origin* ⟨1050⟩). The sampling must be done at the unprocessed bulk harvest stage, because downstream purification processes may remove or inactivate any viruses that might contaminate the starting materials. The harvest sample from the bioreactor should be collected and stored without further manipulation, as soon as practicable, at –60° or below. To prevent multiple freeze and thaw cycles, individual aliquots should be prepared for each individual assay to be performed. Additional aliquots should be retained in case repeat testing is required. Depending on the nature of the manufacturing process, the bulk harvest samples may contain varying quantities of the production substrate cells. Because the bulk harvest does not contain cryopreservatives, the majority of the cells present will lyse upon thawing of the sample, releasing the cell-associated virus. Low-speed centrifugation to clarify the sample will result in a supernatant that may be inoculated directly onto detector cells in cell-based viral infectivity assays. There may be instances where the test sample is cytotoxic to the detector cells of the cell-based assays and procedural modifications may be required to deal with this. A similar sample is prepared for in vivo viral safety testing. In this case, however, the test sample is thawed and injected without clarification into the various animal systems via the various described routes.

### RAW MATERIALS OF ANIMAL ORIGIN

Ingredients of animal origin used in the manufacture of biological products for human or veterinary use must be tested for species-specific viruses of concern as described in 9 CFR 113.53 (see also the *USP* general information chapter *Bovine Serum* ⟨1024⟩, being prepared for future publication). The raw materials may be stored under a variety of conditions, as appropriate to the raw material. Sample preparation and method of application to the test system depend on the nature of the sample. The possibility that animal-derived raw materials may contain bacterial or fungal contaminants should be considered. In some cases, it may be necessary to treat the samples with antibiotics or to filter the samples (0.22 or 0.45 micron pore size) prior to inoculation in order to prevent bacterial or fungal outgrowth in the test system. Animal sera are typically received frozen and are thawed and incorporated into the growth medium at an appropriate concentration (typically 15%, v/v) as a means of exposing the detector cells. Powdered trypsin (not less than 5 grams, as per 9 CFR 113.53) is suspended in a suitable diluent, such as phosphate-buffered saline, and is then subjected to high-speed centrifugation to pellet any virions that may be present. The concentrated pellet is resuspended in phosphate-buffered saline, and the resulting material is used to inoculate appropriate detector cells. Medium additives, such as bovine thrombin, may be incorporated into the growth medium at a predetermined multiple of the nominal concentration to be used in the manufacturing process. The resulting growth medium containing the additives is then used as a means of exposing the detector cells to the test material. The exact multiple to be used in such testing may be limited by such factors as solubility in growth medium or cytotoxicity to the detector cells. These factors should be assessed in advance of testing. The principle of using higher concentrations in the detection method than during processing should be followed, within the bounds of indicator cell toxicity, as a means to increase sensitivity to detection.

### WHOLE CELLS

Intact viable cells are used as the test sample in certain viral detection assays. Because the test cells may attach and proliferate in the culture vessel along with the detector cells, assays using this type of sample are referred to as cocultivation assays. The requirements for the specific assay may vary in relative proportions of detector and test cells, viability of the test cells, or the confluency of test cells at the time of collection.

# Cell Culture-Based Viral Detection Methods

To ensure the absence of adventitious viral agents, cell culture–based viral detection assays are used for a variety of purposes, including but not limited to clinical diagnostic procedures; evaluation of raw materials and cell substrates; assessments of the viral identity, the purity, and the potency of virus seed stocks; and lot release testing of unprocessed bulk harvests during biologics production. An important distinction between cell-based assays and direct detection assays (see the section *Detection of Viral Components*) is that the former will detect only replicating virus, whereas the latter will detect viral antigens, viral genomic material, and the like, which may or may not be indicative of the presence of replicating virus. Similarly, detection of circulating antibodies directed against viral antigens (discussed in the section *Detection of Antibodies to Viral Antigens*), may be indicative of either a current or a past infection of an animal and does not necessarily indicate that the animal is currently harboring an infection.

Infectious viruses detected in cells or in cell-derived materials fall into two broad categories, based on the expectations of the analyst. Endogenous viruses are those normally detected in the cells as a result of the integration of the viral genomic material into the host cell DNA. Exogenous viruses are those not normally present in the cells but found as a result of a viral infection of the cells.

The underlying assumption for all cell-based viral detection methods is the ability of viruses to replicate in an appropriate host cell. Viruses lack the cellular machinery required for producing their own genomic material and structural proteins, and they must therefore enter and subordinate a host cell for this purpose. Cell-based viral infectivity assays use indicator (detector) cells that serve as host cells for viable virions present in test samples.

Cell-based infectivity assays may be placed in three broad categories on the basis of types of viruses to be detected: (1) retroviral assays, (2) virus-specific assays, and (3) viral screening assays. The types of endpoints used to detect the viruses may differ by category. Although screening assays are typically not optimized for single viral entities, the virus-specific assays and titration assays, as well as some of the retroviral assays, may be optimized to some extent for specific viruses. Accurate titration of stock viruses that are used as positive controls or are used to determine the detection limit of an assay is critical.

The regulatory guidance underlying the various viral safety tests depends on the nature of the samples to be evaluated, and analysts are referred for more detail to documentation relevant to their own regulatory environments.

## General Requirements for Cell Culture–Based Assays

### DETECTOR CELLS AND THE CONCEPT OF VIRAL HOST RANGE

The range of viruses detectable using a cell-based infectivity assay depends on a number of factors, including the type of host cell(s) used as the indicator (detector) cultures and the detection endpoints used in the assay. Viruses differ in their abilities to infect specific host cell types. Most viruses exhibit at least some degree of host cell tropism (i.e., ability to infect a specific species or tissue type). This attribute is typically due to a requirement for interaction of a virion with a specific cell membrane receptor during the process of infection of the host cell. A cell susceptible to infection and capable of production of progeny by a given virus is referred to as *permissive* for that virus; cells not supporting viral proliferation are referred to as *nonpermissive,* or *restricted,* for that virus. As a consequence of the differences in host cell tropism, assays intended to screen for a wide range of viruses must include multiple detector cell types. For the same reasons, design of a cell-based infectivity assay for a specific virus must include a detector cell known to be permissive for that virus.

### VIRUS SUSCEPTIBILITY OF COMMON CELL LINES

For most endpoint assays used to determine whether a host cell is infected with a virus, a monolayer culture is preferable to a semiadherent or suspension culture. For instance, cytopathic effect and hemadsorption are visualized microscopically. Cells that are not adherent have little morphology to evaluate, and hemadsorption cannot be properly evaluated in a suspension culture. For this reason, some regulatory documents pertaining to cell-based virus infectivity assays stipulate the use of monolayer detector cultures.

A list of commonly employed indicator cell lines and their application in viral screening assays is provided in *Table 1.* Regarding the viral tropism of these cells, "Points to Consider in the Characterization of Cell Lines Used to Produce Biologicals" (1993) and ICH's Q5A (R1) guidelines (for these references, see *Appendix*) require that human diploid cells such as MRC-5 and WI-38, which are permissive for a range of viruses of human concern, and monolayer cultures of the same species as that of the cell substrate used to produce the product are included in the viral screening test for biologics destined for use in humans.

**Table 1. Indicator (Detector) Cell Lines Used for Adventitious Viral Screening Assays**

| Cell Line[a] | Origin | Endpoint(s)[b] | Target virus(es) |
|---|---|---|---|
| *Cell lines with relatively broad viral tropism:* | | | |
| BHK-21 | Syrian hamster | CPE, HAd, HA | Insect-borne viruses (arboviruses) |
| Vero | African green monkey | CPE, HAd, HA | Viruses infectious to humans, primates |
| *For processes involving human cell substrates:* | | | |
| HeLa | Human | CPE, HAd, HA | Viruses infectious to humans |
| MRC-5 | Human | CPE, HAd, HA | Viruses infectious to humans |
| *For processes involving Chinese hamster cell substrates:* | | | |
| CHO-Kl | Chinese hamster | CPE, HAd, HA | Viruses infectious to Chinese hamsters |

@2024 USPC

**Table 1. Indicator (Detector) Cell Lines Used for Adventitious Viral Screening Assays** *(continued)*

| Cell Line[a] | Origin | Endpoint(s)[b] | Target virus(es) |
|---|---|---|---|
| *For processes involving mouse cell substrates:* | | | |
| MEF | Mouse | CPE, HAd, HA | Viruses infectious to mouse cells |
| NIH/3T3 | Mouse | CPE, HAd, HA | Viruses infectious to mouse cells |
| *For processes involving bovine cell substrates or bovine raw materials:*[c] | | | |
| MDBK | Bovine | CPE, HAd, HA | Bovine viruses |
| BT | Bovine | CPE, HAd, HA | Bovine viruses |
| EBTr | Bovine | CPE, HAd, HA | Bovine viruses |

[a] Examples of cell lines used for viral screening assays are shown. MRC-5 and Vero, or cells with similar host ranges, are used in all assays. Depending on the cell substrate used to manufacture a biologic, additional cell lines are also used in the screening assay. In addition, a bovine cell might be included if bovine serum was used in the manufacturing process.
[b] CPE, cytopathic effect; HAd, hemadsorption; HA, hemagglutination (optional).
[c] Inclusion of a bovine cell in a virus screen should not be construed as a replacement for or alternative to a raw materials test. Raw materials testing is driven in the U.S. by 9 CFR 113.47 and 113.52, and cell lines used for this testing are described in *Table 2*.

A list of commonly employed indicator cell lines and their application in raw materials testing assays is provided in *Table 2*.

**Table 2. Indicator (Detector) Cell Lines Used in Raw Material Testing**

| Cell Line[a] | Assay Type | Endpoint(s)[b] | Animal Origin of Raw Material |
|---|---|---|---|
| Vero | Isolation/detection | CPE, HAd, IFA | All sources |
| BT | Isolation/detection | CPE, HAd, IFA | Bovine; all sources (BVDV)[c] |
| EBTr | Isolation/detection | CPE, HAd, IFA | Bovine; all sources (BVDV)[c] |
| MDBK | Isolation/detection | CPE, HAd, IFA | Bovine; all sources (BVDV)[c] |
| PT-1 | Isolation/detection | CPE, HAd, IFA | Porcine |
| PK-1 | Isolation/detection | CPE, HAd, IFA | Porcine |
| MDCK | Isolation/detection | CPE, HAd, IFA | Canine |
| GT | Isolation/detection | CPE, HAd, IFA | Caprine |

[a] The requirement (9 CFR 113.47 and 113.52) for evaluating raw materials of animal origin is to use (1) Vero cells, (2) a bovine cell for detecting BVDV, and (3) a cell line of the same species of origin as the raw material for detecting viruses of concern from that species. Examples are given of some cell lines that are used in the industry.
[b] CPE, cytopathic effect; HAd, hemadsorption; IFA, immunofluorescent antibody staining.
[c] As per 9 CFR 113.47, raw materials of any animal origin are to be tested for bovine viral diarrhea virus (BVDV).

There may be very specific requirements for detector cells for certain viruses. For instance, assays intended to detect infectious HIV use human peripheral blood lymphocytes and involve a p24 antigen capture enzyme immunoassay endpoint. A list of commonly employed indicator cell lines and their application in the detection of specific viruses is provided in *Table 3*.

**Table 3. Indicator (Detector) Cell Lines Used for Detection of Specific Virus(es)**

| Cell Line[a] | Assay Type | Endpoint(s)[b] | Target Virus |
|---|---|---|---|
| 324K | Isolation/detection | CPE, HAd, IFA | Murine minute virus |
| A9 | Isolation/detection | CPE, HAd, IFA | Murine minute virus |
| BHK-21 | Isolation/detection | CPE, HAd | Arboviruses[c] |
| MRC-5[d] | Isolation/detection | CPE | Human cytomegalovirus |

[a] Examples of cell lines used for optimizing the detection of specific viruses or virus types are shown. In many cases, the assay methodologies must also be optimized for detection of the target viruses.
[b] CPE, cytopathic effect; HAd, hemadsorption; IFA, immunofluorescent antibody staining.
[c] Insect-borne viruses as a group are referred to as arboviruses. This term has no taxonomic significance.
[d] Other human diploid cell lines such as WI-38 are also suitable. Assay duration must be 28 days at a minimum.

## GROWTH REQUIREMENTS FOR DETECTOR CELLS

Viral proliferation within a permissive host cell may be dependent on the rate of host cell proliferation. This is especially true for viruses that display cell-cycle dependence for generation of viral progeny. For most detection assays, detector cultures are seeded at a density intended to achieve a cell monolayer in exponential growth. This corresponds to a cell confluency of 50% or less (optimal cell densities may depend on the assay type and the detector cell to be used) at the time of inoculation of the cultures with virus or test sample. For the same reasons, the assay design may include provision for detector cell subculture (the collection of cells from the original culture and seeding of a predetermined fraction of these into a new flask). Alternatively, a

Official

https://pharmacopeia.cn/
Printed on: Fri Jan 05 2024 06:39:14 AM(EST)
Printed by: USP NF
Do Not Distribute

passage may be performed, consisting of collection of conditioned medium from the original culture and inoculation of this material onto a secondary detector cell culture that is in log-phase growth. The frequency of subculture/passage required in an assay is determined largely by the rate of growth of the detector cell. Incorporation of these steps into detection assay designs helps to ensure that the conditions remain optimal for amplification of viral progeny within the host cells.

### NEED FOR DETECTOR CELL IDENTIFICATION AND BANKING

Detector cells used for cell-based viral detection assays are a critical reagent for ensuring viral safety, viral potency, viral identity, and viral clearance capacity in purification schemes. In many cases this testing is intended to support GMP processes; therefore, the detector cell banks may need to be prepared and qualified in much the same manner as other critical reagents. The details of the viral safety evaluation methods are described in *Viral Safety Evaluation of Biotechnology Products Derived from Cell Lines of Human or Animal Origin* ⟨1050⟩. Regardless of specific compliance requirements, periodic identification and qualification of the detector cell banks to be used subsequently for viral infectivity assays is good practice. The following should be regarded as minimal quality control testing for such detector cell banks: sterility, mycoplasma and viral screening, and cell identity by DNA fingerprinting, karyology, or isoenzyme analysis. In addition, specific assays for bovine and porcine viruses may be required if bovine or porcine raw materials were used in preparation of the banks. *Bovine Serum* ⟨1024⟩ and relevant serum-type specific ancillary materials monographs should be consulted when serum products are used in cell growth media.

## Endpoints for Detection of Viral Infection

The various endpoints used to identify infection of a detector cell with a virus include the following:

- Visual observation of cytopathic effects
- Hemagglutination or hemadsorption of erythrocytes
- Immunofluorescent staining
- Cocultivation with other types of detector cells
- Quantitative polymerase chain reaction (qPCR) for direct detection of viral genomic sequences
- Electron microscopic analysis of viral pellets or fixed cells for visual observation of viral particles
- Biochemical endpoints such as reverse transcriptase assays, which detect virus-specific enzymatic activity

These various endpoints are used in a complementary fashion, because a given virus may not cause a positive response in each endpoint. For instance, some viruses can grow to high titers without producing visible cytopathic effects and so must be detected using other endpoints. Polymerase chain reaction (PCR) and electron microscopic analysis per se are not capable of distinguishing viable from nonviable viruses. However, when used in conjunction with cell culture growth kinetics, these approaches can be powerful orthogonal detection methods to demonstrate the increase of viral replication and therefore viable virus. The failure to observe viral particles in electron microscopic analysis of fixed cells should not be considered absolute proof of the absence of infectious virus in the cells. In a general sense, the same is true for each of the detection endpoints discussed above. Each endpoint has a detection limit below which a virus may be present but not detected.

### VIRAL CYTOPATHIC EFFECTS

Visually observable manifestations of the infection of susceptible host cells with certain types of viruses are collectively referred to as viral cytopathic effects (CPE). Although CPE may be considered an indirect detection of viral infection, in the context of specific host cells they can have distinctive morphological manifestations. These may include the appearance of inclusion bodies, abnormal cell morphology, changes in culture confluency, cell death and cell lysis, and others. The nature of the CPE observed may depend on the host cell and the infecting virus. In addition, for a virus that normally causes CPE, there may exist variants that do not cause CPE. CPE can be differentiated from cytotoxic effect by the tendency of the former to exhibit progression irreversibly with time, whereas the latter may be reversible. In some cases structural proteins of viruses may cause cytotoxic effects similar to the cytopathic effects of the infectious virus. Differentiating the cytotoxic effect of such proteins from the cytopathic effect of infectious virus may require observation of the culture over time to determine whether the effect progresses or the cells appear to recover. Alternatively, cell-free passage of the original culture onto fresh detector cells can be used to differentiate these two apparently similar manifestations. The cytotoxicity associated with the structural proteins in the absence of infectious virus would not be expected to pass to the secondary culture.

Giemsa staining may optimize the ability of the operators to visualize certain inclusion bodies (clusters of viral particles) that are characteristic of viral cytopathic effect and is required by 9 CFR 113.53 in assays used to demonstrate that bovine, porcine, equine, and ovine raw materials are free of species-specific viruses.

### DETECTION OF HEMAGGLUTINATING VIRUSES

A characteristic of certain viruses (referred to as hemagglutinating viruses) is that one or more of their viral proteins cause hemagglutination of one or more types of erythrocytes. Hemagglutination is an interaction between viral proteins or *hemagglutinins* and erythrocytes, leading to adhesion of the erythrocytes to surfaces, cells, and each other. This property forms the basis of two endpoint procedures that are employed in cell-based viral infectivity assays: *hemadsorption* and *hemagglutination.*

Hemadsorption is performed by adding a suspension of one or more erythrocyte types directly to the monolayer culture of detector cells. If viral proteins of a hemagglutinating virus are expressed from infected cell membranes, the susceptible erythrocytes will bind tightly to the cell membranes. Noninfected cells do not display this binding; therefore, the technique can be used to visualize a focus of infected cells against a background of uninfected cells. For this reason, this particular endpoint may display greater detection sensitivity than other assay endpoints, such as cytopathic effect or hemagglutination. In the

@2024 USPC

advanced stages of infection, binding of erythrocytes to cells, to each other, and to open plastic surfaces in the culture vessel may be observed.

The hemagglutination procedure is performed on the conditioned medium and is essentially an evaluation for free virus or viral hemagglutinins in solution. An aliquot of the conditioned medium from a detector culture is combined, in a microwell plate having v-bottomed wells, with one or more types of erythrocytes. After an appropriate amount of time the plates are evaluated. Absence of hemagglutination is reflected by a well-defined pellet (button) of erythrocytes sedimenting to the bottom of the well. In comparison, hemagglutination is reflected by the absence of a button, or by a button with irregular shape. Scoring the latter represents an opportunity for operator subjectivity. In addition, this endpoint can be considered the least sensitive in detection assays, because it is dependent on achieving a sufficient concentration of viral hemagglutinins in solution. For these reasons, hemadsorption is typically viewed as the more useful and reliable of the techniques for detecting hemagglutinating viruses.

The responses obtained in detection assays using hemadsorption and hemagglutination endpoints are highly dependent on the virus being assayed, as well as on the types of erythrocytes used. Many of the viruses of concern to the biotechnology industry do not cause hemadsorption and hemagglutination, or their hemagglutinins react with red blood cell types not commonly used in detection assays.

### DETECTION BY IMMUNOFLUORESCENT ANTIBODY (IFA) STAINING

Certain cell-based viral detection assays are intended to detect specific viral entities and are required for raw materials tests derived from bovine-, porcine-, equine-, and ovine-derived materials (9 CFR 113-53). In order to achieve this, the assays must be optimized with respect to host cell selection, study design, and sample preparation. Specificity of detection is also conferred through use of IFA staining techniques. Primary antisera or monoclonal antibodies directed against the viral antigens of interest are used, either in direct staining applications or in conjunction with a fluorochrome-conjugated secondary antiserum. The immunostained detector cell monolayers are then visualized with an epifluorescence microscope to reveal the presence of reactive infected cells.

## Design of Cell-Based Viral Assays

### VIRAL DETECTION ASSAYS

Detector cell cultures are seeded and allowed to incubate for the appropriate amount of time. Viral samples may be inoculated directly into the medium of the mitotic phase of cell culture, but more typically the medium is removed from the overnight detector cell culture and is replaced with the test sample. For the latter method, the test sample must therefore be approximately isotonic, and cytotoxic agents such as selection agents must be maintained within levels tolerable to the detector cell. For test samples comprised of live cells, the sample must be subjected to freeze-thaw before inoculation in order to lyse the sample cells. If the cells are not lysed, a cocultivation involving the detector and sample cells will result. The latter is part of the design for cocultivation assays. But for most of the cell-based infectivity assays such a cocultivation is not intended and could adversely impact the sensitivity of the assay. The test sample is typically allowed to adsorb to the detector cell monolayers for an appropriate amount of time. It is then removed and replaced with the growth medium suitable for the detector cell. Once inoculated, the detection assay involves incubation of the detector cells for a prescribed amount of time, with periodic refeeding as necessary. Endpoint evaluations as described above are performed according to the study design. Variations of the given procedure may be used for exposing detector cells to raw materials. For raw materials, detector cell exposure may consist of incorporation of the test materials into the growth medium used to maintain the detector cells throughout the assay.

### VIRAL TITRATION ASSAYS

Viral titration assays are designed to generate quantitative information about the virus of interest. These assays do not quantify absolute numbers of viral particles; rather, the results are expressed in terms of infectious units. An infectious unit is the amount of virus required to establish a productive infection, and several categories of titration assays are used. They vary on the basis of the endpoint used to demonstrate infection and include viral plaque titration or plaque-forming units (units: PFU per mL); 50% tissue culture infectious dose (units: $TCID_{50}$ per mL); and 50% fluorescent antibody infectious dose (units: $FAID_{50}$ per mL). The amount of a hemagglutinating virus in a sample can also be expressed in terms of hemagglutinating titer (units: endpoint dilution, i.e., the greatest dilution of the sample which still results in a positive hemagglutination, or HA, response).

Regardless of the endpoint used, a typical titration assay design consists of a sequence of sample dilutions based on 0.5 $\log_{10}$ or 1 $\log_{10}$ increments. The various dilutions of the sample are then applied to an appropriate number of replicate permissive detector cell monolayers. After a suitable incubation time, the monolayers are scored directly for cytopathic effect ($TCID_{50}$ assay), fixed and processed for immunostaining and scored for reactive cells ($FAID_{50}$ assay), or overlaid with agarose and processed for plaque generation PFU assay. $TCID_{50}$ and $FAID_{50}$ titers are typically calculated using published formulas, such as Spearman-Kärber and Reed-Muench. Assay controls for such quantitative assessments should routinely include a reference sample of known potency.

## Detection of Retroviruses

Retroviruses represent a special case for cell-based viral detection assay because of the occurrence of retroviral infection in the absence of responses to the typical endpoints discussed. In order to detect retroviruses, scientists can employ a number of different endpoints. A list of commonly employed indicator cell lines and associated endpoints, and their application in retrovirus detection assays, is provided in *Table 4.*

**Table 4. Indicator (Detector) Cell Lines Used in Retrovirus Infectivity Testing**

| Cell Line | Assay Type | Endpoint(s)[a] | Target Virus |
|---|---|---|---|
| SC-1/XC | Isolation/direct detection | Plaques (XC); RT | Ecotropic murine retrovirus |
| Balb/C | Isolation/direct detection | Plaques (XC); RT | B-Tropic murine retrovirus |
| NIH/3T3 | Isolation/direct detection | Plaques (XC); RT | N-Tropic murine retrovirus |
| Mink Lung | Isolation | RT; mink S+L- | Xenotropic, amphotropic murine retrovirus |
| Mink S+L– | Direct detection | Foci | Xenotropic, amphotropic murine retrovirus |
| Feline S+L– | Direct detection | Foci | Xenotropic, amphotropic murine retrovirus, gibbon ape leukemia virus (GALV), and RD-114 feline retrovirus |
| *Mus dunni* | Isolation, cocultivation | RT; S+L– | Murine retroviruses and retroviruses infectious to humans |
| QT6[b] | Isolation, cocultivation | RT | Avian retroviruses |
| RD | Isolation, cocultivation | RT; S+L– | Retroviruses infectious to humans |
| MRC-5 | Isolation, cocultivation | RT; S+L– | Retroviruses infectious to humans |
| WI-38 | Isolation, cocultivation | RT; S+L– | Retroviruses infectious to humans |
| 293 | Isolation, cocultivation | RT; S+L– | Retroviruses infectious to humans |
| A549 | Isolation, cocultivation | RT; S+L– | Retroviruses infectious to humans |
| Raji | Isolation, cocultivation | RT | Retroviruses infectious to humans |
| Human PBMC | Isolation, cocultivation | RT, HIV p24 EIA | HIV and other human retroviruses |

[a] The endpoint assays include the following: RT, reverse transcriptase; PERT, product enhanced reverse transcriptase (including also product enhanced reverse transcriptase and real-time quantitative product enhanced reverse transcriptase assays); and EIA, enzyme immunoassay.
[b] A quail cell; primary fibroblast cultures of chicken or turkey origin are also sometimes used.

Retroviral infection is dependent on the presence of receptors on the host cell membranes. The presence of such receptors confers host cell tropism.

## DESIGN FOR RETROVIRUS INFECTIVITY ASSAYS

Two types of infectivity assays are used, depending on the nature of the test material. For materials other than intact cells, the test material is inoculated onto one or more of a variety of detector cells, and the latter are then passaged as required to amplify any virus present. Because of the nature of retroviral replication, cytopathic effects typically do not occur during infection, although there are some exceptions. Before the first subculture and at the end of the final passage, one or more endpoint assays are employed to detect the presence of a retrovirus. For test materials in the form of intact cells, detector cells are seeded and subsequently inoculated with the test cells, resulting in a cocultivation. The cultures are passaged five or more times. Before the first subculture and at the end of the final passage, one or more endpoint assays are employed to detect the presence of a retrovirus.

## ENDPOINT ASSAYS FOR RETROVIRUS DETECTION

Endpoint assays may be classified as direct, which lead to distinct morphological changes in the detector cells; or indirect, as measured by the detection of biochemical, molecular, or immunological markers for infection.

**XC-Plaque Assay**—The XC-plaque assay was developed as a direct means of detecting infectious murine retroviruses. Detection of the retrovirus is accomplished by UV-irradiating the detector cells used to amplify the virus and overlaying the irradiated detector cells with a specific rat cell (XC). The presence of infectious murine retroviruses in the detector cells is reflected by the formation of distinctive syncytia in the XC monolayer, which are easily visualized when the cultures are fixed and stained with a suitable dye such as crystal violet.

The N/B tropism of an ecotropic murine virus may be determined by inoculating Balb/c and NIH Swiss detector cells with the isolate, performing one or two passages on each cell line, and comparing the XC-plaque titer post passage to that determined for the initial isolate.

**Mink and Feline S+L– Focus Assays**—The S+L– focus endpoint was developed to facilitate direct detection of infectious murine xenotropic and amphotropic viruses. The test sample may be inoculated directly into cultures of the S+L– cells, or, alternatively, may be amplified first by inoculation into mink lung, human, or *Mus dunni* detector cells. Cell-free supernatants from the detector cell cultures are used to inoculate the S+L– cells. The latter are infected with a sarcoma virus that is replication-defective, requiring the presence of a helper leukemia virus to render it capable of causing transformation of the host cell. The presence of infectious retrovirus virus in the detector cultures is reflected by the formation of characteristic focal areas of cell transformation in the S+L– cells caused by the rescued sarcoma virus.

**Detection of Retroviral Reverse Transcriptase**—Assays designed to measure reverse transcriptase (RT) activity are useful as an indirect detection method, because the enzyme is indicative of the presence of all retroviruses, whether infectious or not. The RT enzyme is encoded for in the retroviral genome and is used by the virus to transcribe genetic information in viral genomic RNA into proviral DNA.

*Radiolabeled Nucleotide Incorporation Assay*—The earliest methods for measuring RT activity were based on the measurement of $^{32}P$- or $^{3}H$-labeled nucleotide incorporation into the complementary cDNA product, using an appropriate RNA template. Incorporation of radiolabeled nucleotide at levels higher than a predetermined threshold is interpreted as evidence of the presence of retroviral RT activity. The contributions of cellular DNA polymerases can be ruled out through use of a dual template assay (having both RNA and DNA templates) or inclusion of activated calf thymus DNA.

*Product-Enhanced Reverse Transcriptase (PERT) or Quantitative PERT (Q-PERT)*—Polymerase chain reaction amplification has been used to increase the sensitivity of RT activity measurement. RT activity is detected by PCR amplification of complementary DNA, newly synthesized from an RNA template by reverse transcriptase. The assay may be performed with a gel endpoint (PERT) or as a quantitative assay (Q-PERT). This method has increasingly gained acceptance by regulatory agencies. For more details on PCR-based techniques, see the USP general information chapter *Nucleic Acid Based Techniques—Amplification* ⟨1127⟩.

### ELECTRON MICROSCOPY

Transmission electron microscopy (TEM) may be used to detect and enumerate viral particles within cells. In addition, the technique allows for differentiation of types A, B, C, and D retroviruses based on morphological considerations and can be used to localize viral particles within the cell. As a technique for identification of viruses (including RNA and DNA viruses in general), TEM of sectioned cells is extremely valuable. The cells, typically sampled during the log phase of growth, are pelleted by low-speed centrifugation, and the cell pellet is fixed with a suitable fixative. The fixed cell pellet is embedded, sectioned, stained, and observed with TEM. Size (diameter) of the particles, morphology, presence or absence of surface features such as envelopes and spikes, and location within the cell can be determined with this technique. Such information is important for the identification of a virus. However, failure to observe viral particles with this method does not conclusively demonstrate the lack of viral contamination in the sample.

Biological fluids may also be evaluated by TEM, primarily to determine particle size and concentration. The cell-free supernatant is subjected to ultracentrifugation to pellet any virus present. The resulting pellet is fixed with a suitable fixative. A predetermined number of grid spaces containing representative areas of thin sections of the pellet are evaluated for particles. The enumeration results obtained may show a high degree of variability, and failure to observe particles does not imply that none were present in the sample. Molecular (quantitative PCR and quantitative PERT) endpoints have also been used as alternative methods for estimation of viral particle load in samples.

### ANTIGEN-CAPTURE ENZYME IMMUNOASSAY

Specific viral proteins (e.g., HIV p24 antigen or avian leucosis viral envelope proteins) may be detected as a means of determining the presence of a retrovirus. Viral antigens are captured by specific antibodies coated onto microtiter plate wells and are detected by the addition of a second labeled antibody and appropriate substrate.

## Assays Designed to Detect Specific Viruses

Additional methodologies have been developed to allow detection of specific viruses or groups of viruses. These types of assays are often used for raw material evaluation. In some cases, these specific assays were developed because the target viruses do not cause endpoint responses in the viral screening assays. In contrast to screening assays, specific virus assays are typically optimized for detection of the target virus or viruses. This optimization takes into account the lability of the virus, the host range, the possible endpoint responses elicited, and any special requirements of the target virus. The use of well-characterized viruses as positive controls in such assays provides assurance that the methodologies are suitable for the target virus or viruses. Spiking of the test sample matrix with the positive control virus enables the investigator to assess the potential for matrix interference and to assess the limit of detection for the method. Such considerations are not applicable to screening assays. Specific virus testing for bovine- and porcine-derived raw materials is discussed below. Evaluation of caprine, ovine, equine, canine, and feline raw materials is also stipulated in 9 CFR section 113.47. This section should be consulted with respect to the viruses of concern, and 9 CFR 113.52 should be consulted for methodology. A list of commonly employed indicator cell lines and their application in raw materials testing assays is provided in *Table 2.* A list of commonly employed indicator cell lines and their application in detection of specific viruses is also provided (see *Table 3*).

### DETECTION OF BOVINE VIRUS CONTAMINATION

Raw materials of bovine origin include such commonly employed medium components as fetal bovine and calf serum, serum albumin, collagen, thrombin, and trypsin. Each of these additives represents a route of entry for adventitious viral contaminants into a cell culture or manufacturing process. Requirements for evaluation of such materials ensure the absence of contaminating viruses.

For the details on testing for bovine serum and its derivatives, see future general chapter *Bovine Serum* ⟨1024⟩.

### DETECTION OF PORCINE VIRAL CONTAMINANTS

Raw materials of porcine origin include trypsin as well as other cell culture reagents. The specific porcine viruses of concern in the United States are stipulated in 9 CFR 113.47 and include porcine parvovirus, porcine adenovirus, transmissible gastroenteritis virus, and porcine hemagglutinating encephalitis virus. In addition, porcine raw materials must also be evaluated for the presence of bovine viral diarrhea virus (BVDV), reovirus, and rabies virus. Porcine tissues intended for xenotransplantation into humans also are routinely evaluated for the porcine endogenous retrovirus (PERV). The host cells typically used in the detection of porcine viruses are porcine testicle or porcine kidney, a bovine cell, and Vero cells. The methodology described in 9 CFR 113.52 is analogous to that for evaluation of bovine raw materials and includes provision for multiple subcultures, for Giemsa staining of fixed cells, for hemadsorption testing, and for use of specific immunostaining of fixed cells.

### CELL-BASED DETECTION OF MURINE MINUTE VIRUS

Murine minute virus (MMV) is a mouse parvovirus that has been detected in biologics manufacturing involving Chinese hamster cell substrates. As with other parvoviruses, MMV represents a special case in that the virus is difficult to inactivate using typical cleaning agents and is capable of surviving for prolonged periods of time on surfaces. Cell-based assays for MMV involve detector cell lines that are especially susceptible to this virus, such as 324K (a human cell) and A9 (a murine cell). Optimization for detection of a parvovirus also includes provision for detector cell subcultures to remain in log-phase division for a significant portion of the incubation period. Endpoints for detection of MMV include one or more of the following: cytopathic effect, hemagglutination of mouse and guinea pig erythrocytes, immunostaining, and polymerase chain reaction.

### CELL-BASED DETECTION OF INSECT-BORNE VIRUSES

Insect-borne viruses include both viruses infectious only for insect cells (e.g., baculovirus) and those transmitted to mammalian cells via insect vectors (arboviruses). Detection of the former may be accomplished using an insect cell as a detector cell. Suitable substrates might include cells of *Spodoptera, Trichoplusia, Drosophila*, mosquito, or other insect origin. Such cells are typically cultured at lower temperatures (25° to 28°) relative to mammalian cells, and many of these cultures are suspension or semiadherent at best. Endpoints may include cytopathic effect, electron microscopy, and PCR.

Of more relevance to patient safety is the detection of arboviruses (insect-borne viruses infectious to animals and humans). This may be accomplished using a suitable mammalian detector cell. The Syrian hamster kidney cell (BHK-21) is a cell line that has shown susceptibility to a wide range of arboviruses. This cell line grows in a monolayer culture, and the endpoints that may be used include cytopathic effect, hemadsorption and hemagglutination, and PCR.

### CELL-BASED DETECTION OF HUMAN CYTOMEGALOVIRUS

Human cytomegalovirus (CMV) is a slow-growing virus of special concern for biologics produced using human cell substrates. It may be detected in cell-based assays using human diploid detector cells such as WI-38 or MRC-5, provided that sufficiently long durations of incubation are employed (28 or more days). The endpoints include cytopathic effects and immunostaining and/or PCR.

## In Vivo Methods

Intact and susceptible animals may serve as potential host organisms for detecting viruses in test samples. In this case, viral proliferation in the tissues of the host animal may be reflected as adverse health effects (including death) that can be monitored and recorded. Viral detection assays based on intact animals are intended to complement in vitro assays, because some viruses that do not cause a response in the in vitro assays may be detectable in the animal systems (and vice versa). Viral safety studies employing live animals must be performed in accordance with applicable regional guidelines for the ethical use of animals, using laboratories that are accredited for the housing of the animals.

### IN VIVO VIRAL SCREEN

The in vivo viral screen is used primarily for cell bank, viral seed stock, and viral vaccine testing and is considered to complement the in vitro virus screening assay. Multiple animal species, as well as multiple injection routes, are employed to provide a broad range of host tissues and possible responses. A list of commonly used host animals, routes of inoculation, and target viruses are shown in *Table 5*.

**Table 5. In Vivo Viral Screening Assays**

| Host Animal | Route of Inoculation | Target Virus |

Following injection of the test sample, each animal model is monitored for an appropriate period of time that allows for the observation of clinical signs of viral infection. Any abnormality is investigated to determine the cause of the effect.

The suckling mice are observed for an appropriate period of time. Pooled homogenates from any surviving animals are then passaged into additional litters of suckling mice. The latter are observed for an additional period of time.

The guinea pigs are observed for clinical signs of viral infection and for injection site lesions. Necropsy for gross tubercular lesions is performed for certain types of test samples.

Allantoic fluids from eggs can be tested for hemagglutination of chicken, guinea pig, and human type-O erythrocytes. Additional fluids are pooled for each treatment group (test article and control), and these are passaged (inoculated) into a new group of embryonated eggs. Following an appropriate incubation period (typically measured in days), the allantoic fluids are again tested for hemagglutination of chicken, guinea pig, and human type-O erythrocytes. Following injection by the yolk sac route, the eggs are incubated for at least 9 days and are assessed for viability. The yolk sacs are then harvested and pooled for each group (test article and control), and a 10% solution of the resulting material is inoculated by the same route into a new group of embryonated eggs. The eggs are again incubated for an appropriate period of time (days) and are assessed for viability.

## IN VIVO ASSAYS INTENDED TO DETECT SPECIFIC VIRUSES

Some in vivo assays are designed to detect, if not specific viruses, at least specific sets of viruses. The antibody production assays use the production of a humoral immune response in susceptible host animals inoculated with test samples. Viral antibody-free animals of the various species are injected with the test sample. At the end of an appropriate incubation period, one or more of a variety of endpoint assays may be performed to detect the generation of a humoral antibody response in the animal sera. Production in the animal of antibodies directed against a specific virus provides evidence of the presence of viral antigen or infectious virus in the test sample. This type of assay is typically used to ensure that rodent cell banks and viral seed stocks are free of adventitious viruses. Three antibody production assays, along with the route of injection and target viruses, are summarized in *Table 6*.

* A group of test sample–injected mice is challenged with a known lethal dose of authentic LCMV. If this group of mice does not die from the challenge dose, a second group with twice the number of mice is used for a repeat challenge. If there are survivors in this group, the test sample is considered positive for LCMV.

## Considerations for Validation, Matrix Qualification, and Quality Control of Cell- and Animal-Based Test Systems

Viral detection assays used to ensure the viral safety of human and animal therapeutics are expected to have undergone validation. The approach to the validation depends on the nature of the assay and associated regulatory compliance level.

Any assay should be sufficiently developed that it can be performed with an appropriate set of predetermined system suitability and acceptance criteria. These criteria usually include the use of relevant negative and positive controls but may also include requirements for linearity and meeting of a predetermined detection limit. The results constituting a positive or negative response in the assay should be established prior to execution of the validation. An assay used under GMP compliance is expected to have been validated according to appropriate guidelines.

An assay used to ensure the safety of a commercially marketed biological product must be further characterized for suitability in the presence of the specific product matrix. The matrix qualification study should address the potential for specific interference with the viral detection endpoints used in the assay, and typically involves spiking of one or more model viruses into the product matrix at levels approaching the limit of detection to ensure the absence of interference.

For quantitative detection assays, the detection limit should be probed. This usually involves spiking of the model virus(es) at decreasing amounts into medium or the product matrix. The lowest spiking level of the virus reliably detected is used as an approximation of the actual limit of detection of the assay. Experimental error for these cell culture-based assays is usually expected to be in the range of 0.5 to 1 $\log_{10}$. The determination of a detection limit is less meaningful for limit tests and viral screening assays in general. For the latter, knowledge of the detection limit for one virus does not imply a similar limit for another

@2024 USPC

virus. Since screening assays are not optimized for a specific virus, the limit of detection for the assay can vary greatly from one virus to another.

Animal-based viral detection systems are generally not subject to the requirements for validation, matrix qualification, use of positive controls, and determination of detection limit that regulatory agencies expect of cell-based and biochemical tests. The use of animals for safety testing is subject to the regional guidelines for the ethical use of animals, and the kinds of activities listed above generally are not considered appropriate use of animals. However, negative control animals are included in these assays, and retrospective validation or gap analysis based on historic incidence of system suitability failures or positive findings is sometimes possible.

## DETECTION OF VIRAL COMPONENTS

Direct detection of viral components can provide a direct measurement of viral levels in a sample preparation. It has also become primarily important for detection or identification of viruses in biological products or in the raw materials used in their manufacture. Systems capable of identifying components unique to specific phases associated with viral latency and replication are now available. During interaction with their host cells, viruses may incorporate modified host molecules during the production of new intact virus particles, or they may induce discernable changes in host cell makeup or function.

Most immunological methods and reagents currently available detect the constituents of intact virions. It is the relative abundance of these proteins that makes them most amenable to the development of antibody-based reagents. Abundance also makes them optimal targets for detection of the virus. Recently developed targeting and detection reagents are aimed at minor viral components that may be found only during specific phases of replication. These allow a more detailed analysis of the stage of viral infection. The basic methodology for the detection of viral antigens is well established, but more recent innovations in materials and reagent development have broadened its application.

Developments in the targeting and detection of viral nucleic acid components have led to enzyme-based systems for the amplification of nucleic acids in vitro and in situ (see *Nucleic Acid-Based Techniques—Amplification* ⟨1127⟩). The potential specificity of this detection method allows the examination of biological systems with a high degree of confidence for the presence or absence of a specific targeted virus. A wide variety of reagents, technology platforms, and methodologies are available. The aim of this section is to elaborate on the most common practices and platforms used in the detection of viral components.

### Sample Selection and Preparation for the Detection of Viral Components

This subsection addresses general considerations for various types of test samples and the most common assay targets (viral proteins and nucleic acids). The target proteins may have varying levels of posttranslational modification (e.g., glycosylation, phosphorylation), and the target nucleic acids may be either RNA or DNA, single or double stranded. Therefore, it is important to have a basic understanding of the physicochemical nature of the virus under study so that the sample handling procedures support the detection of the target component. For detailed considerations regarding the extraction of nucleic acids, see the USP general information chapter *Nucleic Acid-Based Techniques—Extraction, Detection, and Sequencing* ⟨1126⟩.

#### Types of Samples

##### CELLULAR

When viral components are associated with intact cells, samples must be generated either as whole cell lysates or as subcellular fractions. Maintaining the temperature of the test samples at or near freezing (0° to 4°) during processing and limiting the time that samples are held in an unfrozen state will reduce the potential for loss of target antigens and nucleic acids due to cytosolic enzymes (proteases, nucleases) present in the cell lysates. Reagents that can inactivate or limit the activity of such enzymes may be used to prevent degradation of the target components, especially when exceptionally labile samples must be handled at room temperature. Centrifugation of intact cells allows for some additional manipulation of the sample matrix. The growth medium can be discarded and the cells suspended in a buffer formulated to enhance the recovery and detection of the targeted viral component. Collection and storage parameters should also account for the presence of cellular DNA. This can increase the viscosity of the sample, rendering it difficult to pipet.

##### TISSUE CULTURE SUPERNATANT

Depending on the stage of the infection and the type of virus involved, the conditioned medium may represent a preferred test sample. An advantage is that the presence of cellular debris can usually be reduced through use of a low-speed centrifugation (clarification) step. The main disadvantage is the potentially low concentration of the analyte, and therefore concentration of the sample may be required.

##### PROCESS INTERMEDIATE (UNPROCESSED BULK HARVEST)

In general, viral safety lot release testing is done at the bulk harvest stage prior to any purification. This is true regardless of whether the assay detects infectious virus or viral components. The presence of host cell DNA may need to be assessed in the case of biologics manufactured in animal cells.

## Sample Stability and Matrix Effect

Sample stability is a key element in the successful detection of viral components. Protein structure can be altered by numerous environmental factors, including pH, ionic strength, solvents, detergents, temperature, and free radicals. In addition, complex biological matrices frequently contain proteolytic enzymes that can alter or destroy key antigenic features of a protein or peptide. Sample collection, storage, and handling must allow maintenance of the antigenic features targeted by reagent antibodies.

Conformational changes affecting the opportunity for antigen detection are difficult to address. Depending on the reagents required for detection, conformational changes may be required for antigen detection. For example, if antibodies are produced for an antigen detection system using native viral antigen, then unmasking and maintaining the conformation of the antigen throughout the sample preparation is essential. Conversely, if peptide fragments are used to produce antibody, then a denaturation step may be required to allow for effective antigen detection.

Conditions associated with sample preparation must be investigated in a combinatorial fashion whereby one parameter or component is varied while all others remain fixed. In this way, the formulation of lysis and processing buffers can be optimized for pH, ionic strength, and types of detergents and denaturants. The sample preparation steps must condition the targeted antigen in order to obtain the form most readily recognized by the reagent antibody.

The stability of nucleic acids in test samples is largely affected by nuclease activities present in the sample and the degree of protection provided by the intact structure of the virus particle. Encapsidated nucleic acids are particularly stable as long as the integrity of the capsid is maintained. Viral capsids are vulnerable to proteolytic digestion. Virus particles stored at ambient temperature as part of a complex biological matrix are especially susceptible to degradation by proteases. Storage at refrigerated temperatures (2° to 8°) for short periods of time or at temperatures below freezing can be used to limit proteolytic activity. When samples are stored at frozen temperatures, freeze-thaw cycles should be limited. Under conditions where an individual sample must be accessed multiple times, preparation of aliquots is advisable.

### SAMPLE COLLECTION

In a biotechnology setting, sample collection is dictated by sampling plans that are established to meet regulatory requirements. Nucleic acid testing in association with an amplification step has the potential of detecting a virus at the earlier stages of infection. The use of nucleic acid amplification methods reduces the dependence on timing and the amount of material required, because the amplification process effectively boosts assay sensitivity by increasing the amount of target relative to background.

General aspects of nucleic acid sample preparation and stability are discussed in *Nucleic Acid-Based Techniques—Extraction, Detection, and Sequencing* ⟨1126⟩. The following section specifically addresses the unique aspects of viral sample selection and preparation.

### SAMPLE STORAGE

Conditions for sample storage should be consistent with maintaining the antigenic properties of targeted viral proteins and/or preserving the nucleic acid content of the sample. The duration and temperature of storage is dictated also by cycle times associated with testing.

### IMMUNE COMPLEX DISRUPTION

The masking of antigen epitopes may occur when other proteins associate at or near the epitope targeted by reagent antibodies. For viral antigens this may occur when the antigen comprises the structural component of the virus. Such viral antigens are likely to retain strong affinities for other viral proteins or the ability to exist in multimeric form under normal conditions for detection. Another obstacle for epitope recognition is the naturally occurring immune complex when reagent antibodies have been developed to detect native protein in a blood plasma matrix. Immune complexes consisting of viral antigens and host antibodies are normal in such physiologic samples. The stronger the host immune response, the more likely masking of antigen due to immune complex formation will occur. Methods aimed at the preparation of blood and plasma samples for detection should address the presence of preexisting immune complexes and incorporate steps designed to disrupt such complexes to improve the opportunity for viral antigen detection.

## Detection of Viral Antigens

Viral capsid proteins are common targets for antigenic detection methods. Structural proteins that make up the framework of the viral core are often some of the most abundant viral proteins produced during viral replication. In nonenveloped viruses, the core structural proteins are likely to provide the dominant antigenic features. When the virus is enveloped, proteins associated with the envelope often provide key antigenic features. This section examines methods commonly used to detect viral antigens and addresses considerations aimed at optimizing formation of the appropriate immune complex.

### ASSAYS USED FOR THE DETECTION OF VIRAL ANTIGENS

Immunologic methodologies used to detect viral antigens are based on the specificity and affinity of the antibody and viral antigen interaction. Of the various platforms available, one commonly employed in viral safety testing is immunofluorescent antibody staining. This lends some degree of viral specificity to the cell-based methods described in the first part of this chapter. Other techniques include enzyme-linked immunosorbent assay (ELISA), radioimmunoassay, and Western blotting. The principles and general methods for these assays will be described in the USP general information chapters *Immunological Test Methods—General Considerations* ⟨1102⟩, *Immunological Test Methods—Reagent Development* ⟨1103⟩, *Immunological Test Methods—Immunoassay Methodologies* ⟨1104⟩, and *Immunological Test Methods—Assay Design, Quality Control, and Data*

*Analysis* ⟨1105⟩, being prepared for future publication. The following sections will generally address aspects specific to their use in virology.

**Immunofluorescence Assay**—The immunofluorescence assay (also referred to as immunofluorescent antibody staining) is used to detect viral proteins expressed in various cellular compartments. Since the technique can detect viral antigens within single cells, it confers a high degree of sensitivity and enables infection to be detected at a very early stage. The technique is often employed as a detection endpoint for cell-based viral infectivity assays to provide additional sensitivity and specificity (see tests for raw materials as described in 9 CFR 113.53). In addition, the technique is employed for verifying the identity of viral stocks and is useful as a means of identifying viruses detected in viral screening assays.

**Enzyme-Linked Immunosorbent Assay (ELISA)**—ELISA is best suited for detection of soluble antibodies and antigens in a variety of test samples. Sensitivity, quantification, robustness, ease of experimentation, and readily available inexpensive reagents make it adaptable to a high throughput environment. For viral antigen detection, a sandwich ELISA assay is commonly used. A viral antigen specific antibody (preferably a monoclonal antibody with high affinity) is first immobilized onto a solid phase. The test sample is then incubated for a predetermined period under appropriate conditions. After washing, a second antibody that recognizes the viral antigen is incubated. The second antibody is linked to either an enzyme or a chromomeric reagent that emits signal with an appropriate substrate and can be recorded with an appropriate instrument. The assay can be performed in a qualitative or a quantitative manner. For a qualitative ELISA assay, sufficient replicates of both positive and negative control samples are required in order to determine the appropriate cut-off value and the assay acceptance criteria. A mean value of a test sample that is equal to or greater than the cut-off value is considered positive. For a quantitative ELISA assay, an additional standard curve with a positive reference standard material of known quantity must be established. The number of replicates should be adequate to determine the assay variation and linearity. The quantity of test sample can be calculated against the standard curve.

**Radioimmunoassay (RIA)**—The radioimmunoassay is a versatile quantitative immunoassay that can be used to detect substances including viral antigens and antibodies. It even can be applied to nonprotein molecules as long as an antibody that specifically binds the test substance is available. Radioimmunoassays can be customized in different formats to suit specific test requirements. Many of the considerations taken into account with other immunological assays are applicable to the RIA. In general, radioimmunoassays can be divided into two major categories: solution (homologous) and solid-phase radioimmunoassays. Both methods have been successfully used to detect and quantify a variety of viral antigens or components of viruses, such as hepatitis A, B, and C; human and murine retroviruses; adenovirus; avian C-type virus; rubella virus; and respiratory syncytial virus.

**Western Blotting (Immunobloting)**—Western blotting, also known as immunoblotting, is used to identify specific antigens in the presence of other, potentially cross-reactive antigens. In this case, the specificity required is obtained by combining the antigen-antibody reaction with some form of separation (typically electrophoresis). Depending on the visualization methods employed (including digital methods such as densitometry), this method can be quite sensitive and even semiquantitative. One advantage of this approach is that in addition to detecting the antigen using an immunological approach, data on the approximate mass of the target protein may be obtained. A potential caveat is that most test proteins are denatured during this procedure and that antibody that depends on epitope conformation may not recognize the linear epitopes.

## Detection of Viral Nucleic Acids

The detection of viral nucleic acids provides another route for the determination of viral loads and for establishing the identity of a contaminant. Nucleic acids, like protein antigens, are essential components of viruses, and detectable quantities are usually indicative of viral presence. Detection assays can be designed and developed in some cases to parse viremia into phases, especially when the differentiation of nucleic acids along functional forms and configurations can provide clear insight into viral activity. Assays can be designed to determine whether viral DNA has been integrated into the host genome or still is encapsidated. Early viremia may be detected as viral mRNA transcripts prior to the accumulation of detectable viral particles. Nucleic acids may be the only detectable viral component of viruses that do not replicate well in tissue culture systems. Such systems may fail to produce mature virus particles, but the detection of viral transcripts can provide insight into whether the virus has the ability to infect the cell. Nucleic acid testing represents the most useful endpoint for the detection of certain viruses failing to cause responses using typical endpoints.

### SAMPLE PREPARATION: SPECIAL CONSIDERATIONS FOR NUCLEIC ACID TESTING

The degradation of nucleic acids in samples can be limited through proper handling and storage practices and even enhanced by closely linking sample collection and preparation steps. In addition to preparing nucleic acids for further processing, denaturation is an important step toward stabilizing nucleic acids where storage temperatures extend above 0°.

**Denaturation and Dissociation of Virions (Viral Lysis)**—Chaotropic detergents and salts can be important agents for disrupting and removing viral proteins that make up the viral capsid. Their addition can provide a useful first step when concentration of virions is not necessary or even possible. In sufficient quantity they rapidly denature the entire contents of a biological sample, essentially fixing nucleic acid content through the inactivation of nucleases and other proteins that may affect sample stability. Saturated solutions containing guanidium salts, such as guanidine hydrochloride or guanidine isothiocyanate, are commonly used for the dissociation of viral nucleic acids from protein components. These solutions may be used alone or in combination with ionic detergents and other denaturants such as phenol. The main advantage of guanidinium salts is that they are readily removed during the concentration of viral nucleic acids using ethanol or isopropanol. Urea may also be used as a mild denaturing agent, although it does not perform as effectively as guanidine in its ability to disrupt virus particles.

**Deproteinization**—The removal of proteins during the processing of samples for the detection of viral nucleic acids is helpful in ensuring the reproducibility and robustness of assays, particularly those that rely on amplification to detect exceptionally low quantities of nucleic acids. Several strategies may be used to facilitate deproteinization of the sample; they are discussed in *Nucleic Acid-Based Techniques—Extraction, Detection, and Sequencing* ⟨1126⟩.

DOI: https://doi.org/10.31003/USPNF_M915_01_01

**Recovery of Viral Nucleic Acids**—Separation and recovery of extracted viral nucleic acid are important steps in the testing of nucleic acids. Nucleic acid yield and purity obtained at this step are critical determinants of assay robustness. Poor nucleic acid recovery and limited purification may inhibit amplification and detection reaction resulting in poor assay sensitivity. The development of high-yield, high-purity recovery steps is an important goal in the optimization of nucleic acid detection methods. Details on the general aspects of extraction and detection of nucleic acids are discussed in *Nucleic Acid-Based Techniques—Extraction, Detection, and Sequencing* ⟨1126⟩. However, if no inhibitory components are identified in the system, direct testing on an aliquot of a sample may increase the assay sensitivity.

**Isolation of Viral DNA**—Integrated viral genomes must be recovered and processed along with the genome of the host cell. The viral genome is analyzed within the context of the host genome, and therefore similarities between virus and host genomes must be accounted for to ensure that assay results are specific for the virus and do not simply reflect the presence of cross-reacting host genome sequences. Viral genomes that exist as episomal entities require similar consideration, but there may be opportunities during sample preparation to limit the amount of host nucleic acid present in the preparation. Sedimentation gradients or silica-based separation chromatography can sometimes be used to enrich episomal nucleic acids through size-related exclusion or partitioning of processed nucleic acids.

The recovery of encapsidated viral genomes may allow for larger amounts of material, especially if the target virus has accumulated in large quantities in the system being monitored. When the amount of material available for recovery is low or the processing of large amounts of the material is impractical, the process of isolating and conditioning the virus particles, and subsequently the encapsidated genome, must be compatible with the assay system that will be used. Portions of the viral genome may need to be amplified, or the genome itself may be captured in an elaborate process that allows detection through the generation of an amplified signal. A standard method for isolating viral genomes may need to be modified appropriately to ensure that materials used in the preparation do not interfere with steps conducted later in the process.

Viral genomes that consist of RNA are typically converted to a DNA intermediate that is easier to handle and store. Methods aimed at the isolation of viral genomes consisting of RNA, however, require similar considerations concerning the localization of the genome: replicating RNA viral genomes may be recovered as part of a preparation of host total RNA or even mRNA if the genome contains polyA sequences. RNA lends itself more effectively to hybrid capture methods during isolation, and hybrid capture can be used to enrich RNA preparations specifically for RNA viral genomes. RNA genomes can be extracted from virus particles in much the way that DNA viral genomes are extracted. RNA genomes are converted to complementary (cDNA) sequences using retroviral RT. Storage is of greater concern for naked viral RNAs. Storage of RNA usually requires temperatures below –20°.

## Detection of Viral Genome Versus Viral Transcripts

Viral genomes exist as either DNA or RNA, or sometimes both: in the case of retroviruses the integrated genome is DNA, whereas the encapsidated form is RNA. The ability to differentiate among the various forms of viral nucleic acids can help to elucidate the course of specific viral infections. Assays for nucleic acid activity can differentiate readily between integrated and encapsidated genomes when the form of the viral nucleic acid varies between states, as in the case of retroviruses. Incorporation of specific nucleases into the assay methodology can be used to reduce or eliminate one form over the other. If viral genomes are known to integrate at specific sites within the host genome, primers and probes can be developed around the integration site and incorporate significant elements of both host and viral genomes. Some viral mRNAs contain splice sites, and the differentiation of spliced nucleic acid sequences from unspliced sequences creates a unique mechanism for determining the status of nucleic acid localization and infection.

### CHARACTERIZATION OF DNA VIRAL GENOMES

Methods for the recovery and preparation of viral genomes for characterization depend on the state of the viral genome. If the genome has been incorporated into a cellular compartment, the recovery and preparation strategy must take into account the cellular components that make up the sample matrix. If the viral genome targeted for analysis is the encapsidated form, the methods must focus on recovery of the virus particle and must include additional steps aimed at extracting the nucleic acid from the individual particles. Identification and characterization of viral genomes require specific complementary nucleic acid probes and primers whose sequence will be dictated by available information about the sequence of the targeted viral nucleic acids and the type of assay that will be used. Determination of the sequence of the viral nucleic acid of interest usually provides the most unambiguous means for characterization. However, a number of methods can be used as simple indicators for the presence or absence of specific sequence-based characteristics. For example, melting curve profiles using short oligonucleotide sequences can be used to establish whether a specific viral genotype is present.

### IDENTIFICATION AND GENOTYPE ANALYSIS

Nucleic acid testing is often used to identify viral isolates obtained from viral screening assays or to provide identity for viral stocks. Methods used for the identification of viral genomes are not unique to other applications in the field of molecular biology. Typically, an amplification step is required in order to achieve quantities for analysis. Amplified sequencing of the amplicons or application of a standard hybridization technique may be employed for more detail as to the nature of the amplified signal. For more details, refer to *Nucleic Acid-Based Techniques—Amplification* ⟨1127⟩.

### HYBRIDIZATION TECHNIQUES

A variety of hybridization techniques are used to detect viral nucleic acid sequences, including Southern blot, Northern blot, DNAse/RNase protection, in situ hybridization, microarray technology, and other techniques. The description of these methods, which is well beyond the scope of this chapter, can be found in *Nucleic Acid-Based Techniques—Extraction, Detection, and Sequencing* ⟨1126⟩.

# DETECTION OF ANTIBODIES TO VIRAL ANTIGENS

A variety of methods are available for detection and quantification of antibodies to viral agents, including neutralization, complement fixation, and immunoassays based on enzyme- or fluorescently labeled reagents. Although many details of the immunological methods mentioned above are beyond the scope of the chapter, this section addresses specific application aspects of viral antibody detection, including preparation and storage of test samples, common assay methods and platforms available, and specific examples of how these assays may be used to measure antibodies to specific viral agents.

## Viral Structure Relative to Antigenic Composition and Selection of Antibody Assay

Mammalian viruses vary considerably in their nucleic acid content and thus the number of antigenic, virus-specific proteins produced.

Many viral proteins or glycoproteins are highly antigenic and induce a potent humoral immune response during natural infection, whether in humans or in animal models. In most cases, the immune system responds when the virus and its antigens appear in the extracellular fluid or on the infected cell membranes. The degree to which viral antigens are expressed is governed by the intracellular replication and protein synthesis of viruses in host organ tissues and by the several possible types of virus–host cell interaction. Antibodies produced as a result of natural viral infection are likely to represent the broadest response to antigens in their native state.

When selecting, developing, or evaluating an assay method for measurement of antibodies to viral proteins, the analyst must take into account the source of the antibodies and the method by which they were obtained or prepared. Details will be presented in *Immunological Test Methods—Reagent Development* ⟨1103⟩ and *Immunological Test Methods—Immunoassay Methodologies* ⟨1104⟩.

## General Considerations Regarding Sample Preparation for Antibody Detection of Viral Antigens

Antibodies are relatively stable, but care must be taken to ensure the integrity of the test antibodies during sample preparation and storage. Serologic tests may be developed to measure antibodies to viral agents in unfractionated biological fluids. The possibility for matrix interference with the antibody detection method should be considered.

In general, biological test samples should be clarified by centrifugation or filtration, depending on their intended use. Serum samples should not be hemolyzed, lipemic, or icteric. In some cases the specimen should also be heat-treated to inactivate endogenous complement and other components.

Test samples should be processed as soon as possible. When it is necessary to store samples, most test samples should be stored at –20° for short-term storage and below –80° for long-term storage. For all samples, the stability of the material needs to be assessed experimentally. Aliquots of appropriate volume should be prepared in accordance with test procedures to avoid unnecessary freeze-thaw cycles.

## Antibody Methods

This section discusses the primary methods for detecting antibodies directed against viral antigens. The assay methods often include a variety of alternative formats for the detection of antibody. Only the more commonly used formats for antibody detection are discussed in this section. Some methods, including fluorescent antibody assays and enzyme immunoassays, are widely applicable to the detection of antibodies to many different viral agents; others are limited to selected viruses having certain properties (e.g., hemagglutinins).

### IMMUNOFLUORESCENCE MICROSCOPY FOR ANTIBODY DETECTION

When fluorescein isothiocyanate (FITC) is chemically coupled to an antibody molecule, the resulting *FITC-labeled antibody* can be used as a secondary antibody probe to detect the presence of a primary, virus-specific antibody bound to a virus-infected cell on a microscope slide (indirect immunofluorescence).

The indirect immunofluorescence or indirect fluorescent antibody (IFA) assay is one of the most basic and useful methods for detection of antibodies to viruses. The assay can be used to detect both virus-specific IgG- and IgM-class antibodies. When the assay is used to detect IgM antibodies, it usually requires the physical removal or inactivation/binding of IgG-class antibodies. In the absence of this step, the presence of IgM-specific antibody may be masked by excess IgG-specific antibody competing for primary binding sites on the substrate surface. IFA assays may be qualitative or quantitative.

The IFA for antibody to viral agents requires the use of virus-infected cells expressing viral antigens in cellular membranes. Viral stocks are prepared, titered, and used to infect permissive cells in tissue culture. The cells are harvested at appropriate times, washed, and spotted onto multiwell microscope slides at an appropriate density. Control slides are also prepared with noninfected cells. The slides are allowed to air-dry and then fixed in cold acetone. The fixed slides can then be stored under appropriate conditions for extended time periods. The stability of the viral antigens over time should be confirmed.

The test article to be examined for the presence of virus-specific antibodies can be applied to the slide, followed by an appropriate secondary antibody conjugated with a fluorescent tag that can be visualized under a fluorescent microscope. IgG- or IgM-specific antibodies can be distinguished by using the appropriately prepared secondary antibody.

Reading and correctly interpreting endpoints of IFA slides for antibody detection requires an experienced analyst, particularly when cellular location and fluorescent-staining patterns are critical for a specific virus. Such interpretation requires the use of appropriate controls and scoring or intensity of fluorescence. This is highly dependent on the quality of reagents, the consistency of the fluorescent microscopy and light source being used, and the experience of the analyst.

## ENZYME IMMUNOASSAY FOR ANTIBODY DETECTION

The EIA and variations of it are the most widely used methods for the detection of viral antibodies in serum and other biological products. The most commonly used EIA for antibody detection is referred to as a noncompetitive solid phase EIA for antibody detection. The typical configuration of an EIA for antibody involves coating tubes or microwell plates with viral antigen(s), the addition of test serum or product to the tubes or wells, the binding of specific antibody in serum or product to antigen, and the detection of bound antibody by addition of a second antibody with binding affinity to the primary antibody, which is labeled to allow for its detection.

The assays can be specific to IgG- or IgM- class antibody or may detect total antibody. Assays for IgM may achieve improved specificity when performed as *IgM-capture* assays. These assays involve the use of plates or wells coated with anti-IgM antibody to capture total IgM in serum or product as a first step. Subsequently, viral antigen is added; it binds to the plate only if virus-specific IgM antibody has initially been captured, and it is detected by addition of a second labeled antibody specific to viral antigen. The assay is most often performed as a qualitative measure of the presence of an antibody for a specific virus. Sufficient replicates of both positive and negative control samples are required in order to determine the appropriate cut-off value and the assay acceptance criteria. A mean value of a test sample equal to or greater than the cut-off value is considered positive.

## COMPLEMENT FIXATION TEST

Complement fixation has selective value in allowing for simultaneous assay of antibodies to a wide variety of viral agents. The procedure involves multiple variables consisting of two pairs of antigen–antibody reactions. The first reaction, between a known virus antigen and a specific antibody in the test sample, takes place in the presence of a predetermined amount of exogenous complement. The complement is removed by the antigen–antibody complex. The second antigen–antibody reaction consists of sheep red blood cells (SRBCs) and hemolysin (antibody against SRBC). When this indicator system is added to the reaction mixture, the sensitized SRBCs will lyse only in the presence of free complement. The extent of lysis of SRBCs is inversely correlated with the amount of the antibody in the test article.

The experimental procedure involves the optimal titration of concentrations of hemolytic serum, complement, and viral antigen, using chessboard format. If used as the test sample, human serum should be inactivated at 56° for 30 minutes to inactivate the endogenous complement activity. A number of important controls must be run along with the test, and results must be within limits before the test can be properly interpreted. These include the sensitivity of SRBCs to lysis and complement concentration used. The relative amount of virus-specific antibody present can be determined by testing serial dilutions of the serum or product. The *complement-fixing titer* is the reciprocal of the highest dilution that prevents 50% hemolysis.

## NEUTRALIZATION FOR ANTIBODY DETECTION

Neutralization for the measurement of antibodies to viral agents is still one of the most valuable assays available because of its high specificity and its ability to detect neutralizing antibodies. Neutralization is defined as the loss of viral infectivity through the binding of specific antibodies to viral coat proteins (or envelope glycoproteins) on the surface of the infectious viral particle. The assay may be used to measure the presence of antibodies to a known virus in a serum or product sample, or conversely to identify an unknown virus by using a serum or product sample containing known antibodies.

Before performing a neutralization assay to measure the presence of antibodies in serum or product, a known virus must first be grown and titrated in the test system in which the neutralization assay will be performed. For viruses prepared in cell culture, this usually involves inoculating susceptible cultures with relatively low multiplicity of infection (MOI; <1 PFU per cell) and harvesting the infected cells when about 50% to 75% cytopathic effect (CPE) is demonstrated. The virus preparation is then titrated by preparing serial multifold dilutions and inoculating replicate tubes or plate cultures with a fixed volume of the virus preparation. The endpoint of the titration is the dilution of the virus that will infect 50% of the cell cultures inoculated. This endpoint is said to contain one 50% tissue culture infective dose ($TCID_{50}$) in the volume used. If the test system involves animal lethality, the endpoint is referred as one 50% lethal dose ($LD_{50}$). The amount of virus used in the neutralization assay to follow is typically standardized to contain 100 $TCID_{50}$ or $LD_{50}$.

The test or host system used in neutralization assays is chosen on the basis of the specific virus to be tested and its ability to replicate in the system. The commonly used host systems include cell culture, embryonated chicken eggs, and mice. Cell culture is usually the preferred test system, because the viruses used in the neutralization assay usually readily replicate and produce CPE. Susceptible host cells are grown in monolayers in dishes or multiwell plate cultures. After the virus/neutralizing serum mixture is added, the cultures are overlaid with agar-containing medium to restrict spread of CPE and allow development of viral plaques. The prevention of plaque development is indicative of the presence of neutralizing antibody. Alternatively, neutralization can be performed in tube monolayer cultures or even in suspension tissue culture. Embryonated eggs may be used when the virus to be used or tested does not produce plaques in tissue culture systems. The route of inoculation and the endpoint depend on the virus.

Neutralization assays may be set up in various ways, depending on the specific virus of interest and the serum or product to be tested for neutralizing activity. In general, a fixed amount of infectious virus is preincubated with undiluted and serial dilutions of serum or product to be tested for neutralizing activity and separately with preimmune serum or control product; this approach is referred to as the *constant virus–varying serum* method. Following preincubation, the mixtures are separately injected or added to the test system. Reduction in infectivity between test and control serum or product is scored in various ways, depending on the test system. The endpoint of the assay is generally defined as the highest dilution of the serum or product that neutralizes one-half of the initial viral inoculum, as calculated by Reed-Muench or the Spearman-Kärber method.

The titer of neutralizing antibody in the test serum or product is the reciprocal of the highest dilution that completely inhibits CPE or other virus effect in the test system. This dilution is said to contain 1 neutralizing antibody unit per unit volume used in the titration. When a serum or product known to contain neutralizing antibody is used in an assay to determine the identity of

https://pharmacopeia.cn/

an unknown virus, 20 neutralizing antibody units in a fixed volume are generally used in the assay. Positive and negative control sera must give expected reactivity in the assay.

### HEMAGGLUTINATION INHIBITION (HAI)

A number of enveloped viruses, including the influenza and parainfluenza viruses, acquire protein receptors capable of binding RBCs (hemagglutinins) of various animal species on their surface as they bud through infected cell plasma membranes during viral maturation. In addition, some nonenveloped viruses such as adenoviruses and certain enteroviruses have hemagglutinin proteins in their outer capsid. This property allows for detection of a specific virus in a sample if a known specific antibody to the virus is available. Alternatively, the presence of antibody specific to the virus can be detected and quantitated by its ability to inhibit hemagglutination. This is the principle of the hemagglutination inhibition (HAI) test.

The HAI test for antibody is performed by making serial dilutions of the specimen to be tested and mixing the dilutions with a fixed amount of the virus or specific viral hemagglutinin protein in a tube or microtitration plate format. Indicator RBCs from the appropriate animal species are added, the suspension is mixed, and the tubes or plates are allowed to stand for a predetermined period. If specific antibody is present, the virus will bind and the RBCs will not agglutinate; they will settle to the bottom of the tube or plate and form an RBC "button". If specific antibody is absent, the RBCs will be agglutinated by the virus and form a diffuse film. The titer of the serum or product is the reciprocal of the dilution that completely inhibits agglutination.

HAI is very useful for subtyping influenza virus isolates. A number of factors contribute to the potential variability of the HAI test. Certain serum samples and products may contain nonspecific inhibitors of RBC agglutinins, which may yield false-positive results. A number of procedures have been developed to remove such inhibitors, including adsorption and heat inactivation procedures. Specimens may also contain RBC agglutinins other than specific antibody, and these may contribute to false-negative results. Appropriate preparation and titration of reagents, including RBCs and viral hemagglutinin stocks and suspensions, is critical. In addition, controls for nonspecific agglutination or inhibitors of agglutination must be included in every assay.

### WESTERN BLOT (OR IMMUNOBLOT) ASSAY FOR ANTIBODY DETECTION

The immunoblot, or Western blot, assay is a technique for the simultaneous detection of antibodies to various protein antigens of a given virus. The term *recombinant immunoblot assay* (RIBA) is applicable when the starting protein mixtures are recombinant proteins obtained from prokaryotic or eukaryotic expression systems instead of crude or partially purified virus from infected cells. The method is often used diagnostically as a supplementary or confirmatory test in situations where an initial assay for antibody lacks sufficient specificity or is known to be prone to false-positive results. This is especially important when the test is being used to diagnose an infection of clinical significance such as HIV or HCV infection.

A number of commercial immunoblot kits are available, particularly for viruses such as HIV and HCV; several have regulatory approval for diagnostic use. Alternatively, viral antigen preparations may be produced in-house or purchased, along with other reagents required for the assays. Careful control and/or sourcing of these reagents are critical to ensuring that compliance requirements are maintained.

For selected viral agents, there are generally accepted interpretive standards for the analysis of reactivity or positive results in an immunoblot assay. However, the presence of nonspecific bands may be due to antibody reactivity to cellular protein antigens caused by autoimmune diseases and/or the use of crude virus-infected cell proteins as antigen in the assay. Indeterminate reactions may also occur if only a limited number of specific antibody bands are observed.

Appropriate positive and negative control sera must be included in each assay and reactivity must be scored for both the presence and the intensity of expected protein bands.

### APPLICATION OF THE ANTIBODY DETECTION METHODS TO SPECIFIC VIRUSES

Human blood-borne pathogens that may be present in infectious form in human donated blood used directly in the production of biological products are a concern because they may present a risk of transmission to others. Testing for virus-specific antibodies in donated blood serves as a screening procedure for the elimination of suspect units. Alternatively, the viruses may represent important agents for which human vaccines have been or are being developed. Thus the ability to detect virus-specific antibodies in an immunized individual or animal model may be important for demonstrating the efficacy of the vaccine. Currently, in the United States, a number of FDA-approved screening or definitive tests may be conducted on donated units of blood for evidence of the presence of agents of infectious diseases, including hepatitis B and C viruses, human immunodeficiency virus, and West Nile virus. In addition, plasma sent for fractionation before production of plasma-derived products is required to be tested for hepatitis A virus (HAV) and human parvovirus B-19.

## GLOSSARY

**Acceptance Criteria:** Anticipated results, which may be numerical limits, ranges, or other characterization for the tests described. They establish the standards to which a drug substance or drug product should conform in order to be considered acceptable for its intended use.

**Adventitious Agent:** Acquired accidental contaminant in a cell line such as viruses and toxins; the agent is often infectious.

**Amplicon:** A segment of DNA generated by the PCR process whose sequence is defined by forward and reverse primers.

**Antibody:** An infection-fighting protein molecule that binds, neutralizes, and helps destroy foreign microorganisms or toxins. Also known as immunoglobulins, antibodies are produced by the immune system in response to antigens.

**Antigen:** Any agent that induces the production of an antibody and reacts specifically with it.

**Assay Validation:** A formal, archived demonstration of the analytical performance of an assay that provides justification for use of the assay for an intended purpose and a range of acceptable potency values.

**Bioassay:** Analytical method that uses living animals, cells, tissues, or organisms as test subjects.

**Biologics:** Products such as antitoxins, antivenins, blood, blood derivatives, immune serums, immunologic diagnostic aids, toxoids, vaccines, and related articles that are produced under license in accordance with the terms of the federal Public Health Service Act (58 Stat. 682) approved July 1, 1944, as amended, have long been known as "biologics." However, in Table III, Part F, of the Act, the term "biological products" is applied to the group of licensed products as a whole. For Pharmacopeial purposes, the term "biologics" refers to those products that must be licensed under the Act and comply with Food and Drug Regulations —Code of Federal Regulations, Title 21 Parts 600–680, pertaining to federal control of these products (other than certain diagnostic aids), as administered by the Center for Biologics Evaluation and Research or, in the case of the relevant diagnostic aids, by the Center for Devices and Radiological Health of the federal Food and Drug Administration. [Definition from *Biologics* ⟨1041⟩*, USP–NF* vol. 30 (2007), p. 414.]

**Biotechnology-Derived Product:** Macromolecular article derived from biotechnology processes such as recombinant DNA (rDNA) technology, hybridoma technology, and the like.

**Bulk Harvest:** See *Unprocessed Bulk Harvest.*

**Capsid:** The outer protein shell of a virus particle.

**Cell Bank:** A defined population of cells, such as an immortalized cell line, grown by a defined process and cryopreserved in a defined process and within a defined passage number range. The assumption is that each vial from a cell bank is comparable and that when thawed and added to a manufacturing vessel (or an analytical assay), it will perform in a consistent way.

**Chaotropic:** A reagent that causes molecular structure to be disrupted; in particular, those formed by noncovalent forces such as hydrogen bonding, van der Waals interactions, and the hydrophobic effect.

**Complement:** A group of proteins in the blood that work in concert with other immune system proteins and cells (such as antibodies) in attaching foreign substances.

**cDNA:** Complementary DNA. Two strands of nucleic acid that can hybridize by specific base pairing between the nucleotides.

**Confluency:** Refers to the point when 100% of the surface area of the vessel is covered in cells.

**Cryopreservative:** Reagent used to keep a cell alive in deep-frozen condition (usually in liquid nitrogen).

**Cytopathic:** Damaging to cells, causing them to exhibit signs of disease or cell death.

**ELISA:** Enzyme-linked immunosorbent assay. A biochemical technique used to detect the presence of an antibody or an antigen in a sample.

**Endpoint Assay:** An analytical method that measures the amount of accumulated product at the end of the assay.

**Epitope:** A molecular region on the surface of an antigen that is recognized by an antibody and can combine with the specific antibody produced by such a response; also called a determinant or an antigenic determinant.

**Glycoprotein:** Protein that contains sugar side chains added as a posttranslational process; the presence of sugar side chains often affects activity, antigenicity, and in vivo stability.

**Host Cell Tropism:** The range of susceptible cells that a particular microorganism can infect.

**ICH:** The International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use.

**Limit of Detection (LOD):** The lowest concentration of an analyte in a sample that can be detected, not quantitated. It is a limit test that specifies whether or not an analyte is above or below a certain value. It is expressed as a concentration at a specified signal-to-noise ratio, usually 2 or 3.

**Mycoplasma:** Parasitic microorganism that infects mammalian cells, possessing some characteristics of both bacteria and viruses. Prokaryotic microorganisms belong to the family *Mycoplasmataceae,* with no cell walls. They may grow attached or close to cell surfaces in the cytoplasm and subtly change the properties of the cells.

**Passage:** An operational procedure used to feed cultured cells, usually by providing fresh medium and dilution of cells in a new culture vessel. The number of such operations is referred to as the passage number. It is not the same as cell generation number, which is strictly related to cell doubling time.

**qPCR:** Quantitative polymerase chain reaction. A modification of the polymerase chain reaction used to measure the quantity of DNA, complementary DNA, or ribonucleic acid present in a sample. Like other forms of polymerase chain reaction, the process is used to amplify DNA samples via the enzyme DNA polymerase.

**Raw Materials:** All components used to manufacture a drug substance or drug product; regulated by 21 CFR 211.

**RT-PCR:** Reverse transcriptase polymerase chain reaction. A variation of the PCR technique in which cDNA is made from RNA via reverse transcription. The cDNA is then amplified using standard PCR protocols.

**Serotype:** The kind of microorganism as characterized by testing for recognizable antigens on the surface of cells of the microorganism.

**Spiking:** Adding a known amount of analyte from a laboratory standard acting as a tracer to check a method for recovery or accuracy.

**Syncytium:** A multinucleated mass of cytoplasm that is not separated into individual cells.

**System Suitability:** The checking of a system to ensure system performance before or during the analysis of unknowns. Parameters such as plate count, tailing factors, resolution, and reproducibility are determined and compared against the specifications set for the method. These parameters are measured during the analysis of a system suitability *sample,* which is a mixture of main components and expected by-products.

**$TCID_{50}$:** 50% tissue culture infective dose. The level of dilution of a virus at which half of a series of laboratory wells contain active, growing virus.

**Unprocessed Bulk Harvest:** The pooled harvests of cell culture fluids that constitute a homogeneous mixture for manufacture into a unique lot of product.

## INTRODUCTION

An overview of vaccines for human use is presented in *Vaccines for Human Use—General Considerations* ⟨1235⟩, ▲which includes a glossary of terms.▲ (USP 1-May-2021) Bacterial vaccines can be derived from whole cells, either killed or attenuated in their ability to cause disease, or from some component(s) of the intact cell that is important for virulence or damage to the host ▲(see *Table 1* for examples). In some cases, the antigen may be recombinant and produced in a non-pathogenic organism.▲ (USP 1-May-2021) Another subset of bacterial vaccines, derived from toxins, is the toxoids. Bacterial vaccine products can be mixtures of components from different species, from different strains or different serotypes of the same species, or from different components from cells of the same species.

**▲Table 1. Bacterial Vaccines Currently Licensed in the US**

[a] See *Vaccines for Human Use—Polysaccharide and Glycoconjugate Vaccines* ⟨1234⟩ for further information.
[b] Frequently administered with other antigens in a combination vaccine.
[c] Currently there are no inactivated bacterial vaccines licensed in the US.

The simplest bacterial vaccines consist of the purified cell-surface capsular polysaccharides (CPS) from organisms such as *Salmonella enterica* serovar Typhi, various meningococcal serogroups, or pneumococcal serotypes that cause meningitis, otitis media, acute respiratory infections, and pneumonia. Although the typhoid vaccine consists of a single polysaccharide, the meningococcal vaccines contain as many as four serogroup-specific CPS, and the pneumococcal vaccine contains 23 serotypes.

The immunological response to meningococcal and pneumococcal polysaccharides, and to the CPS from *Haemophilus influenzae* type b (Hib), is improved by covalent attachment of the CPS or an oligosaccharide derived from it to a suitable carrier

@2024 USPC

protein, ▲often a bacterial toxoid or naturally occurring non-toxic mutant toxin.▲ (USP 1-May-2021) The immunological response to these glycoconjugate vaccines is elicited via immunologic pathways different from those induced by purified polysaccharides, creates a T-cell-dependent response, and establishes immunological memory. ▲These vaccines are highly effective in infants. Detailed information on polysaccharide and glycoconjugate vaccines is provided in *Vaccines for Human Use—Polysaccharide and Glycoconjugate Vaccines* ⟨1234⟩.▲ (USP 1-May-2021)

Many bacterial pathogens, including those that cause diphtheria and tetanus, produce toxins that kill tissue. Immunological neutralization of these toxins is sufficient to prevent disease. These subunit vaccines consist of chemically detoxified toxins (toxoids) purified from culture supernatant and are capable of eliciting neutralizing antibodies against the native toxin. ▲▲ (USP 1-May-2021)

Although earlier pertussis vaccines consisted of myriad chemically inactivated whole-cell and toxin components, current acellular products contain various combinations of specific purified proteins, sometimes toxoided (e.g., with fimbriae and other cell-surface protein components). Compared to older products, these vaccines apparently produce protection by a different mode of action but have a lower incidence of adverse events. A combination of diphtheria and tetanus toxoids and an acellular pertussis vaccine form the core components of many polyvalent pediatric and adult combination vaccines. Hib glycoconjugate, hepatitis B, and/or inactivated poliovirus immunogens may also be added to these vaccines. ▲No inactivated whole-cell bacterial vaccines are currently licensed in the US.

Another type of meningococcal bacterial subunit vaccine is based upon pathogen-derived lipid vesicles containing a wide range of immunogenic outer membrane proteins. These vaccines may also contain individually produced recombinant immunogens.▲ (USP 1-May-2021)

Live attenuated bacterial vaccines are currently limited to Bacillus Calmette–Guérin (BCG), which protects against tuberculosis when administered through the skin, and the *S. enterica* ser. Typhi Ty21a construct, which is an oral vaccine against typhoid fever.

The immune response against these ▲▲ (USP 1-May-2021) antigens can be increased by the inclusion of adjuvants. ▲Adjuvants included in▲ (USP 1-May-2021) licensed ▲bacterial vaccines▲ (USP 1-May-2021) in the US are based on aluminum salts such as aluminum hydroxide and aluminum phosphate, although the development and characterization of new adjuvants is an active area of research.

## RAW MATERIALS ▲AND MATERIALS OF ANIMAL ORIGIN▲ (USP 1-MAY-2021)

Raw materials can directly affect the identity, strength, purity, and quality of bacterial vaccines. ▲To achieve▲ (USP 1-May-2021) a consistent manufacturing process, it is critical to use consistent raw materials (e.g., during seed banking, fermentation, harvest, and purification). ▲▲ (USP 1-May-2021) Raw materials for bacterial growth media typically consist of both well-defined chemical entities (e.g., amino acids, carbohydrates, vitamins, minerals) and more complex components (e.g., protein hydrolysates, yeast extracts, peptones). ▲Expectations for the sourcing, quality, and control of raw materials are highlighted in ⟨1235⟩ and in *Cell Banking* ⟨1042⟩.▲ (USP 1-May-2021)

***Change to read:***

## CELL BANKS

### Source and History

▲The development, characterization, stability testing, and storage of master cell banks (MCBs) and working cell banks (WCBs) is a unit operation and is described in detail in ⟨1042⟩.▲ (USP 1-May-2021)The source should generate a sufficient ▲quantity▲ (USP 1-May-2021) of antigen(s) to meet the medical need.▲▲ (USP 1-May-2021) For microbial expression systems such as *E. coli*, ▲▲ (USP 1-May-2021) the manufacturer should describe the method used to prepare the DNA coding for the protein, including the cell and origin of the source nucleic acid.

▲▲ (USP 1-May-2021) The steps in the assembly of the expression construct must be described in detail. This description should include the source and function of the component parts of the expression construct (e.g., origins of replication, antibiotic resistance genes, promoters, enhancers, and whether the protein is synthesized as a fusion protein). Manufacturers should provide restriction endonuclease digestion maps that illustrate the sites used in preparing the expression construct and sites used in the identification of DNA fragments.

A complete nucleotide sequence analysis of the expression construct's coding region for the protein of interest should be performed. The sequence analysis should be provided and should include a complete annotation designating all of the important sequence features. The copy number and physical state of the expression construct should be determined.

▲Requirements for defining and reporting the origins and genealogy of the cells used to construct the cell bank are provided in ⟨1042⟩.▲ (USP 1-May-2021)

### Cell Bank Manufacture

▲▲ (USP 1-May-2021)

For microbial expression systems, a single host cell that contains the expression construct is propagated to generate the MCB. Manufacturers should document the cell cloning history and method of transferring the expression construct into the host cell. They also should describe completely the methods and criteria used to amplify the expression construct and to select the cell clone for production. ▲See ⟨1042⟩ for further details.▲ (USP 1-May-2021)

https://pharmacopeia.cn/
Printed on: Fri Jan 05 2024 06:35:23 AM(EST)
Printed by: USP NF
Do Not Distribute
Status: Currently Official on 05-Jan-2024
Official Date: Official as of 01-May-2021
DOI Ref: 6uy7k
DocId: GUID-6055E5D4-81F2-44FD-97E7-FE9D1B07561D_2_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M2755_02_01
@2024 USPC

## Cell Bank Testing

▲▲ (USP 1-May-2021)

Additionally, for recombinant bacterial expression cell lines (e.g., *E. coli*), molecular characterization testing can include DNA sequencing of the target gene sequence along with the flanking regions, expression construct retention, and plasmid copy number. Analysis of the expression construct at the nucleic acid level should be performed with consideration that this verifies only the coding sequence of a recombinant gene. Restriction endonuclease mapping or other suitable techniques should be used to analyze the expression construct for insertions or deletions and for the number of integration sites. For extra-chromosomal expression systems, the percent of host cells that retain the expression construct should be determined under selected and nonselected growth conditions. For cells with chromosomal copies of the expression construct, the nucleotide sequence encoding the product could be verified by recloning and sequencing of chromosomal copies.

▲▲ (USP 1-May-2021)

Characteristics of the recombinant protein product can also be applied (see below) as another means of defining the ultimate output of the cell line.

▲▲ (USP 1-May-2021) If a new MCB is to be generated by expression construct transfer into host cells followed by clonal selection, then acceptance criteria for both the new clone and the protein produced by the clone should be described and justified.

▲Requirements for validation, testing, storage, and stability assessment of the cell banks are provided in ⟨1042⟩.▲ (USP 1-May-2021)

***Change to read:***

## ▲PROPAGATION AND HARVEST▲ (USP 1-MAY-2021)

Production of the drug substance for a bacterial vaccine requires a fermentation process that is consistent and is ▲sufficient▲ (USP 1-May-2021) to support commercial production. The approach to achieving this has become fairly standardized and provides a relatively high probability of success for early batch production to support a development program. It is still a significant challenge to achieve sufficient productivity to support commercial manufacture of a licensed product. Directly after any fermentation process is the harvest process, which serves as a transition step between biomass expansion and downstream process steps. For the purposes of this chapter, harvest will be considered as an extension of the fermentation process.

### Fermentation Starting Materials: Cell Inoculum

The cell inoculum for the fermentation process is the single most important component for establishing a reproducible fermentation process. In early development before finalizing the fermentation conditions, manufacturers typically must generate an interim source of this inoculum, a process development cell bank (PDCB). The origin of the PDCB should be a clonal isolate of the original transfected or isolated strain that demonstrates suitable growth properties and produces the antigen of interest in sufficient quantity and quality for the intended purpose. The use of a clonal isolate ensures that the genetic starting point for each batch is the same and that subtle variations in process conditions will not inadvertently allow one population versus another to dominate the culture. That is, the PDCB is used for fermentation development to ensure that variations in the fermentation conditions can be interpreted without the overlay of competition between populations of transfectants.

Initial development of the fermentation process, preferably with the PDCB, typically precedes production of the MCB and WCB. Best practice is to derive these cell banks from the same clonal isolate as the PDCB to reduce the need for a second cycle of fermentation development when the WCB is deployed. Substitution of a WCB for the PDCB at the final stages of fermentation development is common practice, but care must be taken to constrain such experiments to optimization of the fermentation process. More detail is found in *Cell Banks* above.

### Fermentation Hardware

The biomass production process typically begins with a small-volume inoculum in an initial fermentation volume that is 20- to 100-fold larger than the initial inoculum volume. This initial passage is often followed by one or more intermediate fermentations that expand the production volume by 20- to 100-fold at each step until the production fermentation volume (typically 500–3000 L) is reached. Routine manufacture at these scales requires well-controlled fermentation conditions and physical facilities that meet the economic and current good manufacturing practices (cGMP) ▲requirements▲ (USP 1-May-2021) for a successful product.

Bacterial fermentations have traditionally been carried out in glass, glass-lined, or passivated stainless steel fermenters that comply with cGMP requirements, particularly when using large fermenters (e.g., those with >1000 L working volume) because of containment issues with such large volumes of liquid. Traditional fermentation systems require hard-piped control systems that meet the need for clean-in-place and steam-in-place capability. The bioburden and complexity of the facility will increase if the fermentation operations must also accommodate multiple product lines.

Smaller fermentation batches are increasingly performed in disposable bioreactors such as single-use bags with completely disposable product contact surfaces, including sensors and probes. These systems are becoming readily available, are less expensive, and are more flexible than fixed equipment and they meet the needs of the competitive business and evolving cGMP expectations and requirements. A note of caution is warranted, however, because this disposable technology can lead to changes in the material of product contact surfaces. Such changes then require re-evaluation and sometimes revalidation of the manufacturing process for late-stage development and commercial products. Thus, the reduced cleaning burden may ▲be accompanied by▲ (USP 1-May-2021) an increased need for extractability and leachability studies.

## Harvest Hardware

Harvest of the fermentation product can focus on recovery of either the wet cell mass from which the product will be extracted or the fermentation broth from which the product will be directly purified. In the former case, centrifugal separation is typically employed. Production-scale centrifuges can be either closed operations with a fixed volume of input and manual recovery of the pellet, or continuous-flow operations that automatically eject and recover the clarified supernatant and/or the accumulated pellet. Although centrifuges are efficient in harvesting a fermentation product, shear forces can have significant effects on the product stream (e.g., lysed cells, sheared molecules in solution). Alternatively, and particularly when the product is secreted into the solution rather than retained in the cells, membrane filtration systems may be used to clarify the product stream for subsequent purification. Tangential-flow and depth filtration systems can be effective for recovering soluble product with less concern about shear forces.

In all cases, monitoring the processing of the fermentation output and solids removal from the liquid matrix can be a simple yet effective approach to monitor process consistency and comparability. Off-line tools such as HPLC, sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE), or Western blot analyses can track product integrity issues such as aggregation or proteolysis.

## Process Development

A productive, robust fermentation process is the result of careful consideration of a broad collection of variables, considered alone as well as in conjunction with product design and downstream processing. Fermentation process variables include chemical inputs (e.g., carbon sources, minerals, vitamins, trace elements, antifoam, and gases), physical inputs (e.g., temperature, mixing, and pH), and biological processes [e.g., nutrient utilization rates, metabolite levels, and inductors (quantity/type/addition duration)].

## Product Requirements

A critical consideration in process development is anticipating how much of the product will be needed. Too little product caused by operating at too small a scale imposes supply constraints and often post-licensure urgency to scale up the process. In contrast, too much product results in excess inventory, expiring lots, infrequent manufacturing, ▲▲(USP 1-May-2021) and generally poor economics. A clear market evaluation is needed before designing the manufacturing process or committing to a process for scale-up or -down.

## Process Design

If one has a reasonably defined production need and an initial estimate of product yield, it is possible to extrapolate the scale of the fermentation from the volume (yield), production frequency, and expected productivity. Commercial fermentation of bacterial cultures is routinely carried out in volumes as large as 3000 L, but larger volumes are also used. A few large lots per year can be advantageous for a very robust process but may be limited by downstream process capabilities and/or the stability of the fermentation product as a production intermediate. An additional consideration may be the difficulty in generating enough lots to ensure that the fermentation process is indeed robust. Failure of a large lot carries important financial and inventory risks.

A large number of lots can impose logistical problems if the turnaround time is too tight or the coordination of downstream events becomes too complex. The logistics include quality control testing, which depends on the number rather than the size of lots. Production that involves a large number of smaller lots can require blending of multiple intermediate lots in order to produce a final drug product lot. This can cause challenges if product-related problems occur and may entail root-cause investigations. In general, appropriate fermentation sizing results in a process that has a turnaround time of less than 1 week, that can be accommodated with one or a few purification runs, and that results in one to several fills of final product after each purification cycle.

## Early Development Considerations

During early development of a biological product, the most important fermentation considerations are an appropriate, well-defined MCB and a fermentation process that is reasonably productive, reproducible, and scalable. The fermentation process is often underestimated when one considers the physical, chemical, and biological control of the process as process volumes change by orders of magnitude.

The mechanics of the fermentation process are an important consideration. Fermentations are typically studied in shake flask experiments or even microscale reactors that can readily accommodate many experiments conducted in parallel. Although this is attractive for the initial identification of process conditions, the ultimate culture vessel should be a controlled fermenter where growth conditions can be controlled and monitored in a more rigorous and comprehensive manner. Manufacturers should begin work in small-scale fermenters as early as possible to ensure that robust, controlled experiments can be run to refine the initial fermentation conditions.

Fermentation harvest processes also should be scalable. Although it is possible to scale centrifugation conditions, it is a challenge to maintain equivalent centrifugal conditions, particularly in a flow-through mode. Filtration processes can usually be scaled more predictably, provided that the membrane manufacturer is anticipating the needs of the process development scientist.

When manufacturers define a process, they should evaluate its robustness by purposeful deviations such as changes in the sources of raw materials and the time and temperature limits of unit operations. Such evaluations better define the rationale

@2024 USPC

for setting process limits and for identifying which ▲parameters▲ (USP 1-May-2021) are most critical to the success of the manufacturing process.

## Process Monitoring

On the basis of early development process characterization data, manufacturers should be able to identify key analytical measures that, if applied to all lots, can either verify the correct progression of the process or serve as a sentinel to determine whether a specific batch is showing signs of deviation from the typical profile. In the absence of such data, an aberrant process may go unnoticed or may not be detected until testing of a process intermediate shows either an out-of-trend or out-of-specification result.

For a fermentation process, many critical variables (e.g., optical density, pH, and specific nutrient levels) can be measured online and in real time to potentially allow the intervention to bring a given process back into the normal range, or at least to identify the point in the process at which the deviation occurred. Such data can be valuable in identifying potential process improvements. Conversely, in the absence of such data, troubleshooting can be a challenging and protracted process.

## Scale-Up

Just as early development requires a focus on small-scale operations, scale-up becomes essential at some point to ensure that sufficiently large lots can be made to meet program needs. As these needs become increasingly complex, larger lots are essential to ensure that multiple experiments and observations can be tied to the same lot of product, which in turn is ▲essential▲ (USP 1-May-2021) to understanding critical process and product variables. If proper process engineering considerations were taken into account at the smaller production scale, scale-up can usually be done in 10-fold increments in volume with a reasonable expectation that significant process performance or product changes will not be seen. This approach may require adjustments at an intermediate scale if the initial fermentation was based on too small a volume or if the final production scale is very large. Again, process monitoring data can be very helpful in evaluating the success of the scaled-up process.

If clinical development studies are performed at less than full manufacturing scale, as they usually are, manufacturers will be obliged to relate the comparability of the process performance and the product characteristics at the different scales. Analytical data can be compelling, but in their absence or ▲when scale-related differences are present,▲ (USP 1-May-2021) manufacturers must demonstrate that these differences are not clinically significant. However, the use of comparability protocols for scale changes will ▲need▲ (USP 1-May-2021) to be approved by the local regulatory authority. ▲▲ (USP 1-May-2021) Analysts must take care to ▲separate▲ (USP 1-May-2021) differences caused by fermentation scale-up from changes caused by harvest or purification scale-up. One way to accomplish this is to compare process intermediates obtained, when possible, during the fermentation and harvest processes. As an example, online monitoring of fermentation conditions such as pH or glucose level can be used to demonstrate similarity during the time course of the fermentation. Similarly, measurements ▲obtained▲ (USP 1-May-2021) at the end of the fermentation process (e.g., final cell density, cell viability) and intermediate measurements during harvest (e.g., turbidity of clarified broth, wet cell mass in the pellet) provide useful information for evaluating the similarity or differences during scale-up.

# PURIFICATION

A general overview of purification for ▲▲ (USP 1-May-2021) vaccines is presented in ⟨1235⟩. In addition to a description of critical processing equipment, reagents, and processing steps, manufacturers should provide the rationale for the purification process. ▲▲ (USP 1-May-2021) As with the other processes, analysts should consider the source of all raw materials and ensure that they come from reliable vendors who adhere to cGMP and can ensure a long-term supply. The cGMPs will apply to late-stage clinical supplies and commercial materials. The removal of non-product-related impurities (e.g., processing reagents, endotoxins, contaminating cell proteins or nucleic acids, and other residual contaminants) should be verified.

The drug substance can be one of several types of compounds, e.g., polysaccharides (wild type or modified), proteins (wild type, mutant, toxoids, or recombinant), products of conjugation of polysaccharides and proteins, or products of conjugation of peptides and proteins.

To define and control purification processes for drug substances and drug products, the manufacturer should establish targets for process parameters and tolerances for all critical process steps including yields, activity, and purity to ensure the efficacy, safety, and consistency of the final product. Requirements for pooling, if applicable, should be established. The requirements and conditions for storage of intermediates, bulks, and final containers must be established by an official stability program. The use, reuse, regeneration, and cleaning of all drug product/drug substance contact equipment (e.g., filters, chromatographic columns and resins, tanks, and process lines) should be validated. In addition, extractable/leachable studies should be performed for all product contact equipment (e.g., disposable bag systems, chromatographic column resins, and process lines).

## Polysaccharide Purification

▲Methods for the purification and in-process control of the quality of polysaccharide antigens used as vaccines or for the manufacture of glycoconjugate vaccines are presented in ⟨1234⟩.▲ (USP 1-May-2021)

https://pharmacopeia.cn/

## Protein Purification

The classes of bacterial protein vaccines include toxoids, nontoxoid ▲antigens▲ (USP 1-May-2021) (e.g., pertussis antigens), engineered recombinant products, and naturally occurring ▲variants▲ (USP 1-May-2021) (e.g., CRM197) used as carrier proteins ▲in glycoconjugates.▲ (USP 1-May-2021)

### TOXOIDS

At the end of fermentation, the toxin-containing culture medium should be separated aseptically from the bacterial mass as soon as possible or placed in a cold room until separation can be effected. The toxin content, ▲expressed as limit of flocculation▲ (USP 1-May-2021) (Lf/mL), is checked using a flocculation assay with the appropriate antitoxin standard to monitor production consistency (the culture should contain NLT 40 Lf/mL). The toxin is purified first to remove any components that could cause adverse reactions in humans. A typical process includes depth filtration followed by 0.2-µm filtration to assist in the removal of cellular debris. Following preliminary purification, the toxin is then detoxified with formaldehyde or glutaraldehyde or any suitable chemical reagent by a method that avoids both destruction of the immunogenic potency of the toxoid and reversion of the toxoid to toxin, particularly upon exposure to heat. Some toxoids require a single addition of formaldehyde, but others can require multiple additions. Alternatively, the toxin could be detoxified and then purified or partially purified by depth filtration, detoxified by the addition of an appropriate aldehyde, filtered using 0.2-µm filtration, and then pooled. The pooled toxoid solution is further purified by clarification with activated carbon, followed by multiple ammonium sulfate precipitation steps that further fractionate and concentrate the toxoid. Typical additional purification steps include concentration, diafiltration, and/or chromatography. Purification before detoxification results in a purer product and can be advantageous if the toxoid is to be used as the protein component of a protein–carbohydrate conjugate (because copurifying high-molecular-weight glycans will be removed before detoxification).

During detoxification and purification, ▲testing must be performed to control and ensure the consistency of the purification process, including▲ (USP 1-May-2021) endotoxin testing according to *Bacterial Endotoxins Test* ⟨85⟩, ▲testing for▲ (USP 1-May-2021) formaldehyde and protein ▲content, and testing of the▲ (USP 1-May-2021) irreversibility ▲of toxoiding.▲ (USP 1-May-2021) If the material must be sterile, ▲the sterility test described in▲ (USP 1-May-2021) *Sterility Tests* ⟨71⟩ can be performed.

### PROTEINS/RECOMBINANT PROTEINS

Proteins used to make vaccines can be recombinant (in their native state or engineered to modify certain amino acids) or they can be naturally occurring ▲variants▲ (USP 1-May-2021) that have no wild-type activity but are capable of inducing the appropriate immune response. Proteins are harvested from the fermenter and are extracted (for example, by mechanical and chemical disruption) and then purified by suitable methods, typically consisting of filtration–concentration steps (e.g., ultrafiltration, tangential-flow filtration, diafiltration, centrifugation, selective precipitation, and even direct capture using expanded-bed chromatography or big-bead technologies). The enriched protein solution can be further purified using appropriate filtration and chromatographic steps. For all equipment that contact drug substances (e.g., chromatographic resins, membranes, disposable bag systems, or process lines), manufacturers should assess extractables and leachables. Analysts should determine the column resin life for all chromatographic systems used in the purification (including number of uses, reconditioning requirements, and storage conditions).

The type of chromatography used to purify proteins depends on the physical/chemical properties of the desired protein as well as those of other molecular entities in the harvest culture. As an example, $CRM_{197}$ can be purified using a multi-step chromatographic process: production material is first diafiltered and then separated by ion-exchange chromatography [diethylaminoethyl (DEAE-Sepharose)] in order to purify the target protein from other molecular entities present in the purification stream. The peak of interest is collected and ammonium sulfate is added, followed by 0.22-µm filtration to condition the material before loading on the hydrophobic-interaction chromatography column (phenyl-Sepharose) for purification of the target protein based on its surface hydrophobicity. The peak fraction is then diluted with Water for Injection and is separated onto a ceramic hydroxyapatite column to further purify the target protein based on its surface charge. The eluted peak is then buffer exchanged into the storage buffer by ultrafiltration/diafiltration using cross-flow membrane filtration, followed by 0.22-µm filtration to yield the sterile purified concentrate.

In-process control of protein purification includes monitoring specific protein content and critical process steps as well as monitoring the removal of unwanted fermentation and purification components. The pH is critical for ion-exchange chromatography, and therefore pH should be monitored. For steps designed to remove endotoxin, procedures in ⟨85⟩ are used to monitor column eluants. Bioburden is monitored according to *Microbial Enumeration Tests* ⟨61⟩ after filtration and chromatography steps. If the material must be sterile, the sterility test in ⟨71⟩ should be performed.

### POLYSACCHARIDE–PROTEIN CONJUGATES

▲An overview of the production, purification, and in-process testing of glycoconjugate vaccines is presented in ⟨1234⟩.▲ (USP 1-May-2021)

***Change to read:***

## INTERMEDIATES

An intermediate or process intermediate in vaccine manufacture is the reaction product of each step in the process except the last one, which forms the final product. Examples of intermediates are bulk-purified polysaccharides, proteins, and activated polysaccharides that conjugate to protein.

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M2755_02_01
@2024 USPC

Most vaccine production processes are stepwise and take more than one elementary step to complete. An intermediate is produced from raw materials at one or more process steps (e.g., bacterial growth, extraction and purification, and▲/or▲ (USP 1-May-2021) chemical modification), eventually resulting in the drug substance. The identification of the key intermediates, their production, and sampling for analytical tests must be defined in controlled documents (e.g., batch records, analytical protocols).

Intermediates, which can ▲sometimes▲ (USP 1-May-2021) be stored for considerable periods of time before further processing, ▲must▲ (USP 1-May-2021) be included in a formal stability program. ▲▲ (USP 1-May-2021) Stability studies in normal or accelerated conditions should be performed to define the maximal hold time for intermediates and ▲also should be performed▲ (USP 1-May-2021) when significant process changes are implemented.

From raw material to finished drug substance, testing throughout the process ensures a quality product. Testing of intermediates is a key quality control step to ensure their identity and purity. The quality attributes of the intermediate are commonly tested in conjunction with further processing, and their release testing should be considered. Standard operating procedures (SOPs) must be properly defined for the analytical control tests. Because of their critical role in the production process, some key intermediates could be included in formal release testing, in addition to the intermediates identified for in-process testing.

▲▲ (USP 1-May-2021)

Examples of tests for the structural characterization and purity estimation of protein-based intermediates include the following:

- Identity and molecular size [(SDS–PAGE), Western blot, size-exclusion chromatography–ultraviolet (SEC–UV), SEC–fluorescence, size-exclusion chromatography–multi-angle laser light scattering (SEC-MALLS), reversed-phase chromatography]
- Endotoxin content (see ⟨85⟩)
- Residual nucleic acids (colorimetric assay; see *Nucleic Acid-Based Techniques—Approaches for Detecting Trace Nucleic Acids (Residual DNA Testing)* ⟨1130⟩)
- Bioburden (total viable aerobic count of microbial contamination; see ⟨61⟩)
- Other proteins as impurities (SDS–PAGE, Western blot, SEC–UV, SEC–fluorescence, reversed-phase chromatography)

The tests previously ▲described▲ (USP 1-May-2021) for protein-based intermediates are also applicable when the protein-based product is defined as the drug substance. In addition to the examples above, many other methodologies can be applied for the identity and purity evaluation. ▲Appropriate tests for saccharide and glycoconjugate intermediates are discussed in ⟨1234⟩.▲ (USP 1-May-2021)

Stability tests for intermediates can include physicochemical methods (see *Intermediates* above), which are formally included within an analytical panel for the stability study. In addition, biological and immunochemical tests [e.g., enzyme-linked immunosorbent assay (ELISA)] can be included. Bioburden and endotoxin testing may not be required at each level (each intermediate, drug substance) provided that testing is performed at a sufficient number of steps in the overall production process. Bioburden is typically performed prior to sterile filtration via in-process testing. If intermediates must be stored and/or subsequently shipped to a different location for further processing, the stability of these materials must be demonstrated.

***Change to read:***

## ▲FILTERED BULK▲ (USP 1-MAY-2021) (DRUG SUBSTANCE)

▲The final step in the manufacturing of antigen drug substance is the preparation of filtered bulk or drug substance.▲ (USP 1-May-2021)

The drug substance is the final product of the antigen manufacturing process, before the formulation of the final vaccine dosage. The final bulk may be prepared aseptically or may include a sterilization step. Sampling for analytical tests for release and stability studies ▲▲ (USP 1-May-2021) must be defined in controlled documents (e.g., batch records, analytical protocols).

A drug substance can be stored ▲▲ (USP 1-May-2021) before further processing, but if it is stored the drug substance must be included in a formal stability program. ▲▲ (USP 1-May-2021) Stability studies in normal or accelerated conditions should be performed to define maximal hold times. A stability program is required for formal stability studies, and the studies must be executed according to a protocol that contains detailed information about the types of tests, specifications, ▲storage conditions,▲ (USP 1-May-2021) testing intervals, and time points.

Testing of the drug substance must be performed to ensure its identity and purity. All testing must be done according to established SOPs, and all tests must have specifications (or provisional specifications, where applicable).

▲Many▲ (USP 1-May-2021) methodologies can be applied for identity and purity evaluation. For instance, the specific impurities that must be measured are determined based on negotiations between manufacturers and the national drug regulatory agency during the licensure process. Bioburden and endotoxin testing may not be required at each level (each intermediate, drug substance) provided that testing is performed at sufficient steps in the overall production process. Bioburden is typically performed prior to sterile filtration via in-process testing.

All of the results must be reported in a controlled document. Stability tests can include both physicochemical methods (see stability information, above) and biological/immunochemical tests (e.g., ELISA and serum bactericidal activity; see *Quality of Biotechnological Products: Stability Testing of Biotechnological/Biological Products* ⟨1049⟩).

## DRUG PRODUCT AND LOT RELEASE

General principles are described in ⟨1235⟩, which outlines the lot release procedure in accordance with 21 Code of Federal Regulations (CFR) §610.1 and 21 CFR §610.2. For products that will be used in the US, samples and protocols containing all appropriate tests must be submitted to the FDA for review and/or testing. If the FDA determines that the lot meets the standards of safety, purity, and potency required for the particular vaccine, the ▲manufacturer distributes and markets the product.▲ (USP 1-May-2021)

Tests required for each lot-release protocol include potency, general safety, sterility, purity, identity, and constituent materials. Potency and potency-related tests are different for each bacterial vaccine. The inclusion of these tests makes each bacterial vaccine lot-release protocol unique.

The contents of a final container of each filling of each lot are tested for identity after labeling is completed. Identity is established based on either physical or chemical characteristics of the vaccine, inspection by macroscopic or microscopic methods, specific culture tests, or in vivo or in vitro immunological tests. In large part, identity testing is performed to distinguish the vaccine from other materials that are manufactured at the same site (21 CFR §610.14). The same tests that establish identity may also be appropriate for defining the quantity of immunogen present in the final vial. This is especially important for carbohydrate-based vaccines that are dosed by mass and for which physicochemical measures of antigen quality are used.

Immunochemical methods, which include immunoprecipitation methods and immunoelectrophoretic methods, have been useful. Immunoprecipitation methods, such as flocculation and precipitation, can be carried out in solution or in a gel matrix and involve mixing the antigen with an appropriate antibody, leading to the formation of flocculating or precipitating aggregates that can be detected visually or by light scattering (▲e.g.,▲ (USP 1-May-2021) nephelometry). The ratio of reactants must be varied to optimize the detected response. In solution this can be achieved by titrating one reactant with the other, and increased sensitivity can be obtained by using antigen- or antibody-coated particles (e.g., latex) as reactants. In gel systems, a gradient is created as one or more of the reactants diffuse, creating a visible line where precipitation occurs. Immunoelectrophoresis (IE) is a qualitative technique that combines two methods: gel electrophoresis followed by immunodiffusion. Crossed IE is a modification of the IE method that is suitable both for qualitative and quantitative analysis. Visualization and characterization of immunoprecipitation lines can be performed using selective or nonselective stains, fluorescence, enzyme or isotope labeling, or other relevant techniques. Selective staining methods are usually performed to characterize nonprotein substances in the precipitates. In translucent gels, such as agar or agarose, the precipitation line becomes clearly visible in the gel provided that the concentration of each of the reactants is appropriate.

Where multiple active components are present as a result of copurification (e.g., certain acellular pertussis vaccines), the manufacturer must demonstrate that the composition of the product is consistent between batches, unless this has been validated during the development of the manufacturing process.

▲For toxoid vaccines or toxoid carriers in glycoconjugate vaccines,▲ (USP 1-May-2021) manufacturers should demonstrate that reversion to toxicity has not occurred (and will not occur over the shelf life) for a product derived from or containing a toxoid material, unless the contrary has been validated. This may require the use of a cell line or an in vivo test, although enzymatic approaches are being validated.

An antigenic purity test is an assay that assesses the ▲quality▲ (USP 1-May-2021) of antigen and is used for diphtheria and tetanus toxoid vaccines. The antigen content is determined by a flocculation assay ▲and is typically expressed in Lf/mg.▲ (USP 1-May-2021)

The manufacturer should prove a high and consistent level of immunogen adsorption to any solid-phase adjuvant (such as aluminum phosphate or aluminum hydroxide) that is consistent with the release specification.

For certain vaccines such as the anthrax vaccine and toxoid vaccines, the manufacturer is required to demonstrate that the vaccine is protective against disease or death in animal models challenged with a predefined dose of the target pathogen. This generally requires definition of the animal model, route of administration, vaccine dilutions required, a means to observe effects, and a reference vaccine against which effects are compared. The data should be analyzed appropriately (see *Analysis of Biological Assays* ⟨1034⟩).

Stability-indicating assays are those used to determine the stability of the product. Of primary importance is the potency assay, although glycan degradation may be important ▲when evaluating▲ (USP 1-May-2021) glycoconjugate vaccines.

### Other Vaccine Components and Vaccine Properties

Aluminum compounds are the primary adjuvants used in vaccines in the US. Chapter ⟨1235⟩ provides provisions of 21 CFR §610.15 governing the use of aluminum and amounts allowed. The adjuvants widely used in bacterial vaccines include aluminum potassium sulfate (alum), aluminum phosphate, aluminum hydroxide, and combinations of these compounds. Bacterial vaccines formulated with such adjuvants are referred to as adsorbed vaccines, and this term may be included in the official name of the vaccine. Other adjuvant systems may be evaluated. Aluminum is quantitated using colorimetry, titrimetry, emission or atomic absorption spectroscopy, or inductively coupled plasma–mass spectrometry.

For regulations regarding residual manufacturing reagents, see the FDA's 1999 *Guidance for Industry: Content and Format of Chemistry, Manufacturing, and Controls Information and Establishment Description Information for a Vaccine or Related Product*. Manufacturing reagents such as formaldehyde and glutaraldehyde are sometimes used in inactivation, the toxoid-making processes, or elsewhere during manufacture and may be present in residual amounts in the final product. Limits for formaldehyde and other residuals must be minimized in accordance with the approved product license.

Common preservatives used in bacterial vaccines include thimerosal, phenol, 2-phenoxyethanol, and benzalkonium chloride. 21 CFR §610.15 provides additional information about the minimization of thimerosal content and the production of thimerosal-free vaccines. Limits and content specifications are set for each bacterial vaccine in the product license.

Each lot of final containers of a vaccine intended for use by injection is tested for bacterial endotoxins ▲(when required),▲ (USP 1-May-2021) as indicated in ⟨85⟩.

Each lot of final containers of a vaccine intended for use by injection may be tested for pyrogenic substances as indicated in *Pyrogen Test* ⟨151⟩ and 21 CFR §610.14.

Each lot of dried product ▲must▲ (USP 1-May-2021) be tested for residual moisture [see *Loss on Drying* ⟨731⟩ and FDA's *Guideline for the Determination of Residual Moisture in Dried Biological Products* (January 1990)]. Residual moisture should be determined for lyophilized vaccines.

▲In some cases, a▲ (USP 1-May-2021) general safety test is performed on biological products intended for administration to humans with the purpose of detecting extraneous toxic contaminants. Procedures and exceptions are specified in 21 CFR §610.11.

▲Excipients, preservatives, diluents, and adjuvants are tested to meet generally accepted standards of purity and quality per 21 CFR §610.16 and/or applicable guidance documents at an appropriate stage of manufacture.▲ (USP 1-May-2021)

The sterility of each lot of each product is ▲evaluated▲ (USP 1-May-2021) according to procedures described in ⟨71⟩ and 21 CFR §610.12 for both bulk and final container material.

▲Information on retention samples, record keeping, storage conditions, and expiry dates, as well as guidelines for the package insert, is included in ⟨1235⟩.▲ (USP 1-May-2021)

***Delete the following:***

## ▲OTHER REQUIREMENTS

Retention samples are held by the manufacturer for at least six months after the expiration date. Enough material of each lot of each product is held for examination and testing for safety and potency (see 21 CFR 600.13).

Records are maintained concurrently with each step in the manufacture and distribution of product such that at any time successive steps of manufacture and distribution may be traced (see 21 CFR 600.12).

For storage conditions, see 21 CFR 610.50 and 53.

For shelf life/expiry date, see 21 CFR 610.50 and 53.▲ (USP 1-May-2021)

## INTRODUCTION

Vaccines for the prevention of at least 15 human viral diseases have been commercialized in the United States (see *Table 1*); others have been licensed outside the US. Together, these vaccines have formed a primary public health measure for the prevention of these viral diseases worldwide. For the purposes of this chapter, a viral vaccine is a vaccine that prevents a viral disease; this includes products derived from cultured viruses and those derived from recombinant expression of viral antigens. General considerations for both viral and bacterial vaccines are provided in *Vaccines for Human Use—General Considerations* ⟨1235⟩.

| | • Hepatitis B<br>• Human papillomavirus bivalent (types 16 and 18)<br>• Human papillomavirus quadrivalent (types 6, 11, 16, and 18)<br>• Human papillomavirus 9-valent (types 6, 11, 16, 18, 31, 33, 42, 52, and 58) |
| | **Nonreplicating Viral Vaccines** |
| | • Human papillomavirus 9-valent (types 6, 11, 16, 18, 31, 33, 42, 52, and 58) |

[a] Typically referred to as inactivated.

## General Categories of Viral Vaccines

There are currently two general categories of viral vaccines that have received regulatory approval: 1) live and attenuated and 2) nonreplicating. The nonreplicating viral vaccines contain three subgroups: virus-derived (killed/inactivated), split/subunit vaccines, and virus-like particles (VLP). Other strategies, including DNA and RNA-based vaccines, are under development. The characteristics, advantages, and challenges of viral vaccines are listed in *Table 2*.

**Table 2. Characteristics, Advantages, and Challenges of Viral Vaccines**

| Live and Attenuated Viral Vaccines | | |
|---|---|---|
| **Characteristics** | **Advantages** | **Challenges** |
| • Able to replicate in the host<br>• Attenuated in pathogenicity | • May elicit broader immune responses than other vaccine types (i.e., both humoral and cellular)<br>• May require fewer doses<br>• Highly effective<br>• Protection is generally longer lasting | • Limited understanding of mechanism of action and stability of attenuation<br>• Ensuring stability<br>• Characterization<br>• Manufacturing<br>• Possible transmission to another person via "shedding"<br>• Controlling reactogenicity |
| **Nonreplicating, Subunit, and Recombinant VLP Viral Vaccines** | | |
| **Characteristics** | **Advantages** | **Challenges** |
| • Unable to replicate in the host<br>• Not pathogenic<br>• Elicit mostly humoral immune responses | • Cannot multiply or revert to pathogenicity<br>• Generally less reactogenic<br>• Not transmissible to another person<br>• More stable than live viral vaccines | • Ensuring sufficient immunogenic potency<br>• May require adjuvant to enhance immune responses<br>• Stimulating cell-mediated immune responses<br>• Variable efficacy |

### LIVE AND ATTENUATED VIRAL VACCINES

Live viral vaccines contain live viruses or live viruses that have been attenuated (weakened) to reduce or eliminate their virulence (i.e., their ability to cause disease). Attenuation results from reassortment or from mutations induced by the passage of the virus in embryonated eggs, tissue culture using semi-permissive or atypical animal cells, or under altered growth conditions (e.g., at temperatures lower than the host's body temperature), or a combination of these mechanisms. Alternatively, live viral vaccines can be produced using recombinant technology. Attenuated vaccine strains are still immunogenic and replicate at a reduced rate compared to the wild type strain in their original host. The development of live viral vaccines is not standardized and the passage and propagation history varies between different vaccine viruses. Viruses for this group of vaccines are grown in human (e.g., MRC-5, WI-38) and non-human (e.g., primary chick embryo cells, Vero cells) cells, and do not undergo an inactivation step in their manufacturing process. Therefore, contamination by extraneous viruses and other adventitious agents already present in these substrates or introduced during manufacturing (e.g., raw material contamination) is a potential risk. This contamination risk requires a control strategy for manufacturing and testing that ensures vaccine purity, quality, and safety. Some live viral vaccines (e.g., yellow fever or live influenza) are produced using specific pathogen-free (SPF)

Official

https://pharmacopeia.cn/v-download/

eggs. These eggs are produced by chicken flocks that are regularly screened for avian pathogens (e.g., avian leukosis virus) and are maintained using appropriate animal husbandry practices.

### NONREPLICATING VIRAL VACCINES

**Inactivated or killed viral vaccines:** Inactivated (or killed) viral vaccines are produced by culturing and isolating the virus and then killing it chemically or with heat. The goal is to destroy the viruses' replicative function while keeping the outer virion coat intact. Nonreplicating viral vaccines may or may not be purified after harvest and before inactivation. Although many such vaccines have been successful in controlling viral diseases, not all viral proteins are equally immunogenic, and an unbalanced presentation (greater number of less immunogenic proteins) can dampen the immune response to protective antigens. Modification of the primary protective antigens can induce atypical immune responses that may enhance disease upon natural infection. This phenomenon was observed for formalin-inactivated measles virus and respiratory syncytial virus in early vaccines developed in the 1960s. Because of this experience, the use of attenuated measles vaccines is now recommended.
**Subunit or split virus vaccines:** Subunit vaccines are composed of viral gene products, which may be extracted from a cultured virus or produced via recombinant technology, e.g., in insect cell lines using baculoviruses. Traditional inactivated influenza A and B vaccine components are grown in embryonated eggs; and antigens of interest [e.g. hemagglutinin (HA) and neuraminidase (NA)] are purified following membrane solubilization (splitting). Recombinant HA antigens can be produced using the baculovirus expression vector system (BEVS), leveraging the natural infection process of insect cells by baculoviruses. For example, in one such vaccine, r-hemagglutinin proteins are produced in a continuous insect cell line derived from Sf9 cells of the fall armyworm, *Spodoptera frugiperda* (related to moths, caterpillars, and butterflies).
**Recombinant virus-like particle vaccines:** VLP vaccines, in which recombinant viral antigens are assembled (or self-assembled) into particles or are incorporated into a lipid vesicle, have been developed for human papillomavirus (HPV) and hepatitis B vaccines. The most common recombinant platforms are yeast (*Saccharomyces cerevisiae* for hepatitis B) and insect cell lines (*Spodoptera frugiperda* or *Trichoplusia ni* for HPV). Although they are more immunogenic than the monomeric antigen, some currently manufactured VLP vaccines based on recombinant protein technology require the addition of adjuvants [e.g., aluminum salts, monophosphoryl lipid A (MPLA), squalene emulsions] to optimize immunogenicity. These vaccines have similar advantages and challenges to nonreplicating viral vaccines.

## RAW MATERIALS AND MATERIALS OF ANIMAL ORIGIN

General guidelines for viral vaccines are found in ⟨1235⟩.

Culture ingredients must be selected carefully, especially for enveloped viruses since many of these can only be partially purified before losing infectivity or antigenicity. In such cases, the suitability of raw material for human administration can be a key criterion. A formal risk analysis of all raw materials should be performed to assess any risk of low-level contamination by unwanted entities. Media components for cell culture of viral vaccines (both during isolation and subsequent culture) need to be documented in detail. Chemically defined media without materials of animal origin are preferred. The cell culture medium should be suitable for the cells used in production. If human albumin is used, it must be licensed by the FDA for use in vaccines. The final product should be within specified limits of residual medium components such as serum, antibiotics, selection agents, or reagents added for growth enhancement. In the case of recombinant technology-based viral vaccines, fermentation media may consist of materials like proteins, sugars, inorganic trace elements, amino acids, and vitamins needed for cell growth. The protein component may be as simple as free casein (milk protein), or it can be as complex as extracts from bacterial, plant, or animal sources. The composition of a medium is often customized to optimize product quality attributes. Medium components that are known to cause allergic reactions should be avoided (e.g., eggs, gelatin).

For animal-derived raw materials it is particularly important to guard against the entry of adventitious agents into the process. Many vaccine viruses cannot be separated from environmental contaminants, and therefore prevention of environmental contaminant entry is required to ensure the safety of the product during the manufacturing operation. Animal raw materials are controlled in several ways. The origin of the herd(s) or flock(s) used is documented, controlled or isolated, and monitored to ensure the absence of disease. The material is harvested from the animals under controlled conditions using standardized, documented practices designed for pharmaceutical use to avoid contamination of the raw material with other viruses or microbes. The material is processed and stored accordingly and is often treated to destroy or remove any microbes that may have been introduced from the source or during processing (e.g., by sterile filtration, UV or gamma irradiation, detergents, heat, or a combination thereof). If additives from animal sources are added to the culture medium, they should be carefully sourced and certified to be free from contaminants and adventitious agents such as those that cause bovine spongiform encephalopathy or transmissible spongiform encephalopathy. To ensure an appropriate level of product safety, quantitative risk analysis with careful documentation should be performed on all factors that impact viral safety. For specific guidance on bovine serum quality attributes, sourcing, and testing, see *Bovine Serum* ⟨1024⟩ and *Fetal Bovine Serum—Quality Attributes and Functionality Tests* ⟨90⟩.

## EGGS AND PRIMARY CELL LINES USED IN VIRAL VACCINE PRODUCTION

The embryonated chicken egg is a highly productive growth substrate for certain viruses, such as those used to make vaccines for yellow fever and several influenza vaccines. In the case of influenza vaccines, the vaccine virus is harvested from egg allantoic fluid. In the case of yellow fever vaccine, the vaccine virus is harvested from embryo tissues. Therefore, residual egg or embryo components are special considerations in vaccine purification.

Egg-based vaccine production, like all biomass expansions, requires care and quality control of the virus seed lots and egg substrates to avoid contamination with other organisms. For example, chicken flocks used to prepare chicken embryo cells undergo extensive serological testing for adventitious agents before the flock can be used to prepare the cells. For vaccines

https://nhathuocngocanh.com/

produced in embryonated eggs the eggs may be either SPF (for viral seed production) or may be from healthy flocks (for vaccine production) monitored using methods approved by local animal health authorities.

Appropriate records must be retained for documentation [21 CFR 610.18(d)].

### Maintenance of Flocks

For in ovo cultured vaccines, eggs are derived from isolated healthy flocks of birds that are established for several generations and tested to ensure absence of common transmissible pathogens. Potential contaminants of the avian flocks (including those that infect nonhuman species) are routinely tested for and monitored. Flock origin and husbandry, isolation and management practices, health history, and testing should be documented clearly.

### Handling of Eggs

The number of eggs used for vaccine production varies according to the validated process in the manufacturers' license. Upon arrival at the facility, the eggs are first candled for egg selection and held up to light to view the embryo to determine its viability and lack of contamination. The eggs are then sanitized and injected with the vaccine virus of interest, which is allowed to propagate until harvest. Embryo age, candling procedures, sanitization methods, and injection and incubation methods are all critical manipulations performed under cGMP.

### Primary Avian Embryo Cell Lines

For vaccines produced in primary avian embryo cells, the practices described above should be followed and described up to the step of sanitization. Embryo retrieval, tissue dissection, and dissociation methods before in vitro culture should be conducted under highly controlled environmental conditions and with reagents of appropriate quality. The methods and raw materials used should be described. For these cultures, a substantial portion of cells is held aside uninfected for several weeks after the virus culture has been completed to ensure detection of any slow-growing microbes or viral agents. These uninfected control cell cultures are propagated and handled following the same process used for the virus-inoculated cells to help ensure that the cells used for vaccine production are free of adventitious agents.

### Primary Cell Lines from Other Animal Sources

Primary cell cultures from tissues can be cultured in vitro and used for vaccine production. Animals used to generate the primary cells or cell bank must be screened for potential viruses or have their serum tested to detect specific antibodies (see *Virology Test Methods* ⟨1237⟩ for specific guidance). Use of controlled colonies, herds, or flocks is recommended to monitor for specific pathogens. The use of primary cells requires additional testing from each manufacturing run to ensure the absence of contamination by infectious agents. To support the reduction of animal use, diploid and continuous cell lines are recommended. Continuous cell lines can be characterized extensively (including tumorigenicity testing, if required), and the culture conditions can be optimized and standardized. The Cell Banking system will provide production consistency. Continuous cell lines that express endogenous virus should be tested with tests capable of detecting such agents (see FDA Guidance for Industry-Characterization of Cell Substrates and Other Biological Materials Used in the Production of Viral Vaccines for Infectious Disease Indications and ICH Q5A).

Human diploid cells are used in the manufacturing process of several vaccines. The two most commonly used diploid cell lines, MRC-5 and WI-38, are derived from human embryonic cells and have the normal diploid number of human chromosomes. They are widely used to manufacture vaccines because they have been shown to have no tumorigenic or oncogenic potential and have been shown to be susceptible to a wide range of human viruses. However, unlike continuous cell lines that can be passaged indefinitely, human diploid cell lines can only be passaged a limited number of times, after which they experience a rapid decline in their ability to proliferate. This issue is managed by freezing multiple aliquots of master and working cell banks.

## CELL BANKS AND SEED LOT SYSTEMS

To produce vaccines in cell culture, two seed bank systems are required: one for the cell substrates and another for the viral seed lots. General information on the development, characterization, testing, and production of mammalian and bacterial cell banks and the related documentation requirements is provided in *Cell Banking* ⟨1042⟩ and ⟨1235⟩. Routine testing for master cell bank (MCB), working cell bank (WCB), control cells, and end of production cells (EOPC) is presented in *Table 3* below. A risk assessment for adventitious agents testing should be performed to determine if additional tests are needed (see note below *Table 3*). In cases where recombinant technology is used to develop the seed, the applicable guidance for information that should be supplied regarding the characterization and expression of such recombinant vectors can be found in *Quality of Biotechnological Products: Analysis of the Expression Construct in Cells Used for Production of r-DNA Derived Protein Products* ⟨1048⟩. Stability of cell-line viability under cryopreservative storage conditions must be demonstrated using real-time testing; see *Cryopreservation of Cells* ⟨1044⟩ for guidance on cryopreservation of cell lines.

### Viral Seed Lots

New master viral seed preparations are established under current good manufacturing practices (cGMP) conditions in a manner that is similar to the preparation of the cell banking process, as described in ⟨1235⟩ and ⟨1042⟩. The derivation and passage history of viral seeds (including the sourcing of all biological materials used: plasmids, animal-sourced raw materials, donor isolate and strain) are recorded in detail [21 Code of Federal Regulations (CFR) §610.18, *Cultures*]. Any manipulation of

@2024 USPC

the viral phenotype (e.g., cold adaptation, development of temperature sensitivity, or attenuation of virulence) or intentional genetic manipulations (e.g., reassortment or recombination) should be documented (*e.g.* viral sequence level).

Viral seeds are commonly differentiated into a master viral seed and working viral seeds or working viral stock. Manufacturers should assess the following characteristics of the viral seed stock (characteristics assessed will depend on type of seed stock/ production process *i.e.* egg or cell line):

- Growth characteristics on the intended production cell substrate
- Tissue tropism
- Genetic markers
- Identity (for recombinant vectors)
- Viability during storage
- Genetic stability through production
- Attenuation properties
- Purity
- Microbial contamination

Absence of adventitious agents; if attenuation or derivation is achieved by passage through different species, the viral seed should be assessed for absence of adventitious agents also common to those species as well as for adventitious agents for the species in raw materials used.

The master viral seed should be extensively characterized to demonstrate the stability of the relevant genotype to a passage level comparable to a production batch. Cultures from the working seed lot should have the same relevant characteristics as the master seed lot from which they are derived. For influenza vaccines, which may be reformulated with new virus antigens each year, certified seed lots can be obtained from national regulatory agencies. A working seed lot is derived from the master seed within a limited number of passages. The working seed is tested to ensure its purity, freedom from adventitious agents based on viral risk assessment, and appropriate biochemical properties. The working seed is used for vaccine production without intervening passages. Reagents used for viral seed processing must be of appropriate quality.

Tests should be performed for identity (e.g., sequencing the entire virus or a portion of it), adventitious agents, viral phenotype, genetic stability, and, agents that might be present in the seed as a result of its passage history if applicable. Viral phenotype can be further assessed for tissue tropism, attenuation properties, and temperature sensitivity. Not all of these tests may be necessary for every viral seed strain.

Tests for identity, microbial contamination, mycoplasma, and adventitious agents should be performed based on established compendial and regulatory requirements (regulatory requirements vary and may be different outside the US). Depending on past treatments of the virus isolate (raw materials, agents, and biological reagents that the seed was in contact with), specific tests for additional adventitious agents that could potentially be present must also be carried out on the master viral seed preparation based on a risk analysis approach. The master viral seed bank is used to produce a working viral seed bank. The subsequent testing of the working viral seed preparation is dependent on the extent of testing carried out on the master seed, as well as the process and raw materials used to produce the working viral seed preparation. In the case of live and attenuated viral vaccines, the following tests should be included either on master or working viral seed:

- Safety test (microbial contamination, mycoplasma, mycobacteria)
- Whole genome sequencing
- Phenotypic, genotypic or any other attenuation test
- Genetic stability of seed virus
- Neurovirulence test (if virus is neurotropic, e.g., monkey neurovirulence test for yellow fever virus)

[NOTE—Assessment of neurovirulence should be performed if the virus is known to be neurotropic. Manufacturers should consult with regulators about appropriate animal models, methods, and scoring systems for this assessment before they initiate such studies. For viruses that are neurovirulent or may revert to neurovirulence (e.g., polioviruses), it may be necessary to assess neurovirulence beyond the master seed.]

## Cell Culture

In some cases, the viral seeds may have a broad host range and therefore may require neutralization of the vaccine virus before they are tested for adventitious agent(s). The neutralization procedure must be demonstrated to not interfere with detection of adventitious agents. If possible, testing for adventitious agents should be done without neutralization to avoid an antiserum that may inadvertently neutralize an adventitious agent present in the seed.

A strategy for testing adventitious agents in viral vaccines must be developed based on a risk assessment following the principles of viral contamination risk. This strategy includes a full range of suitable tests able to detect different families of adventitious agents that may infect the source of virus strains including cell substrates and raw material of animal or plant origin. The capacity of the manufacturing process to remove or inactivate viruses is evaluated as part of the risk assessment. The list of tests must be adapted depending on the extraneous agents that have the potential to contaminate the product: for in vitro tests, the risk assessment may allow, with the agreement of the competent authority, the use of other permissive cell lines or molecular biology methods depending on the manufacturing process and the incubation temperature for the growth of particular viruses. If in vivo tests are more relevant than in vitro tests for the detection of some adventitious viruses (e.g. suckling mice for the vesicular stomatitis virus and fertilized SPF eggs for the influenza virus) the decision to maintain or to introduce such in vivo assays in a testing strategy must be justified by the risk assessment.

New, sensitive molecular methods with broad detection capabilities are available. These new approaches include high-throughput sequencing (HTS) methods, nucleic acid amplification techniques (NAT) (e.g. polymerase chain reaction (PCR), reverse transcriptase PCR (RT-PCR), product-enhanced reverse transcriptase (PERT) assays) for whole virus families or random-priming methods (associated or not with sequencing), hybridization to oligonucleotide arrays, and mass spectrometry with broad-spectrum PCR. These methods may be used either as an alternative to in vivo tests and specific NAT or as a supplement/alternative to in vitro culture tests based on the risk assessment and with the agreement of the competent authority.

If the master viral seed is well characterized, the working viral seed may not require extensive characterization. For example, it may not be necessary to repeat testing for all the relevant viruses from the derivation history.

## Seed Storage

To ensure consistent production of the viral vaccine product, a well-defined storage system is required. Viral seeds should be stored at temperatures to maintain their stability (i.e. in liquid nitrogen or ultra-low temperature freezers) and in more than one location within a facility or at a distant site (if possible) to decrease risk of loss in case of a catastrophic event. Manipulation

@2024 USPC

of all vials must be controlled and documented to ensure the consistency of viral seed stock inventory. Viral seeds are stored under validated temperatures that support their stability.

A strategy to demonstrate the stability of the master and working viral seed preparations under the frozen storage conditions should be established, preferentially using real-time testing. Virus replication (infectious titer) can be determined during routine production. Trending the infectivity titer will alert the manufacturer to any stability issues and the need to produce a new working viral seed preparation. The master viral seed preparation should also be monitored in real time during the preparation of a new working viral seed. In the event that the master viral seed is not required for an extended period of time, a stability protocol with defined testing intervals should be implemented. If the infectious titers of the working viral seed are not decreasing, and the viral seed was produced and stored in a manner similar to the master viral seed preparation, stability of the master viral seed preparation may be inferred, and its testing may be reduced to conserve the supply.

### Recombinant Cell Lines

To date, the production of recombinant viral antigens has used yeast and insect cell lines. The requirements, as for any other recombinant expression system, are outlined in ⟨1235⟩. For cell lines containing exogenously assembled expression constructs (recombinant cell lines), characterization of nucleotide and amino acid sequences should be performed. Extensive characterization of cell banks should use the most relevant qualified technology. Chapters ⟨1042⟩ and ⟨1048⟩ provide advice on the characterization of the engineered cell line and expression construct.

## PROPAGATION AND HARVEST

Manufacturing of live and inactivated viral vaccines using eukaryotic cell culture is a two-phase production process. The first phase is the expansion of the cell cultures used as a substrate for viral replication. The second phase includes the initial virus infection and subsequent replication and virus production. Note that production of nonreplicating, recombinant viral antigens in yeast or insect cell lines does not involve infection of the growing cell and the requirements for these vaccines are essentially the same as the requirements for other recombinant proteins, described in the relevant compendial guidance for recombinant protein products.

## CELL SUBSTRATE GROWTH PHASE

The cell substrate expansion process for viral production is the phase designed to prepare the cells in an appropriate physiological state to sustain virus growth. Cell substrates often require complex animal-derived supplements such as serum. The source and testing requirements of bovine serum are subject to regulatory requirements (also see ⟨1024⟩).

## VIRUS PRODUCTION PHASE

Relatively few cell types have been used as substrates in US-licensed viral vaccines. Vaccine manufacturers have optimized nutrient requirements, growth factors, and serum concentration to support robust growth and strong virus productivity for these cell lines.

### In Ovo Cultivation

The embryonated chicken egg is a highly productive growth substrate for certain viruses, such as those used to make vaccines for yellow fever and several influenza vaccines. The culture of viruses in ovo is fairly straightforward. In the case of yellow fever vaccine, the vaccine virus is harvested from embryo tissues. In the case of influenza vaccines, the vaccine virus is harvested from egg allantoic fluid. Egg-based vaccine production, like all biomass expansions, requires care and quality control of the viral seed lots and egg substrates to avoid contamination with other organisms. Flock genetics, nutrition, and age can all affect in ovo virus propagation, as can egg sanitization procedures that may compromise the allantoic membrane cells. Optimization of the parameters should be documented to control the viral production process. Common egg culture variables include: egg age, amount of virus inoculated per egg, mode of inoculation, and harvest timing. Depending on the virus strain, the incubation temperature can also be critical. These factors have to be optimized for each individual serotype and master/working seed (for influenza viruses in particular), and the impact of all these factors should be investigated and documented.

### Establishment of Primary Cell Cultures

Procedures for recovery of primary cells should be described from organ recovery through dispersed cell suspension, with attention paid to the reproducibility of the cell substrate's properties in culture. This analysis may involve subsequent growth reproducibility, or if minimal growth is involved, it should be aimed at reproducibility of metabolism and viral receptivity and productivity. In cases where whole organism harvest is involved (e.g., whole avian embryo dissociation), only a fraction of the resulting cells may be susceptible to viral infection. Other cells from the harvest provide a supporting matrix and other factors and can potentially inhibit virus replication. Preferably, modern analytical methods would be used to characterize the spectrum of cells harvested. Under conditions suitable for viral replication, little or no cell growth is expected.

Official

https://pharmacopeia.cn/v29240/

## Cell Culture

Culture for live virus vaccine production generally consists of two phases: a cell growth phase and a virus production phase. These processes are often complicated due to the diversity of cell types and their general dependence on a surface for growth. Virus properties—including replication cycle speed, yield of virus from the cells, and stability of infectious virus or antigen under culture conditions—also exert major influences on process technology, configuration, and operation in the manufacturing setting. Reproducibility of the cell processing steps is critical, and therefore good documentation of each manipulation ensures consistency of key parameters for product manufacturing. The virus culture process begins with the establishment of a receptive cell mass of sufficient size to produce a batch, which is typically about $10^5$–$10^6$ doses of vaccine. Generally, about $10^6$–$10^8$ cells are cryopreserved in one or more aliquots, whereas about $10^8$–$10^{12}$ cells may be required for a production batch. Historically, processes have also used secondary or tertiary cultures, in which primary tissues are grown for several cell divisions to either increase the biomass size and batch size, or to minimize the amount of primary tissue required per batch, or both.

Recovery of cells from cryopreservation involves thawing the cells and diluting out the cryoprotective (banking) medium such that maximum cell viability is preserved and reproducible cell growth is ensured. Practices should be documented and justified on the basis of development experiments; typical parameters investigated are thaw rates and temperatures, dilution rates, and dilution factors. A protocol must be devised that results in reproducible cell numbers in a state conducive to virus production. This requires passaging the cells and providing a larger surface area for growth for attachment-dependent cells. Cell expansion output:input ratios for a passage are typically 2:1–20:1, depending on the cell type and growth medium. In certain contexts, cells require a minimum threshold concentration to provide each other with growth factors, and this requirement may reduce the passage ratio. Other cell types, or media that provide these growth factors, can allow much lower inocula and larger ratios.

Two typical objectives for expansion passaging reproducibility are: 1) ensuring that cells experience a minimal “lag phase” (sometimes caused by the need for sufficient production and accumulation of growth factors and cellular attachment factors) and 2) ensuring that cells do not grow to the point of stagnation/death (often caused by nutrient exhaustion, or by crowding on the surface that causes “contact inhibition” of growth). Either of these issues can lead to a lag phase in the next passage. Early cell expansion is usually performed in a separate production area to avoid the potential for cross-contamination. The earliest, small-volume passages are often conducted in open laboratory vessels (e.g., flasks, roller bottles). However, it is highly desirable to use closed containers to facilitate aseptic handling of containers and to minimize or eliminate operator exposure risk. Control of the environment and aseptic handling practices are written into the procedures for use during development and are maintained during manufacturing.

The final cell expansion is typically an integral part of virus production, with goals of achieving the final biomass required for production and producing cells that are highly productive for virus. In batch or fed-batch cultures, a “cell density effect” may exist, whereby growth to higher cell concentrations correlates with lower virus productivity on a per-cell basis. This can be caused by many factors and should be characterized to ensure that the process operates in a robust and predictable manner.

## Virus Culture

The final cell expansion and virus culture are typically a biphasic process in which the cells are grown in the final production vessel(s) and then are inoculated with virus. The viral inoculation often coincides with medium replacement or addition, as well as alteration of other culture parameters such as temperature. If cells are grown in a serum-containing medium, the medium for viral production is usually switched to a serum-free medium to minimize serum carryover into the harvest. If the virus is secreted into the medium and cannot be purified rigorously after harvest, extensive washing may be required to reduce residual serum to acceptable levels (see 21 CFR §610.15, *Constituent materials*). Documentation of washing effectiveness should be developed. Replacement of serum may be required for maximal virus yield, and this may entail the addition of other protein sources such as albumin, transferrin, or insulin.

Virus infection results are known to be sensitive to cell concentration; time of harvest; future cell substrate growth trajectory at the point of infection; and the “multiplicity of infection” (MOI), which is the number of infectious virus particles inoculated per cell. These factors, with the duration of viral culture, affect the quantities of infectious virus and total virus and can govern the quality of a vaccine via the ratio of infectious to total virus, the genetic stability, coupled with the degradation products that may have reduced immunogenicity. In addition to assessing titers over the duration of infection, it is useful to characterize virus stability under culture conditions with cell-free culture broth samples, because this can inform whether titer changes are due to changes in synthesis or degradation. High MOIs that occur over repeated passages are generally undesirable, especially for RNA viruses, because of the propagation of defective genomes that are trans-complemented by co-infection of a cell by another viral genome. Genetic stability of the vaccine virus should be well characterized. During development, the infection parameters need extensive characterization against all of the key quality attributes for the vaccine to ensure a robust process; thus, these parameters should be described.

Virus disposition upon replication is a significant determinant of the infection process configuration. Enveloped viruses are typically 1) secreted into the culture medium as they acquire their lipid envelope at the cell membrane or 2) fusing as secretory vesicles with the plasma membrane. For non-lytic viruses, multiple batch-wise harvests of the culture supernatant are common and re-feeding the culture upon harvest can promote higher yields. Perfusion processes are not used often because of product dilution and the difficulty, as well as added expense, of downstream concentration. For lytic viruses, destruction of the cells allows only for a single harvest; depending on the time elapsed from infection to lysis, feeding of the culture may maximize yields. Other viruses remain intracellular or cell associated, and processes for these may allow for extensive feeding to accumulate virus product. If the cell integrity is not compromised, washing to remove undesirable medium constituents may be performed at the end of the culture.

Many parameters of the culture environment also affect virus growth and stability, and it is expected that all relevant process parameters will be controlled to meet product quality expectations, as well as their acceptable ranges (“operating space”) as defined in the International Council for Harmonisation (ICH)’s *Q8(R2) Pharmaceutical development*. It is important to note that there is biological variability in cell growth, virus–host cell interactions are not well defined, and the analytics for potency and

DOI: https://doi.org/10.31003/USPNF_M2756_02_01

other parameters are highly variable and should be defined. Consequently, despite efforts to characterize viral vaccines and their processes, it is not uncommon to experience root mean square variances of 50%–100% in process output, even for a well-controlled process, unlike some other biological medicines.

## Control Cells During Production

Control cells are recommended for use when it is not feasible to directly test cells or product at various production stages. Control cells are tested for adventitious agents. For vaccines produced in cell cultures (e.g., live, attenuated, nonreplicating, and recombinant vaccines manufactured in insect cell lines), control cells may be evaluated for the presence of adventitious agents in conjunction with product testing using the same tests that are performed on the production culture and at the same time as a similar test would be performed on a manufactured product.

The national regulatory authority guidance-recommended volume of cell suspension used for seeding vaccine production culture should be used for the preparation of control cells. For static cell culture (using flask, roller bottle, cell stacks, or cell factory), the World Health Organization guideline recommends using a fraction equivalent to at least 5% of the total or 500 mL of cell suspension, or 100 million cells to prepare uninfected control cell cultures. For large scale production using a bioreactor, the volume of control cells should be as agreed with regulatory authority. The control cell culture should be treated similar to the production cell culture except the control is not infected with the vaccine virus under production; otherwise, the control cell culture should be maintained in conditions that are equivalent to those used for production culture, including the same batches of media and media changes, etc. The control cell should be incubated under the same condition of the production cell culture for 14 days or until the last virus harvest from production culture, whichever happens later. The control cells should be tested for identity and observed for cytopathic and morphological changes during this incubation period. For the test to be valid, at least 80% of control cells should not show any cytopathic or morphological changes during the observation period. Control cells should be tested for hemadsorbing viruses at the end of the observation period or at the time of viral harvest (whichever occurs later). At least 25% of the control cells are tested. If red blood cells to perform hemadsorption were stored, storage should be at 2°–8° and should not exceed 7 days. Calcium and magnesium ions should be absent from the medium for hemadsorption testing. The control cell culture supernatant should be tested for extraneous agents based on risk assessment aligned with the analytical testing strategy. For testing other extraneous agents, indicator cell lines (cell lines from simian origin and from human origin; production cell of a different batch if production cell is not of simian or human origin) should be inoculated with a control cell supernatant and incubated under the same conditions of the production cell culture for a period of 14 days. If any cytopathic changes due to extraneous agents occur in any of the cultures, the virus harvest produced from the batches of cells from which the control cells were taken should be discarded.

If avian tissues are used for propagation of a vaccine virus, avian leucosis virus (ALV) tests should be carried out using control cell culture supernatant. This testing may be carried out directly on the cell substrate. In some cases, detailed documentation of the health of a specific pathogen free flock may be sufficient to ensure absence of ALV.

For live attenuated vaccines that are produced in eggs, a risk-based control strategy for extraneous agents should be used. For example, control eggs may be tested for extraneous viruses. A portion of uninoculated embryonated eggs from the same batch of eggs used for vaccine production should be incubated under the same condition as those maintained for production and for the same incubation period. Allantoic fluid from control eggs should be checked for hemagglutinating agents and extraneous agents e.g., ALVs.

## Culture Process Technologies and Facility

Because of safety concerns regarding the use of tumorigenic cell types, the cells used for viral vaccine culture are almost uniformly dependent on an attachment surface for growth, with few anchorage-independent exceptions (e.g., Madin–Darby canine kidney cells for influenza). The attachment requirement creates a need to supply not only soluble nutrients but also an attachment surface for the common cell types (e.g., MRC-5 and Vero). Given the large variability in virus yields and production volumes, surface area requirements can differ substantially. This has created a situation in which a variety of technologies are used for cultivation. For small-scale operations, simple adaptation of laboratory vessels may suffice, and scale-up consists of scale-out (i.e., increasing the number of vessels). Beyond a certain point, aseptic risk precludes further scale-out. Intermediate scales of culture involve the use of specialized culture vessels, along with robotics where scale-out strategies are still used. Many of these technologies use disposable vessels and reactors with a focus on: 1) minimizing the risk of contamination and 2) the compatibility of product contact surfaces with the cells and virus. An extractable and leachable assessment should be performed for each disposable system of novel components used (see *The Biocompatibility of Materials Used in Drug Containers, Medical Devices, and Implants* ⟨1031⟩).

Large-scale production is performed in engineered bioreactor systems that use agitation technology similar to the technology for bacterial vaccines and other biologicals. In the most common reactors using agitation, attachment-dependent cells use "microcarrier" technology, which consists of small beads of about 150-µm in diameter that are easily suspended by agitation and provide a very large surface area in a given volume of culture. Other configurations with packed or static beads are also used for these systems. The vessels used can be made of either disposable plastics or stainless steel. Compatibility of the material with the medium and the cells, and the non-impact of leaching, should be evaluated for either type of vessel, as well as for fittings and probes used in monitoring and controlling the cultures. For nondisposable equipment, cleaning and sterilization procedures must be established, validated, and well documented. For reactors with loose or suspended carriers, the carriers should be readily excluded from the product stream and should not shed pieces or chemicals that are not suitable for human administration.

For all systems, the environment should be designed appropriately, reflecting the need for aseptic manipulations if they are required for either culturing or bioreactor set-up. In addition, the potential for spills or breakage and the risk of operator exposure need to be taken into account, especially when culturing wild-type virus strains. In a multi-product facility, changeover procedures that minimize the potential for cross-contamination and validation of inactivation should be established and

documented. Operator training and facility management procedures must be established for handling cultures and avoiding contamination of the product, the facility, and the operators themselves.

## PURIFICATION

A general overview of purification of vaccines is presented in ⟨1235⟩. Special considerations are observed depending on the types of vaccines and production system used, as discussed below.

For live, attenuated, and nonreplicating virus vaccines, the desired antigen is a virus entity that is amplified from a working viral seed, in a complex biological substrate, and generally with minimal downstream processing to prepare the drug substance. Although nonreplicating viral vaccines also require viral seed expansion, virus inactivation and purification are more complex to ensure complete removal of infectious virus, removal of inactivating agents, and maintenance of the desired antigenic properties. Many factors should be considered in developing a downstream purification strategy, with the understanding that all processing steps will result in some loss of viable virus. Downstream processing steps are designed to: 1) remove or reduce cellular debris (e.g., host cell protein and DNA) from the vaccine harvest; 2) remove impurities or reduce their levels; 3) concentrate the virus; 4) add a virus stabilizer; and 5) remove or reduce potential microbial contamination from the virus preparation to meet a specified level of adventitious agent removal by filtration. The ability to do this may be limited in the case of live virus vaccines.

If a continuous cell line (e.g., Vero) is used for vaccine production, a validated filtration step is necessary to separate the virus from intact cells. The quantity and size of any residual host cell DNA should also be determined (see *Nucleic Acid-Based Techniques—Approaches for Detecting Trace Nucleic Acids (Residual DNA Testing)* ⟨1130⟩). Currently, NMT 10 ng of host cell DNA is permitted per dose of a parenterally administered vaccine, and regulatory agencies continue to consider the level of risk posed by host cell DNA for vaccines that are administered by other routes (e.g., nasal or oral) on a case-by-case basis. Multiple purification methods to reduce the size and amount of residual host cell DNA present in the vaccine are desirable and include steps such as treatment with DNase, diafiltration, ultrafiltration, and column chromatography.

### Viral Inactivation

Because of the pathogenic nature of the viruses (e.g., hepatitis A, Japanese encephalitis, rabies, and poliomyelitis), many viral antigens must be inactivated while maintaining their antigenic properties. Inactivation may involve the use of chemicals, detergents and surfactants, or irradiation, or various combinations thereof. Removal or reduction of the inactivating chemicals, detergents, and surfactants from the antigen to acceptable levels may be achieved by centrifugation, chromatography, ultrafiltration, diafiltration, or combinations of the above. The viral inactivation process should be optimized, validated, and well-documented. Inactivation is confirmed by carrying out a test for residual infectious viral particles on each lot.

### Live, Attenuated, and Nonreplicating Viral Vaccines

To preserve the infectivity and antigenic integrity of the vaccine viruses while removing egg-derived components, relatively simple, mild methods (e.g., zonal sucrose gradient centrifugation and diafiltration) are used for vaccine virus concentration, purification, and buffer exchange. After removal of cellular debris, further purification can be accomplished by using zonal centrifugation on a density gradient or by using column chromatography. Nucleic acid in Vero cell-produced vaccines can be reduced by treatment with suitable endonucleases, and removed by ultrafiltration using a 50-kDa membrane or by ion-exchange chromatography. The resulting drug product may be stabilized via cryoprotectant or lyophilization formulation (e.g., combinations of materials such as sucrose, phosphate, glutamate, and processed gelatin as stabilizers), filtration (using a filter of 0.22-µm pore size), for low bioburden bulk, and may be stored frozen at a temperature validated to support stability.

Some viruses may be heat labile, e.g., varicella virus, therefore precaution should be taken throughout manufacturing and distribution to maintain viral viability.

Viruses for nonreplicating vaccines can be produced using non-SPF eggs because of required chemical inactivation steps in the manufacturing process. Because the vaccine virus needs to be retained intact while removing egg-derived components and inactivating chemicals, relatively mild purification and concentration methods (e.g., zonal sucrose gradient centrifugation) are used. If chemical agents are used in the process, they should be minimized in the final product to below prespecified levels.

In some cases (e.g., the Varicella live vaccine) viruses are not released in the culture medium but remain associated to the cell substrate. In this case, the infected cells constituting a single harvest are rinsed, removed from the attachment surface, and subsequently disrupted by sonication to release the virus.

### Virus-Derived Subunit Vaccines

Although most seasonal influenza vaccines (influenza A and B) are prepared either in embryonated eggs or via cell culture, the derived virus is processed using different manufacturing methods to make the drug substance. The drug substances can be live or attenuated viruses (whole virus), a detergent-solubilized "split vaccine", or a subunit vaccine resulting from purification of the surface glycoproteins (e.g., HA and NA in the case of influenza virus) from the internal nucleocapsids. To produce the split virus and subunit vaccines, the whole virus is subjected to disruption with a surfactant, which solubilizes the viral membrane. For subunit vaccines, the internal subviral core of the virus is separated from the surface proteins on the basis of their differing sedimentation rates. With split-virus vaccines, the choice and use of surfactant ensures that the subviral core itself is disassembled. Diafiltration is normally used to remove the surfactant and other media components from the product, and then the process is terminated with a sterile filtration step to produce a monovalent bulk solution.

Viruses for split virus and purified subunit influenza vaccines are produced in embryonated eggs. Inactivation and purification of vaccine viruses are achieved by chemical treatment (e.g., formaldehyde or β-propiolactone) and zonal sucrose gradient

centrifugation, respectively. Split virus vaccines are prepared by the disruption of vaccine virus particles using a detergent (e.g., sodium deoxycholate) that preserves antigenic integrity.

### Recombinant or VLP Vaccines

Recombinant proteins that are components of VLP vaccines, such as hepatitis B and HPV, undergo stronger, more stringent purification processes. As with nonreplicating viral vaccines, the purification methods must maintain the desired antigenic properties. After cell culture propagation of recombinant proteins or VLPs, the cells are harvested and purified by downstream processing. This may involve chromatography, precipitation, microfiltration, ultrafiltration, or other techniques that will be specific for the vaccine being produced by each manufacturer.

The first licensed human vaccine using recombinant DNA technology was the hepatitis B VLP vaccine. The hepatitis B VLP vaccine is derived from non-infectious hepatitis B virus particles. The vaccine drug substance consists of spherical particles of the recombinant hepatitis B virus surface antigen (HBsAg), a lipidated protein whose viral gene component was cloned into the yeast *Saccharomyces cerevisiae*. The HBsAg particles consist of approximately 30% lipid by mass. For hepatitis B VLP production it is necessary to express the particles in host cells that have the appropriate environment and lipid composition for the HBsAg to self-assemble into spherical particles of the correct size.

In the case of the HPV vaccine, formation of VLPs can coincidentally result in the incorporation of host cell components (e.g., DNA) into the quaternary structure of the molecular assembly, resulting in a class of impurities that has a tight association with the active pharmaceutical ingredient. As a result, in some cases modern approaches to VLP production include a disassembly step that dissociates impurities from the viral proteins. This procedure is followed by a reassembly step that reforms the VLPs in the absence of the host components. Liquid-phase extractions and chromatographic procedures can be used to provide high-purity components for use in vaccine products with no substantial risk of carrying over significant residual host components. One HPV vaccine is bivalent and consists of recombinant proteins expressed and purified from insect cells infected with recombinant baculovirus (the vaccine contains no viral genetic material). The second HPV vaccine is tetravalent and consists of recombinant proteins purified from yeast cells. After purification, the VLPs may be mixed or absorbed onto an adjuvant to increase the immune response.

Recombinant influenza virus can be produced in continuous insect cell cultures which are grown in a serum-free medium composed of chemically-defined lipids, vitamins, amino acids, and mineral salts. Each of the four HAs is expressed in this cell line using a baculovirus vector (*Autographa californica* nuclear polyhedrosis virus), extracted from the cells with Triton X-100 and further purified by column chromatography. The purified HAs are then blended and filled into single-dose syringes. Manufacturers must also ensure that residual host cell components are sufficiently removed during the purification of recombinant-derived vaccine components.

Characterization of the recombinant monomeric antigens follows the typical requirements for recombinant proteins and would include peptide mapping coupled with mass spectrometry to assess the integrity of the primary structure, as well as sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) and other appropriate assays. Characterization of the intact VLPs will focus on assessing the size distribution of the particles using techniques such as transmission electron microscopy (TEM) or cryo-electron microscopy (cryoEM) and dynamic light scattering (DLS).

### In-Process Controls

Manufacturers identify critical process parameters and perform appropriate tests to monitor the purification process. Among the latter are filter integrity tests, microbial enumeration tests (see *Microbial Enumeration Tests* ⟨61⟩ and *Bacterial Endotoxins Test* ⟨85⟩), and other suitable tests for known process residues of concern. Process residues include raw materials, culture medium components (e.g., serum and antibiotics), cell substrates (e.g., proteins and DNA), buffer components (e.g., EDTA), and other materials (endonucleases, protamine sulfate, detergents/surfactants) used during purification. In addition to in-process control tests, manufacturers may perform in-process monitoring tests to monitor total protein, specific antigens, or ancillary materials at various steps in the purification process of intermediates. These in-process monitoring tests are carried out to gather product and process knowledge to evaluate consistency in the manufacturing process.

To demonstrate process performance and reliability, manufacturers should characterize inherent process-related impurities (e.g., protein, DNA, and lipids). Process validation studies may be carried out to demonstrate sufficient and consistent removal of certain residuals to an acceptable level such that routine testing is no longer required. If material must be sterile, analysts can perform *Sterility Tests* ⟨71⟩.

## INTERMEDIATES

Intermediates are defined as the unformulated active drug substances that are further processed before final formulation and can potentially be stored for long periods of time (see ⟨1235⟩). If intermediates are to be stored, hold times should be validated through a formal stability study or program. Stored intermediates are often suitable for more detailed characterization studies than are harvest bulks or final products (see, for example, *Table 4*). Some release tests are routinely performed before the intermediates are converted to the final bulk; this varies depending on the individual vaccines.

### Tests for Intermediates

In general, viral safety lot release testing is done at the bulk harvest stage before any purification. This is true regardless of whether the assay detects the infectious virus or viral components. Typically, the prefiltered harvest stage is the most concentrated due to the limited processing that has occurred; therefore, it is likely to be the best stage of production for testing for adventitious agents. Depending on the specific vaccine, different intermediates than the unprocessed harvest may be

@2024 USPC

preferred for viral safety, for example, in cases where cytotoxicity of the unprocessed bulk harvest may be a concern. The presence of host cell DNA may need to be assessed in the case of biologics manufactured in animal cells. A hold step may be introduced at this processing step, for example, to combine two or more single virus harvests for further processing.

**Table 4. Example list of generic tests used for unprocessed bulk harvest (not required for all vaccine products). A risk-based approach for control should be performed and agreed to with the competent authority.**

| Assay | Purpose | Method |
|---|---|---|
| Adventitious agent | Verify absence of viral contamination | Cell culture with cytopathic effect (CPE) and hemadsorption endpoints |
| Mycoplasma | Detect mycoplasma | Cell culture, PCR, growth, or fluorescent staining as endpoints (*Mycoplasma Tests* ⟨63⟩) |
| Microbiological purity | Find evidence of microbial or fungal contamination | Bioburden/absence of bacterial and fungal contamination, other as appropriate aligned with manufacturing conditions |
| Potency | Measure quantity of infectious virus or antigen | Cell culture with plaque or tissue culture infective dose ($TCID_{50}$) endpoints; RNA quantification, egg infective dose ($EID_{50}$), plaque assay, single radial immunodiffusion (SRID), immunochemical method |

In-process adventitious agent inactivation steps are not included for live viral vaccines, because these steps could compromise the live nature of the vaccine itself. As a result, it may not be possible to validate clearance of any adventitious agents. Therefore, comprehensive testing for adventitious agents and qualification and control of the vaccine source materials (including cell substrate) are essential as part of vaccine safety control. Bioburden is monitored using appropriate microbiological methods based on technical principles described in, for example, ⟨61⟩ or ⟨71⟩.

Other product-specific testing may be appropriate. For example, for live influenza vaccines, each lot of viral harvest is tested for the cold-adapted phenotype (can grow at 25°) and the temperature-sensitive phenotype (restricted replication at 37°–39°). [NOTE—The attenuation phenotype (restricted replication in the upper and lower respiratory tract of ferrets) is tested at viral seed stage.] Each lot of viral harvest is also tested extensively by in vitro methods for contaminating agents. Viral harvests from the A and B strains are subsequently blended and diluted as required to the desired potency to produce bulk vaccine. If intermediates are stored prior to drug substance manufacturing, stability over the hold time should be established.

## DRUG SUBSTANCE

The drug substance is normally the bulk antigen stored in an appropriate container and may be partially formulated in anticipation of subsequent steps. In some cases, the drug substance might already have been combined with adjuvants and excipients to be exceptionally agreed with the National competent authority. The drug substance may have been filtered, sterile filtered, or aseptically processed and then tested respectively for bioburden with adequate acceptance limits or for sterility.

Drug substances can be stored in containers at temperatures that ensure their stability before further processing. Storage times for drug substances should be validated through a formal stability study or program. Purity testing may occur with the drug substance in lieu of drug product. Product- and process-related impurities are monitored to confirm that their levels meet the requested specifications. Because viral vaccine drug substances generally have high potency, and subsequent dilution to the drug product potency may be significant, measurements of process impurities are best obtained from the drug substance rather than from the final container.

Examples of release tests for the drug substance may include:

- Appearance
- Identity of antigen
- Potency and activity, or quantity of epitope or antigen
- Infectious titer (live, attenuated viral vaccines)
- Protein integrity and purity [e.g., by SDS–PAGE, size exclusion–high-performance liquid chromatography (SEC–HPLC), cation exchange (CEX)]
- Monomer content in multimeric VLP vaccines
- Impurities
- Endotoxins content
- Bioburden or sterility
- Mycobacteria
- Mycoplasma and spiroplasma

In addition to the examples listed above, other methodologies can be applied for identity and purity evaluation. For instance, specific impurities that must be measured are agreed upon between manufacturers and the licensing authority during the licensure process.

## DRUG PRODUCT

General guidelines for vaccine products are provided in ⟨1235⟩. This includes information regarding labeling and assessing the stability of vaccines.

@2024 USPC

Mechanically, the processes of formulation and filling for viral vaccines have changed little over time. Formulation is usually a simple dilution of high-potency drug substance to the appropriate strength for filling that takes into account yield losses expected through subsequent temperature exposures (including freeze–thaw cycles) and, where applicable, losses due to lyophilization. Some nonreplicating, subunit, and recombinant VLP vaccines are produced as formulations that are adjuvanted, alum adsorbed, or both. It is important to note that production of drug product lots involves filling containers into the tens or hundreds of thousands, and special attention must be paid to ensuring homogeneity of product over so many containers with volumes ranging from 0.1 to 10 mL. For live products, thermal degradation can occur over the course of the filling operation, which should be considered in process design. For products containing aluminum suspensions, homogeneity of the suspension is a significant concern. Generally, upon agreement with the relevant licensing authority, liquid product is "overfilled", both with respect to volume (to ensure the ability to withdraw a full dose) and with respect to potency (to ensure a statistically acceptable probability that each container receives the declared potency at the end of expiry), given the variability of the process and assays used.

## LOT RELEASE TESTS

General requirements for drug product lot release testing of vaccines are detailed in ⟨1235⟩.

### Potency Assays

General requirements for potency tests are described in ⟨1235⟩. Many types of potency-indicating tests exist for viral vaccines and the selected potency test depends on the type of vaccine. Examples of viral vaccine potency assays include:

- Specific virus neutralization assay
- Quantitative PCR
- Viral antigen quantitation
- Viral titre
- Quantitative plaque formation assay
- Immunogenicity assay

### Common Tests

Tests for sterility, purity, residual moisture (lyophilized product), bacterial endotoxins, identity, excipients, and manufacturing residuals are described in ⟨1235⟩, except as described below. Viral and rickettsial vaccines and antigens are generally exempted from a requirement for a pyrogenicity test.

### Manufacturing Residuals

Expectations for the control of manufacturing residuals, including surfactants and those chemicals used in the inactivation process(es) are described in ⟨1235⟩. Formaldehyde and other chemicals used to manufacture vaccines must be minimized by purification steps in the manufacturing process. Limits are set on their residual content in the final vaccine, and content specifications are defined in the approved product license application.

Requirements to control residual material from cell substrates are described in ⟨1235⟩, including the steps that should be taken to prevent potential complications for hyper responsive recipients of these vaccines.

### Preservatives

Chapter ⟨1235⟩ provides information on the acceptable use of antimicrobial preservatives, the types of preservatives used, the minimization of thimerosal content as far as possible, and the production of thimerosal-free vaccines. Limits and content specifications are set for each vaccine in the product license.

### Excipients

Formulation chemicals for viral vaccines are often introduced during drug substance production, during the infection phase, or at harvest to enhance process productivity, particularly for enveloped live virus vaccines. Non-enveloped viruses or vaccines with extensive purification may introduce formulation chemicals only at the end of the purification process. A notable exception is formulation for combination viral vaccines, where the individual viruses may need stabilizers that are different from the global optimum for the mixture. In these cases, the final formulation of chemicals may be introduced late in the process to preserve maximum potency.

Formulation components may be included to minimize oxidation, to compete for other reactions that would damage the product, to provide pH buffering or tonicity, and in the case of lyophilized formulations, to replace water that would otherwise bind to proteins or provide other functions in the lyophilization process (e.g., cake formation/integrity). Chemically defined components are desirable and all components should meet appropriate pharmacopeial standards. In some instances, macromolecules such as albumin or dextran or fragments thereof (such as hydrolyzed gelatin) may be included in formulations to function as highly effective stabilizing agents. For those that originate from animal or plant sources or for new excipients, risk assessment should be conducted on the origin and processing of the materials to ensure freedom from infectious agents, and for other biological safety aspects (see *Excipient Biological Safety Evaluation Guidelines* ⟨1074⟩). Where pharmacopeial monographs exist, the excipients should conform. In addition to stabilizing agents, viral vaccines may contain preservatives if

the final container contains multiple doses. Preservatives should meet antimicrobial effectiveness testing requirements in the formulation (see *Antimicrobial Effectiveness Testing* ⟨51⟩). It is common for preservatives to reduce the sensitivity of drug product sterility testing. This needs to be addressed during sample qualification for release testing to ensure adequate safety (see *Validation of Microbial Recovery from Pharmacopeial Articles* ⟨1227⟩). In addition, some formulations may be incompatible with other in vitro or in vivo safety testing and may require alterations of conditions or sample pretreatments to achieve valid test results.

### Adjuvants

Aluminum compounds including aluminum potassium sulfate (alum), aluminum phosphate, aluminum hydroxide, and combinations of these compounds are currently approved adjuvants for vaccine use. Chapter ⟨1235⟩ outlines sections of the 21 CFR §610.15 regulation governing the use of aluminum and the allowed amounts. Aluminum is quantified using colorimetric, titrimetric, or emission or atomic absorption spectroscopic methods of analysis (see *Aluminum* ⟨206⟩). The degree of adsorption of protein components to the adjuvant should be determined.

The adjuvants MPLA and squalene emulsions (AS03 and MF59 C.1) are licensed for vaccine use. MPL is quantified either through degradation to fatty acid methyl esters (FAMEs) and quantification by gas chromatography, or through quantification of the glucosamine content. Squalene is usually quantitated by HPLC.

## OTHER INFORMATION

Additional guidelines for viral vaccines covering product retention, shelf life, expiry dates, storage, container, and labeling are detailed in ⟨1235⟩.

# ⟨1240⟩ VIRUS TESTING OF HUMAN PLASMA FOR FURTHER MANUFACTURE

## SCOPE

The scope of this chapter is limited to the virus testing performed on human plasma for the further manufacture of pharmaceuticals, which are referred to as plasma-derived products (see *Virology Test Methods* ⟨1237⟩ for virus testing of other therapeutic products). These types of plasma include either source plasma collected by apheresis or recovered plasma obtained from whole blood collection or as a byproduct in the production of blood components. In all cases, the source material is obtained through voluntary donations. The following topics are specifically excluded from the scope of this chapter:

- Virus testing of nonhuman blood or plasma; for example, fetal bovine serum (see *Bovine Serum* ⟨1024⟩ for more information on testing this material), which may be used in the production of biological or recombinant therapeutics
- Virus testing of human-derived whole blood, blood components used for transfusion, and materials in tissue and organ banks
- Testing for nonviral organisms; for example, bacteria, fungi, and parasites (some of these topics are discussed in *Sterility Tests* ⟨71⟩), or the causative agent of transmissible spongiform encephalopathy.

This chapter introduces the virus testing that is performed on plasma used for the production of therapeutic proteins. Topics that are addressed include:

1. The rationale for implementing tests for viruses
2. The types of testing applied to plasma donations destined for further manufacture
3. The current regulatory environment for such virus testing

The chapter also includes an *Appendix* that contains pertinent regulatory guidances and supporting references.

## INTRODUCTION

Human-plasma-derived products are used to treat coagulation disorders, primary immune deficiency, and congenital emphysema as well as other diseases (see *Human Plasma* ⟨1180⟩). Because these products are manufactured from pooled human plasma donations, the presence of blood-borne viral pathogens from individual plasma donations can potentially contaminate the resulting final products manufactured from a large pool of donations and thus transmit the virus to many recipients. Sufficient measures must be taken to ensure that these products are as safe as possible. In order to minimize the risk of transmission of viruses by these products, manufacturers use several strategies, which include:

- Selection and management of the donors (see also ⟨1180⟩)
- Selection and management of donations or units (see also ⟨1180⟩)
- Testing for infectious viral pathogens in plasma in the form of samples of individual or pooled donations and fractionation pools (defined for the purposes of this document as the first homogenous pool or early production intermediate suitable for testing and representative of the material to be used for product manufacturing)
- Donor-screening methods, which also include a look-back procedure for the quarantine and destruction of unused, previously donated units from an infected donor (see also ⟨1180⟩)
- Incorporation of validated virus inactivation and removal steps (pathogen-reduction steps) into the manufacturing processes (see also ⟨1180⟩)
- Monitoring and investigating adverse events in recipients of final products, both hemovigilance and pharmacovigilance (see also ⟨1180⟩)
- Adherence to Good Manufacturing Practices at all levels of the production process as a strategy to reduce risk of virus transmission (see GAO-HEHS-98-205, 21 CFR Part 606, and WHO Technical Report Series 941 cited in the *Appendix*).

Plasma used for further manufacture can be either source plasma or recovered plasma. In the United States, licensed human plasma products are derived mainly from source plasma. Because plasma for further manufacture is obtained by pooling a large number of donations, there is a risk of viral contamination of the pool, thus resulting in a much higher potential risk of virus transmission to multiple recipients than is the case for blood for transfusion. The manufacturing process, which is used to purify and concentrate the desired protein, is not capable of completely removing the viral load, and therefore validated virus-reduction steps capable of effectively reducing transfusion-transmissible viruses in the starting material are included in the manufacturing process. A detailed discussion of virus inactivation and removal procedures for pathogen reduction can be found in the 2004 WHO Technical Report Series 924 cited in the *Appendix*.

Approaches for screening plasma for further manufacture can be categorized into two groups: donor-screening and in-process testing methods. The donor-screening method takes into account not only the plasma-derived end product but also the plasma donor. This category of testing typically is required for blood-transmissible viruses such as human immunodeficiency virus (HIV), hepatitis C virus (HCV), and hepatitis B virus (HBV). Virus transmission is a major public safety concern, because infections with these highly pathogenic viruses typically progress to chronicity. During donor screening the objectives of the test laboratory or manufacturer are not only to identify positive units for destruction before production pooling but also to identify and notify infected donors. Donors who test positive for HCV or HIV are permanently deferred from donating both blood and plasma. Although fewer than 5% of HBV-infected adults develop persistent asymptomatic infection (i.e., a carrier state), HBV-positive donors are deferred permanently. Collection of source plasma from donors who are convalescing from HBV is sometimes permitted for further manufacturing into plasma-derived products such as Hepatitis B Immune Globulin (Human) [21 CFR 610.41(3)].

In contrast to viruses that are associated with donor screening, viruses such as hepatitis A virus (HAV) and parvovirus B19 (B19V) usually cause self-limiting infections in immunocompetent individuals, and thus manufacturers use in-process nucleic acid amplification technology (NAT) testing that results in only the removal of plasma units with high levels of virus before pooling for production. In these cases, there is no donor-management procedure and hence no requirement to inform the donor of the result. This approach focuses primarily on the product, not the donor, because some recipients of these products are susceptible to an infection that may occur if the pathogens were present in the plasma-derived product. Donor and donation-management procedures are well developed in the blood and plasma industry, and more details on these specific topics can be found in ⟨1180⟩. Other permanent or temporary donor-deferral criteria are in place to avoid donations from potentially infected donors based on the epidemiological surveillance of a country or region or donor population for transfusion-transmissible infections relevant to the safety of blood components.

Viruses that greatly affect public health, such as HIV, HBV, and HCV, are detected by serological assays that measure either a viral antigen, such as hepatitis B surface antigen (HBsAg), or an antibody, such as anti-HCV or anti-HIV-1/2 antibodies, in infected donors and associated donations. These immunoassays for detecting viral markers in plasma donations must be sensitive and able to detect a viral infection as early as possible following infection in order to identify and exclude potentially infectious donations.

There is a finite time period, known as the window period, between the infection of a donor and the time at which the test method can detect the antibody response to the virus, the viral antigens, or the viral nucleic acid. This window period varies from disease to disease as well as from person to person. The window period can be effectively "shortened" by changing from a test based on detecting antibodies to one based on detecting the virus directly, namely the viral antigen or, especially, the viral nucleic acid (see *Figure 1*), thereby interdicting donations that contain transfusion-transmissible viruses. Tests for detecting the viral nucleic acids (i.e., NAT tests) were introduced in the 1990s. NAT tests are sensitive and can considerably shorten the window period (see *Figure 1*). In a later development after B19V transmission incidents involving plasma-derived products, NAT tests were initiated to interdict high-titer donations, thereby decreasing the B19V virus load in manufacturing pools.

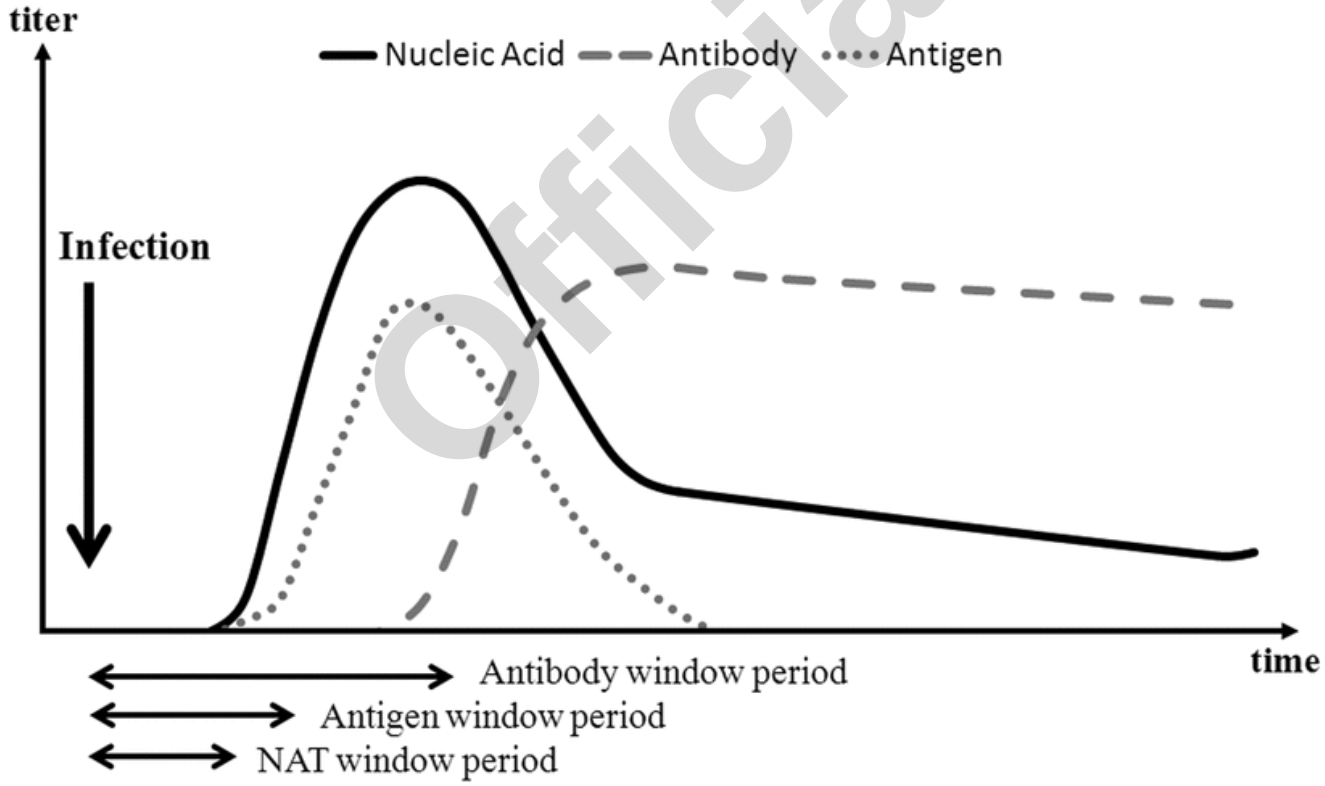

Figure 1. Dynamics of virus replication and detection of an infection.

Both source plasma and recovered plasma are tested by serological and NAT tests that are approved by competent regulatory authorities or, in the case of in-process testing, are validated to manufacturers' requirements. Plasma units found acceptable by these tests are combined into large pools, called fractionation pools, for manufacturing of plasma-derived products. The fractionation pool size can vary from several hundred donations (typically used for the production of specific immunoglobulins) to several thousand donations (used, for example, for the manufacture of albumin). Finally, the fractionation pools are retested for the target viruses. Testing of the plasma donations, at the individual or minipool level, and the fractionation pools are two of the elements that manufacturers put into place to maintain the safety margins of these products. Serology testing is performed on the individual donations. In contrast to serology tests, current NAT tests are highly sensitive and specific; therefore, manufacturers, in addition to testing individual donations, test minipools made up of equal volumes of each donation. Currently, the minipool size used for NAT testing varies from 6 to 512 donations. The high sensitivity of NAT tests also allows earlier virus detection compared to an antigen- or antibody-based test, thereby reducing the average length of the window period.

Official

https://pharmacopeia.cn/v-download/

Plasma-derived products are produced from tested fractionation pools and are further manufactured by using a combination of fractionation and purification steps. These steps may have some inherent potential to remove or inactivate viruses and thus reduce viral contaminants that may have been present in the starting plasma. Nevertheless, manufacturing of plasma-derived products also includes dedicated steps designed solely to inactivate (e.g., by solvent-detergent treatment) or remove (e.g., by virus filtration) potential viral contaminants.

## RATIONALE FOR VIRUS TESTING OF PLASMA FOR FURTHER MANUFACTURE

Historically, virological test methods have been used for detecting viral antigen or antibodies in clinical settings for disease diagnosis, intervention, and containment. Subsequently, these methods were adapted to screen blood and plasma donations with high sensitivity and specificity for transfusion-transmissible viruses. In order to develop a new virus screening test, scientists must know the biochemical properties of a new emerging pathogen (e.g., the nucleic acid sequence) for the development of an NAT test or the protein (e.g., antigen) for immunological tests. When implementing such a test for a given pathogen, the public health implications of positive test results and the potential for early intervention and treatment of the disease have to be considered. In addition, the availability of plasma for further manufacture and the effects of the virus on the safety of the finished product should be taken into consideration.

The emergence of a viral pathogen in the donor population could result in a considerable virus load in the plasma donations and in the resulting fractionation pools. For viruses such as HBV, HCV, HIV-1, and HIV-2 that can cause chronic diseases with potential public health effects, all donations positive for one or more of these viruses, irrespective of the virus titer, must be removed, and the donor must be informed. Some viruses such as B19V are prevalent in the population (as many as 1 in 5000 individuals may be infected during an epidemic period) and can be present at high virus titers in infected individuals. Thus, the removal of all B19V-positive donations could lead to a shortage of plasma. Instead, in-process NAT testing is done to interdict high-titer donations and thereby limit the B19V load in the manufacturing pool. The rationale for such screening is that B19V causes a self-limiting infection in most immunocompetent individuals. Following recovery, such individuals have neutralizing antibodies to B19V. Seroconversion occurs early in life, because B19V infection is common in childhood, and approximately 50% of 15-year-old adolescents have B19V antibodies. Infection of susceptible individuals continues throughout adult life, and B19V seroprevalence increases with age. The B19V neutralizing antibodies present in a plasma pool and the validated virus reduction steps included in the manufacturing process ensure that the inclusion of such donations does not compromise either the safety of the plasma-derived products or the availability of plasma for further manufacture.

In some instances it may not be necessary or feasible to test for a blood-borne virus. For example, testing of plasma for cell-associated viruses such as Human T Lymphotropic Virus (HTLV) types I and II, which present with no or with only limited virus load in plasma (but with a considerable virus load in whole blood donations) is not required. Similarly, testing for West Nile Virus (WNV), a member of the Flaviviridae family, is unnecessary because the virus load is low during the asymptomatic window period, the prevalence in the donor population is low (resulting in a low virus load in a plasma pool for fractionation), and WNV can be effectively inactivated by the manufacturing process as demonstrated by validation studies using relevant Flaviviridae model viruses. Therefore, WNV NAT testing for plasma (source and recovered) for further manufacture is not required. However, in the United States, the Food and Drug Administration (FDA) recommends WNV NAT testing for blood and blood components for transfusion because of the epidemiological situation and the risk of WNV transmission by blood components (see the FDA Guidance for Industry cited in the *Appendix*).

Other pathogenic viruses such as influenza viruses and severe acute respiratory syndrome coronavirus (SARS-CoV) are associated with clinical disease after a short incubation period and have a low or no virus load during the asymptomatic window period. No transmission by blood transfusion or plasma-derived products has been reported for these viruses. Furthermore, the manufacturing process for plasma-derived products has been shown to effectively inactivate influenza viruses. Therefore, NAT testing of plasma is not required for these viruses.

For a virus with a high prevalence in the donor population but without known clinical implications, no screening program, neither NAT nor serology, is required because the majority of donors would no longer be eligible to donate, thereby threatening the supply of blood and plasma and of plasma-derived products. Viruses that fall in this category are Torque Teno Virus (TTV), which is present in greater than 80% of the general population, and GB virus C (GBV-C, previously known as hepatitis G virus, HGV).

Newly emerging pathogens such as hepatitis E virus (HEV) can potentially enter the blood and plasma donor population, resulting in viral infections in recipients of blood and plasma-derived products. Monitoring the emergence of such agents is a continuous effort that involves academia, public organizations that monitor health and develop early warning systems, regulatory agencies, and industry. Currently, several epidemiological surveillance systems are in place and include hemovigilance or biovigilance to address the potential risk of emerging pathogens to the recipients of blood and plasma-derived products. This risk can be mitigated by appropriate measures, such as donor deferral because of geographic risk and risk behaviors, the testing of donations if appropriate, and the inclusion of virus-reduction steps for a wide range of enveloped and nonenveloped viruses during the manufacturing process.

## APPROACHES TO TESTING

Virological screening assays are designed to detect antibodies, antigens, or nucleic acid sequences of the infectious virus via serological and NAT testing. Sensitive virological test methods are a prerequisite for the quality control of fractionation pools in order to interdict and discard infected donations before manufacturers process these donations into pools to produce plasma-derived products.

All assays used to screen blood or plasma donations should be designed for their intended use and should meet the performance requirements specified by the Clinical and Laboratory Standards Institute (CLSI) guidelines for qualitative and quantitative tests. Assays also should comply with guidance from regulators, such as the European Common technical

specifications for in vitro diagnostic assays (see *Appendix*). Associated calibrators or control materials must be traceable to reference material of a higher order or to reference measurement procedures. The *Appendix* includes FDA guidance documents pertaining to the manufacture and clinical evaluation of these assays and the use of controls. U.S. and EU requirements or recommendations for tests for screening plasma for further manufacture are described in the *Regulatory Environment* section.

### Serological (Immunological) Assays

Serological assays detect antibodies, antigen, or a combination of both. Antibody-detection assays usually are performed by incubating an immobilized virus antigen (virus lysate or, more common currently, virus proteins produced by recombinant protein technology) with a plasma sample. If antibodies specific to the viral protein are present in the sample, they bind to the target antigen. The virus-specific, bound antibody is in turn incubated with a labeled secondary antibody that is specific for the virus-specific, bound antibody. The label yields a signal that then is detected. Alternatively, for the measurement of a viral antigen present in a sample, immobilized antibodies specific for the viral antigen first are incubated with a plasma sample, a labeled antibody (often a monoclonal antibody) against the virus protein is added, and the mixture is incubated. For more details about these assays, see *Immunological Test Methods—Enzyme-Linked Immunosorbent Assay (ELISA)* ⟨1103⟩.

### Nucleic Acid Amplification Technology Tests

NAT is a collective term for the various methods that are used to amplify and detect the specific genomic sequences in various sample types. These methods include polymerase chain reaction (PCR), transcription-mediated amplification (TMA), and branched DNA (bDNA) and are detailed in *Nucleic Acid-Based Techniques—General* ⟨1125⟩, *Nucleic Acid-Based Techniques—Extraction, Detection, and Sequencing* ⟨1126⟩, and *Nucleic Acid-Based Techniques—Amplification* ⟨1127⟩. NAT tests typically use gene-specific oligonucleotides (e.g., primers, probes), enzymatic amplification reagents (e.g., buffers, nucleotides, enzymes, cofactors), and a method that allows the detection of the resulting amplification products. Currently, NAT tests for HBV, HCV, HIV, B19V, and, in some cases, HAV, are used to screen plasma for further manufacture.

For high-throughput testing, which is desired for the testing of plasma donations used for further manufacture, NAT offers distinct advantages over serological testing. First, because of the high sensitivity of these methods, samples of plasma donations can be combined into pools (minipools) that allow simultaneous testing of multiple samples, in contrast to serological assays that are performed on individual samples. Although the operational logistics used in donation minipool testing are more complicated than those involved in testing individual donations, the minipool approach generally allows an improved turnaround time for the release of negative samples compared to the traditional nonpooling method. A reactive minipool is deconstructed to identify any positive donation(s). However, because of the dilution of virus in any given donation, minipool testing has an inherently decreased sensitivity compared to individual donation testing.

*Table 1* summarizes the potential viral load, which could be avoided by NAT testing, in a fractionation pool caused by the inclusion of a single serological-window-period donation for the five major transfusion-transmitted viruses.

**Table 1**

| Virus | Potential Viral Load in Fractionation Pool Caused by Contamination with One Window-Period Donation (Approximate Values)[a] |
|---|---|
| HBV | $8 \times 10^5$ IU |
| HCV | $8 \times 10^{10}$ IU |
| HIV-1 | $8 \times 10^9$ IU |
| HAV | $8 \times 10^9$ IU |
| B19V | $8 \times 10^{14}$ IU |

[a] Assuming one plasma donation is approximately 800 mL. References supporting these values are found in the *Appendix*.

## REGULATORY ENVIRONMENT

Regulatory agencies have the goal of ensuring that plasma-derived products are safe with respect to risk from blood-borne pathogens. In addition to regulating the final products, regulators also oversee the assays used to test for infectious agents and set policies about how those tests will be used. Although regulatory agencies in the United States and Europe share the common goal of safety, they use different legal structures and strategies. In general, the hierarchy of regulatory documents is similar. Both start with laws that set the definitive requirements for donor selection and plasma screening.

In the United States, the primary laws that regulate plasma-derived products and the assays that test their safety are the Public Health Service (PHS) Act and the Federal Food, Drug, and Cosmetic (FD&C) Act. The PHS Act addresses biologics and communicable disease controls, and the FD&C Act addresses drugs and medical devices. Donor-screening tests are licensed under the PHS Act rather than being cleared or approved under the medical device provisions of the FD&C Act. Testing requirements for communicable disease agents, including viral pathogens such as HBV, HCV, and HIV, are required under 21 CFR, including not only test requirements (21 CFR 610.40) but also donor deferral (21 CFR 610.41) and look-back requirements (21 CFR 610.46 through 610.48). If a plasma or blood donation is reactive in one of the screening tests, especially in the donor-screening tests for HBV, HCV, or HIV, supplementary or confirmation tests should be conducted to clarify whether the donor is infected [21 CFR 610(b)]. The donor must be informed (21 CFR 630.6) and should be excluded from donating blood or plasma (temporarily or permanently according to 21 CFR 630.6), and manufacturers should initiate a look-back procedure (21 CFR 610.40–48). For HIV and HCV, the procedure includes not only the quarantine and destruction of unused,

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M3147_01_01

previously donated units from an infected donor, but also the further testing of the donor and notification of the recipients of the blood and blood components (21 CFR 610.47–48). The look-back period can be as long as 1 year (21 CFR 610.46–48).

The responsibility for legislation of the European Union (EU) is shared between the EU and the European Member States. The European Commission (EC) is responsible for the regulation of the common European market and thus is responsible for medicinal products for human use, whereas the Member States are responsible for health care, which includes the supply of hospitals with blood components such as plasma and cellular components for transfusion. Because the EC is responsible for the regulation of medicinal products derived from human blood or plasma, it is, as a consequence, also responsible for the regulation of plasma for further manufacture. The laws of the EU are found in regulations and directives from the EC and in the binding monographs of the *European Pharmacopoeia* (*Ph. Eur.*).

Additional tests and specifications for plasma for further manufacture have been developed as part of the Plasma Product Therapeutics Association (PPTA) Voluntary Standards Program. The PPTA Quality Standard for Excellence, Assurance, and Leadership (QSEAL) includes additional routine testing of blood and plasma donations or plasma pools for HCV RNA, HIV RNA, HBV DNA, HAV RNA, and B19V DNA. Companies certified by PPTA under the QSEAL program have implemented this testing.

## Testing of Plasma for Further Manufacture

In the United States, all virus tests intended for donor screening, such as HBV, HCV, and HIV, are regulated as biologics and are subject to clinical validation and licensure by FDA's Center for Biologics Evaluation and Research (CBER). Clinical specificity must be evaluated and demonstrated with healthy donors and follow-up testing when applicable, and clinical sensitivity should be evaluated and demonstrated with high-risk donors and follow-up testing. Use of reference panels (from FDA or a designated source) is needed for release of each lot of kits intended for market distribution. In-process tests such as NAT testing for HAV or B19V do not require clinical trials to demonstrate assay effectiveness. However, the manufacturers of plasma-derived products should perform preclinical validation and should submit data for review and approval by CBER as analytical procedures for plasma-derived products.

In the European Union, donation screening tests are regulated as medical devices. Specifically, Directive 98/79/EC outlines requirements for the approval of tests or test kits, which require the CE mark before marketing and use for testing. The CE mark confirms that the test or the test kit meets specified quality criteria. Screening tests for manufacturing pools must be validated by the end user following specific guidelines. As in the United States, in-process tests are not licensed, and the end user is responsible for validating the test.

In Europe, in addition to virus screening of plasma pools by the manufacturers of plasma-derived products, screening for defined viruses is part of the official batch-release procedure. The EC and the Council of Europe agreed in May 1994 to create a network of Official Medicines Control Laboratories (OMCLs). The OMCLs perform tests on each batch of plasma-derived medicinal product, including virus testing of the fractionation pool used to produce the batch. All required tests are performed and documented in the European Batch Release Certificate that is accepted by each Member State as the basis for placing the product on the market. In order to comply with the sensitivity limits set for NAT testing, minipools of various sizes (6–512 donations) are tested by the manufacturer or by the blood donation centers where the collection and testing of blood or plasma is performed. Only donations that meet the requirements are used for pooling.

## Serological Tests

### FDA REQUIREMENTS OR RECOMMENDATIONS

An individual donation of source plasma or recovered plasma derived from whole blood must be tested for HBsAg, anti-HIV-1, anti-HIV-2, and anti-HCV, but not for anti-HBc, anti-HTLV-I, and anti-HTLV-II by FDA-licensed serological tests intended for donor screening (*Table 2*). A reactive donation must be further tested by a supplemental (i.e., additional, more specific) test that has been approved for such use. Even with the implementation of corresponding NAT tests, serological testing of each donation still must be performed.

Currently, FDA recommends using licensed donor-screening kits that are capable of detecting anti-HBsAg, the antibody capable of neutralizing HBV, at 0.5 ng/mL or less. Whole blood sometimes is tested for anti-HBc, but because anti-HBsAg often occurs with anti-HBc, plasma for further manufacture is not required to be tested for anti-HBc. Therefore, although recovered plasma is derived from whole-blood donations that might have been tested for anti-HBc, it can be shipped for further manufacturing regardless of the test results.

FDA first recommended standardized anti-HIV-1 donor-screen tests in 1989 in a draft Points to Consider document that described test kit manufacture and the preclinical and clinical studies needed for licensure, and this recommendation generally can be applied to other serological tests. Since the availability in 1991–1992 of licensed serological kits for simultaneous detection of antibodies to HIV-1 and HIV-2, FDA further recommends the use of either a licensed combined test or two separate licensed tests for donor screening.

FDA licensed an anti-HCV test containing multiple recombinant antigens in 1992, and a subsequent guidance recommended that all donations for blood and blood components intended for transfusion and source plasma intended for further manufacture be screened by an FDA-licensed test for anti-HCV.

### EU REQUIREMENTS

Requirements for collection of blood and plasma, for selection of donors, and for testing of donations in Europe were released in 2003. Directives 2002/98/EC and 2003/63/EC contain donor-selection criteria and testing requirements for blood and plasma independent of its use. The requirements of the directives are standards for plasma for further manufacture but can be extended by a Member State for the regulation of blood components. An overview is provided in the Reports of the European Committee (Partial Agreement) on Blood Transfusion (CD-P-TS). The report indicates that in addition to the serological standard tests that are obligatory for the testing of plasma for fractionation (summarized in *Table 2*), testing for HIV antigen, anti-HBc antibodies,

https://pharmacopeia.cn/v29240/

HCV antigen, anti-HTLV-I, and anti-HTLV-II antibodies is required in some Member States, and testing for antibodies against cytomegalovirus is performed in certain cases. However, these additional rules are applicable only if blood components for transfusion (erythrocytes, platelets, or plasma) are produced.

The test regime required for donations used for production of plasma derivatives are summarized in the *Ph. Eur.* monograph *Human Plasma for Fractionation (0853)*. Only licensed tests or test kits can be used for donor screening. Licensed tests have a CE mark, which confirms that the quality of the test meets predefined criteria (e.g., an HBV screening test must detect HBsAg in a concentration of 0.5 ng/mL or less). The most important quality attributes, namely specificity and sensitivity, are tested in clinical trials using donor samples (minimum of 5000 samples) and clinical samples (minimum of 200 samples). Sensitivity of the tests must be demonstrated with positive samples (minimum of 400 samples) and with seroconversion panels (minimum of 20 panels).

HBsAg tests and antibody tests against HIV Types 1 and 2 also are used for the testing of fractionation pools. The plasma manufacturer should demonstrate that the test is qualified for this use and meets the requirements laid down in the appropriate guidelines of the European Medicines Agency.

The current test regime is discussed regularly among EU Member States and may be subject to change if necessary because of the epidemiological situation. If changes in the requirements are made, the *Ph. Eur.* monograph *Human Plasma for Fractionation (0853)* and the product-specific monographs will be adopted accordingly (e.g., a change in the monograph *Human Plasma (Pooled and Treated for Virus Inactivation) (1646)* is proposed; it requires testing for HEV by NAT).

## NAT Tests

As described previously, only licensed serological tests that use antibody- or antigen-detection technology are required to screen plasma in single-donation format. However, NAT testing generally can detect evidence of viral infection at an early stage, and FDA licensed NAT tests for HIV-1 and HCV in 2001 for source plasma donors and in 2002 for whole-blood collections. Thus NAT tests are used to screen plasma donations, generally in a minipool format, using pool sizes that depend on the analytical sensitivity of the NAT test and, in some cases (HCV and B19V), the fractionation pool. In general, plasma donations are screened in a minipool format in which the pool size depends on the analytical sensitivity of the NAT test. The size of the minipool used for source plasma donations generally is much larger than that for blood donation testing (as large as 512 compared with 96 for blood donations). The turnaround time required for retesting a reactive pool in order to identify the reactive donation is less critical for plasma compared with that for blood for transfusion because some blood components such as platelets have a short shelf life.

### FDA REQUIREMENTS OR RECOMMENDATIONS

To adequately and appropriately reduce the risk of transmissions of HIV-1, HCV, and HBV, FDA-licensed NAT tests are required for donor screening. A list of FDA-licensed, donor-screening NAT tests and serological tests is updated as needed and is available on the FDA website.

FDA's initial guidance for HIV NAT in 1999 recommended standards for the manufacture and clinical evaluation of tests to detect nucleic acid sequences of HIV-1 and HIV-2 for licensure. This guidance provided some of the major regulatory and scientific guidance for NAT assays not only for HIV but also for other transfusion-transmitted viruses. Since then FDA has revised the requirements for the analytical sensitivity of HIV-1 and HCV NAT tests as 100 IU/mL for HIV-1 RNA and HCV RNA when tested in a minipool or as 10,000 IU/mL HIV-1 RNA or 5000 IU/mL HCV RNA when tested in an individual donation. FDA's 2004 guidance on NAT screening of HIV-1 and HCV in donor whole blood, blood components, and source plasma and a further guidance in 2010 contain recommendations about testing, product disposition, and donor deferral and reentry. The latter supersedes earlier recommendations for reentry of donor deferral and reentry because of serological testing results for anti-HIV-1 and anti-HCV.

The source plasma industry has voluntarily implemented HBV NAT testing in minipool format. Several FDA-licensed HBV NAT tests for donor screening are available. In 2012 FDA finalized a guidance recommending the use of HBV NAT on pooled and individual samples from donors of whole blood and blood components for transfusion or for further manufacture, including recovered plasma and source plasma. The guidance recommends an NAT test sensitivity of 100 IU/mL for testing individual donations of whole blood and blood components intended for transfusion. Because of the virus-reduction step(s) used during the manufacturing of plasma-derived products and the presence of neutralizing anti-HBsAg in the manufacturing pools, FDA recommends a NAT test sensitivity of 500 IU/mL for individual donations when manufacturers test minipools of plasma for further manufacture. The guidance also contains recommendations about product testing and disposition, donor management, methods of donor requalification, and product labeling. The guidance also supersedes the relevant recommendations based on HBsAg and anti-HBc serological testing results.

In 2009 FDA issued a final guidance for B19V NAT testing following a postmarket surveillance study report of a B19V transmission incident associated with solvent and detergent-treated (S/D-treated) pooled plasma. The guidance recommends the use of B19V NAT as an in-process test for plasma for further manufacturing to ensure that the level of B19V DNA in fractionation pools does not exceed $10^4$ IU/mL. The guidance document recommends that the primers and probes selected for a B19V NAT test should detect all known genotypes of the virus. The WHO International B19 Genotype Panel containing three genotypes is available for validation purposes. Currently, in-process HAV NAT testing is widely implemented by fractionators who use source plasma as starting plasma, but FDA has not issued a relevant guidance document. Because the in-process B19V NAT test is used to limit the virus load in the plasma pool, these tests must be capable of B19V DNA quantitation (unlike the NAT tests for HBV, HCV, HIV, and HAV, which are qualitative NAT tests).

### EUROPEAN REQUIREMENTS

NAT tests used for donor screening are subject to licensing and receive the CE mark if a test meets the predefined test specifications. NAT tests for plasma pool samples must be validated according to the *Ph. Eur.* general test *Nucleic Acid*

Official

*Amplification Techniques (20621)*. Currently, plasma for manufacture (plasma pools for fractionation) must be tested for HCV RNA by a NAT test, but there are no requirements for NAT testing for HBV DNA and HIV RNA although most plasma manufacturers voluntarily test for all three viruses. The guideline requires that a test should be able to detect all HCV genotypes. However, in view of the difficulty of obtaining rare HCV genotypes, it is sufficient that at least the most prevalent genotypes (in Europe, genotypes 1 and 3) are detected at a suitable level. Plasma should be negative when screened with a test that can detect a sample containing 100 IU/mL of HCV RNA (calibrated against the WHO HCV International Standard).

Testing for B19V DNA generally is not required but must be performed for products that are seen as a higher risk for patients if this virus is present (e.g., anti-D immunoglobulin products and plasma that is pooled and inactivated by S/D treatment). In addition, the latter product also must be tested and found nonreactive for HAV RNA, and in the future it also should be nonreactive for HEV RNA. Unlike testing for HCV and HAV where the fractionation pool should be nonreactive for these viruses, for B19V testing the virus load in the fractionation pool and pooled S/D-treated plasma should not exceed 10 IU/µL B19V DNA. The requirements are detailed in the product-specific *Ph. Eur.* monographs. In order to avoid a reactive pool, which would have to be discarded, NAT testing also is performed on single donations or preferentially on minipools comprising 16–512 donations. Although the requirement for B19V and HAV NAT testing is applicable only to plasma used for the manufacture of pooled S/D-treated plasma and anti-D immunoglobulin products, most plasma manufacturers voluntarily test plasma destined for manufacture of all plasma-derived products to reduce the virus load in the fractionation pools.

The current FDA and EU requirements for testing plasma for further manufacture are summarized in *Table 2* and *Table 3*.

**Table 2. FDA and EU Serology Testing Requirements for Plasma for Further Manufacture**

| Screening Test | FDA | EU |
|---|---|---|
| **Serological Testing of Individual Plasma Donations (Recovered and Source)** | | |
| HBsAg | Required | Required |
| Anti-HBc | Not required | Not required |
| Anti-HIV-1/Anti-HIV-2 | Required | Required |
| Anti-HTLV-I/II | Not required | Not required |
| Anti-HCV | Required | Required |
| **Serological Testing of the Fractionation Pool** | | |
| HBsAg | Not required but widely implemented by plasma fractionators | Required |
| Anti-HIV | Not required but widely implemented by plasma fractionators | Required |

**Table 3. FDA and EU NAT Testing Requirements for Plasma for Further Manufacture**

| Screening Test | FDA | EU |
|---|---|---|
| **NAT Testing of Plasma Donations in Minipool Format** | | |
| HIV-1 RNA | Required, using tests with a sensitivity of 10,000 IU/mL for the individual donation | Not required but widely implemented by plasma fractionators |
| HCV RNA | Required, using tests with a sensitivity of 5000 IU/mL for the individual donation | Not required but recommended in order to avoid unnecessary loss of a fractionation pool (see below) |
| WNV RNA | Not required | Not required |
| HBV DNA | Required, using tests with a sensitivity of 500 IU/mL for the individual donation | Not required but widely implemented by plasma fractionators |
| B19V DNA | Required with a manufacturing pool limit of $\leq 10^4$ IU/mL B19V DNA | Required for specific products (anti-D immunoglobulin and pooled S/D-treated plasma); a manufacturing pool limit of B19V DNA $\leq$10 IU/µL is required. This limit is voluntarily implemented by most plasma fractionators for all products. |
| HAV RNA | Not required but widely implemented by plasma fractionators | Required only for S/D-treated plasma; not required for other products but widely implemented by most plasmafractionators |
| HEV | Currently not required | Testing not yet required; testing requirements will be introduced for a specific product only (pooled S/D-treatedplasma). |
| **NAT Testing of the Fractionation Pool** | | |
| HIV-1 RNA | Not required but widely implemented by plasma fractionators | Not required but widely implemented by plasma fractionators |
| HCV RNA | Not required but widely implemented by plasma fractionators | Required; the fractionation pool must be nonreactive using a test that detects 100 IU/mL of HCV RNA. |
| WNV RNA | Not required | Not required |
| HBV DNA | Not required but widely implemented by fractionators | Not required but widely implemented by fractionators |
| B19V DNA | Required; a limit of $\leq 10^4$ IU/mL B19V DNA for fractionation pools is required. | Required for specific products (anti-D immunoglobulin and pooled S/D-treated plasma); a limit of B19V DNA $\leq$10 IU/µL for fractionation pools is required. This limit is voluntarily implemented by most plasma fractionators for all products. |

## CONCLUSIONS

All the measures discussed in this chapter, along with virus-reduction steps included during the manufacturing process, ensure the safety of plasma-derived products. However, testing of plasma for further manufacture is only one of the steps taken to ensure the safety of the final plasma-derived products. Both manufacturers and regulators face continuing challenges because of the emergence of new blood-borne viruses, mutants, and variants of existing viruses not detected by current serological/NAT technology. The development of new screening tests and regulatory guidance documents depends on whether the emerging virus is a risk to the safety of plasma-derived products.

# ⟨1241⟩ WATER–SOLID INTERACTIONS IN PHARMACEUTICAL SYSTEMS

## INTRODUCTION

This general chapter is harmonized with the corresponding texts of the *European Pharmacopoeia* and/or the *Japanese Pharmacopoeia.* These pharmacopeias have undertaken not to make any unilateral change to this harmonized chapter. Portions of the present general chapter text that are national USP text, and therefore not part of the harmonized text, are marked with symbols (•,•) to specify this fact.

Pharmaceutical solids as raw materials or as constituents of dosage forms most often come in contact with water during processing and storage. This may occur (a) during crystallization, lyophilization, wet granulation, or spray drying; and (b) because of exposure upon handling and storage to an atmosphere containing water vapor or exposure to other materials in a dosage form that contain water capable of distributing it to other ingredients. Some properties known to be altered by the association of solids with water include rates of chemical degradation in the "solid-state", crystal growth and dissolution, dispersibility and wetting, powder flow, lubricity, powder compactibility, compact hardness, and microbial contamination.

Although precautions can be taken when water is perceived to be a problem, i.e., eliminating all moisture, reducing contact with the atmosphere, or controlling the relative humidity of the atmosphere, such precautions generally add expense to the process with no guarantee that during the life of the product further problems associated with moisture will be avoided. It is also important to recognize that there are many situations where a certain level of water in a solid is required for proper performance, e.g., powder compaction. It is essential for both reasons, therefore, that as much as possible is known about the effects of moisture on solids before strategies are developed for their handling, storage, and use.

Some of the more critical pieces of required information concerning water–solid interactions are:

- total amount of water present;
- the extent to which adsorption and absorption occur;
- whether or not hydrates form;
- specific surface area of the solid, as well as such properties as degree of crystallinity, degree of porosity, and glass transition and melting temperature;
- site of water interaction, the extent of binding, and the degree of molecular mobility;
- effects of temperature and relative humidity;
- essentially irreversible hydration;
- kinetics of moisture uptake;
- various factors that might influence the rate at which water vapor can be taken up by a solid;
- for water-soluble solids capable of being dissolved by the sorbed water, under which conditions dissolution will take place.

## PHYSICAL STATES OF SORBED WATER

Water can physically interact with solids in different ways. It can interact at the surface (adsorption) or it can penetrate the bulk solid structure (absorption). When both adsorption and absorption occur, the term sorption is often used. Adsorption is particularly critical in affecting the properties of solids when the specific surface area is large. Large values of specific surface area are seen with solids having very small particles, as well as with solids having a high degree of intraparticle porosity. Absorption is characterized by an association of water per gram of solid that is much greater than that which can form a monomolecular layer on the available surface, and an amount that is generally independent of the specific surface area.

Most crystalline solids will not absorb water into their bulk structures because of the close packing and high degree of order of the crystal lattice. Indeed, it has been shown that the degree of absorption into solids exhibiting partial crystallinity and partial amorphous structure is often inversely proportional to the degree of crystallinity. With some crystalline solids, however, crystal hydrates may form. These hydrates may exhibit a stoichiometric relationship, in terms of water molecules bound per solid molecule, or they may be non-stoichiometric. Upon dehydration, crystal hydrates may either retain their original crystal structure, lose their crystallinity and become amorphous, or transform into a new anhydrous or less-hydrated crystal form.

Amorphous or partially amorphous solids are capable of taking up significant amounts of water because there is sufficient molecular disorder in the solid to permit penetration, swelling, or dissolution. Such behavior is observed with most amorphous polymers and with small-molecular-mass solids rendered amorphous during preparation, e.g., by lyophilization, or after milling. The introduction of defects into highly crystalline solids will also produce this behavior. The greater the chemical affinity of water for the solid, the greater the total amount that can be absorbed. When water is absorbed by amorphous solids, the bulk properties of the solid can be significantly altered. It is well established, for example, that amorphous solids, depending on the temperature, can exist in at least one of two states: "glassy" or "fluid"; the temperature at which one state transforms into the other is the glass transition temperature, $T_G$.

Water absorbed into the bulk solid structure, by virtue of its effect on the free volume of the solid, can act as an efficient plasticizer and reduce the value of $T_G$. Because the rheological properties of "fluid" and "glassy" states are quite different, i.e., the "fluid" state exhibits much less viscosity as the temperature rises above the glass transition point, it is not surprising that a number of important bulk properties dependent on the rheology of the solid are affected by moisture content. Because amorphous solids are metastable relative to the crystalline form of the material, with small-molecular-mass materials, it is possible for absorbed moisture to initiate reversion of the solid to the crystalline form, particularly if the solid is transformed by the sorbed water to a "fluid" state. This is the basis of "cake collapse" often observed during the lyophilization process. An additional phenomenon noted specifically with water-soluble solids is their tendency to deliquesce, i.e., to dissolve in their own sorbed water, at relative humidities, $RH_i$, in excess of the relative humidity of a saturated solution of the solid, $RH_0$. Deliquescence arises

Official

https://pharmacopeia.cn/v29240/

because of the high water solubility of the solid and the significant effect it has on the colligative properties of water. It is a dynamic process that continues to occur as long as $RH_I$ is greater than $RH_0$.

The key to understanding the effects water can have on the properties of solids, and vice versa, rests with an understanding of the location of the water molecule and its physical state. More specifically, water associated with solids can exist in a state that is directly bound to the solid, as well as in a state of mobility approaching that of bulk water. This difference in mobility has been observed through such measurements as heat of sorption, freezing point, nuclear magnetic resonance, dielectric properties, and diffusion.

Such changes in mobility have been interpreted as arising because of changes in the thermodynamic state of water as more and more water is sorbed. Thus, water bound directly to a solid is often thought as unavailable to affect the properties of the solid, whereas larger amounts of sorbed water may become more clustered and form water more like that exhibiting solvent properties. In the case of crystal hydrates, the combination of intermolecular forces (hydrogen bonding) and crystal packing can produce very strong water–solid interactions. Recognizing that the presence of water in an amorphous solid can affect the glass transition temperature and hence the physical state of the solid, at low levels of water, most polar amorphous solids are in a highly viscous glassy state because of their high values of $T_G$. Hence, water is "frozen" into the solid structure and is rendered immobile by the high viscosity, e.g., $10^{13}$ Pa · s. As the amount of water sorbed increases and $T_G$ decreases, approaching ambient temperatures, the glassy state approaches that of a "fluid" state and water mobility along with the mobility of the solid itself increases significantly. At high RH, the degree of water plasticization of the solid can be sufficiently high so that water and the solid can now achieve significant amounts of mobility. In general, therefore, this picture of the nature of sorbed water helps to explain the rather significant effect moisture can have on a number of bulk properties of solids such as chemical reactivity and mechanical deformation. It suggests strongly that methods of evaluating chemical and physical stability of solids and solid dosage forms take into account the effects water can have on the solid when it is sorbed, particularly when it enters the solid structure and acts as a plasticizer.

### Rates of Water Uptake

The rate and extent to which solids exposed to the atmosphere might either sorb or desorb water vapor can be a critical factor in the handling of solids. Even the simple act of weighing out samples of solid on an analytical balance and the exposure, therefore, of a thin layer of powder to the atmosphere for a few minutes can lead to significant error in, for example, the estimation of loss on drying values. It is well established that water-soluble solids exposed to relative humidities above that exhibited by a saturated solution of that solid will spontaneously dissolve via deliquescence and continue to dissolve over a long time period. The rate of water uptake in general depends on a number of parameters not found to be critical in equilibrium measurements because rates of sorption are primarily mass-transfer controlled with some contributions from heat-transfer mechanisms. Thus, factors such as vapor diffusion coefficients in air and in the solid, convective airflow, and the surface area and geometry of the solid bed and surrounding environment, can play an important role. Indeed, the method used to make measurements can often be the rate-determining factor because of these environmental and geometric factors.

## DETERMINATION OF SORPTION–DESORPTION ISOTHERMS

### Principle

The tendency to take up water vapor is best assessed by measuring sorption or desorption as a function of relative humidity, at constant temperature, and under conditions where sorption or desorption is essentially occurring independently of time, i.e., equilibrium. Relative humidity, RH, is defined by the following equation:

$$RH = (P_C \times 100)/P_0$$

$P_C$ = pressure of water vapor in the system

$P_0$ = saturation pressure of water vapor under the same conditions

The ratio $P_C/P_0$ is referred to as the relative pressure. Sorption or water uptake is best assessed starting with dried samples and subjecting them to a known relative humidity. Desorption is studied by beginning with a system already containing sorbed water and reducing the relative humidity. As the name indicates, the sorption–desorption isotherm is valid only for the reference temperature, hence a special isotherm exists for each temperature. Ordinarily, at equilibrium, moisture content at a particular relative humidity must be the same, whether determined from sorption or desorption measurements. However, it is common to see sorption–desorption hysteresis.

### Methods

Samples may be stored in chambers at various relative humidities. The mass gained or lost for each sample is then measured. The major advantage of this method is convenience, while the major disadvantages are the slow rate of reaching constant mass, particularly at high relative humidities, and the error introduced in opening and closing the chamber for weighing. Dynamic gravimetric water sorption systems allow the on-line weighing of a sample in a controlled system to assess the interaction of the material with moisture at various programmable levels of relative humidity at a constant temperature. The major benefit of a controlled system is that isothermal conditions can be more reliably established and that the dynamic response of the sample to changing conditions can be monitored (see *Figure 1*).

Figure 1. Example of an apparatus for the determination of the water sorption (other designs are possible).

Data points for the determination of the sorption isotherm (e.g., from 0% to approximately 95% RH, noncondensing) are only taken after a sufficiently constant signal indicates that the sample has reached equilibrium at a given level of humidity. In some cases (e.g., deliquescence), the maximum time may be restricted although the equilibrium level is not reached. The apparatus must adequately control the temperature to ensure a good baseline stability as well as accurate control of the relative humidity generation. The required relative humidities can be generated, e.g., by accurately mixing dry and saturated vapor gas with flow controllers. The electrostatic behavior of the powder must also be considered. The verification of the temperature and the relative humidity (controlled with, for example, a certified hygrometer, certified salt solutions, or deliquescence points of certified salts over an adequate range) must be consistent with the instrument specification. The balance must provide a sufficient mass resolution and long-term stability.

It is also possible to measure amounts of water uptake not detectable gravimetrically using volumetric techniques. In the case of adsorption, to improve sensitivity, the specific surface area of the sample can be increased by reducing particle size or by using larger samples to increase the total area. It is important, however, that such comminution of the solid does not alter the surface structure of the solid or render it more amorphous or otherwise less ordered in crystallinity. For absorption, where water uptake is independent of specific surface area, only increasing sample size will help. Increasing sample size, however, will increase the time to establish some type of equilibrium. To establish accurate values, it is important to get desolvation of the sample as thoroughly as possible. Higher temperatures and lower pressures (vacuum) facilitate this process; however, care must be taken to note any adverse effects this might have on the solid such as dehydration, chemical degradation, or sublimation. Using higher temperatures to induce desorption, as in a thermogravimetric apparatus, likewise must be carefully carried out because of these possible pitfalls.

## Report and Interpretation of the Data

Sorption data are usually reported as a graph of the apparent mass change in percent of the mass of the dry sample as a function of relative humidity or time. Sorption isotherms are reported both in tabular form and as a graph. The measurement method must be traceable with the data.

Adsorption–desorption hysteresis can be interpreted, for example, in terms of the porosity of the sample, its state of agglomeration (capillary condensation), the formation of hydrates, polymorphic change, or liquefying of the sample. Certain types of systems, particularly those with microporous solids and amorphous solids, are capable of sorbing large amounts of water vapor. Here, the amount of water associated with the solid as relative humidity is decreased, is greater than the amount that originally sorbed as the relative humidity was increased. For microporous solids, vapor adsorption–desorption hysteresis is

DOI: https://doi.org/10.31003/USPNF_M99960_01_01
@2024 USPC

an equilibrium phenomenon associated with the process of capillary condensation. This takes place because of the high degree of irregular curvature of the micropores and the fact that they "fill" (adsorption) and "empty" (desorption) under different equilibrium conditions. For nonporous solids capable of absorbing water, hysteresis occurs because of a change in the degree of vapor–solid interaction due to a change in the equilibrium state of the solid, e.g., conformation of polymer chains, or because the time scale for structural equilibrium is longer than the time scale for water desorption. In measuring sorption–desorption isotherms, it is therefore important to establish that something close to an equilibrium state has been reached. Particularly with hydrophilic polymers at high relative humidities, the establishment of water sorption or desorption values independent of time is quite difficult, because one is usually dealing with a polymer plasticized into its "fluid" state, where the solid is undergoing significant change.

In the case of crystal hydrate formation, the plot of water uptake versus pressure or relative humidity will in these cases exhibit a sharp increase in uptake at a particular pressure and the amount of water taken up will usually exhibit a stoichiometric mole:mole ratio of water to solid. In some cases, however, crystal hydrates will not appear to undergo a phase change or the anhydrous form will appear amorphous. Consequently, water sorption or desorption may appear more like that seen with adsorption processes. X-ray crystallographic analysis and thermal analysis are particularly useful for the study of such systems.

For situations where water vapor adsorption occurs predominantly, it is very helpful to measure the specific surface area of the solid by an independent method and to express adsorption as mass of water sorbed per unit area of solid surface. This can be very useful in assessing the possible importance of water sorption in affecting solid properties. For example, 0.5% m/m uptake of water could hardly cover the bare surface of 100 $m^2/g$, while for 1.0 $m^2/g$ this amounts to 100 times more surface coverage. In the case of pharmaceutical solids that have a specific surface area in the range of 0.01 $m^2/g$ to 10 $m^2/g$, what appears to be low water content could represent a significant amount of water for the available surface. Because the "dry surface area" is not a factor in absorption, sorption of water with amorphous or partially amorphous solids can be expressed on the basis of unit mass corrected for crystallinity, when the crystal form does not sorb significant amounts of water relative to the amorphous regions.

## DETERMINATION OF THE WATER ACTIVITY

### Principle

Water activity, $A_W$, is the ratio of vapor pressure of water in the product (P) to saturation pressure of water vapor ($P_0$) at the same temperature. It is numerically equal to 1/100 of the relative humidity (RH) generated by the product in a closed system. RH can be calculated from direct measurements of partial vapor pressure or dew point, or from indirect measurement by sensors whose physical or electric characteristics are altered by the RH to which they are exposed. Ignoring activity coefficients, the relationship between $A_W$ and equilibrium relative humidity (ERH) are represented by the following equations:

$$A_W = P/P_0$$

$$ERH(\%) = A_W \times 100$$

### Method

The water activity is determined by placing the sample in a small airtight cup inside which the equilibrium between the water in the solid and the headspace can be established. The volume of the headspace must be small in relation to the sample volume in order not to change the sorption state of the sample during the test. The equilibration as a thermodynamic process takes time but may be accelerated by forced circulation within the cell. The acquired water activity value is only valid for the simultaneously determined temperature. This requires a precise temperature-measuring device as part of the equipment. Furthermore, the probe must be thermally insulated to guarantee a constant temperature during the test. The sensor measuring the humidity of the headspace air above the sample is a key component. Theoretically, all types of hygrometers can be used, but for analytical purposes miniaturization and robustness are a precondition. The $A_W$ measurement may be conducted using the dew point/chilled mirror method.[1] A polished, chilled mirror is used as a condensing surface. The cooling system is electronically linked to a photoelectric cell into which light is reflected from the condensing mirror. An air stream, in equilibrium with the test sample, is directed at the mirror which cools until condensation occurs on the mirror. The temperature at which this condensation begins is the dew point from which the ERH is determined. Commercially available instruments using the dew point/chilled mirror method or other technologies need to be evaluated for suitability, validated, and calibrated when used to make water activity determinations.

These instruments are typically calibrated over an adequate range, for example, using some saturated salt solutions at 25° such as those listed in *Table 1*.

**Table 1. Standard Saturated Salt Solutions**

| Saturated Salt Solutions at 25° | ERH (%) | $A_W$ |
|---|---|---|
| Potassium sulfate ($K_2SO_4$) | 97.3 | 0.973 |
| Barium chloride ($BaCl_2$) | 90.2 | 0.902 |
| Sodium chloride (NaCl) | 75.3 | 0.753 |

# ⟨1251⟩ WEIGHING ON AN ANALYTICAL BALANCE

## INTRODUCTION

Weighing is a frequent step in analytical procedures, and the balance is an essential piece of laboratory equipment. The general information described here applies directly to electronic balances used in analytical procedures. Although many portions of the chapter are applicable to all balances, some are applicable only to analytical balances. This chapter should not be considered all-inclusive, and other sources of information (e.g., the US National Institute of Science and Technology and balance manufacturers) may be useful and applicable when analysts perform a weighing operation or implement a weighing procedure. The information given in this chapter is applicable not only to balances used for materials that must be accurately weighed (see *Balances* ⟨41⟩) but also to balances used in all analytical procedures.

## QUALIFICATION

Users should consult *Analytical Instrument Qualification* ⟨1058⟩, standard operating procedures, and recommendations from manufacturers when they devise qualification plans.

### Installation

The balance's performance depends on the conditions of the facility where it is installed. Analysts should consult information provided by the manufacturer before they install a balance.

#### SUPPORT SURFACE

The balance should be installed on a solid, level, nonmagnetic surface that minimizes the transmission of vibration (e.g., a floor-mounted, granite weigh bench). If a metallic support surface is used, the surface should be grounded in order to prevent the buildup of static electricity.

#### LOCATION

If possible, the balance should be located in a room that is temperature and humidity controlled. The location should have a clean, consistent electrical power supply. The location should be free of drafts and should not be near ovens, furnaces, air conditioner ducts, or cooling fans from equipment or computers. The balance should be positioned away from outside windows so that direct sunlight does not strike the balance. The balance should not be installed near sources of electromagnetic radiation such as radio-frequency generators, electric motors, or hand-held communication devices (including cordless telephones, cellular telephones, and walkie-talkies). The balance should not be located near magnetic fields induced by laboratory instrumentation or other equipment.

The performance of the balance should be assessed following installation and before use in order to demonstrate adequate performance. In some situations, it may not be possible to position the balance in an optimum environment. Examples of potential facility issues include the following:

1. Air currents sometimes are present in the laboratory.
2. Temperatures in the laboratory vary excessively (check the manufacturer's literature about temperature sensitivity).
3. Humidity is either very low or very high. Either condition may increase the rate at which the sample weight varies because of pickup or loss of water. Low humidity increases the buildup of static electricity.
4. Adjacent operations are causing vibration.
5. Corrosive materials are used nearby or are routinely weighed.
6. The balance is located within a fume hood because it is used to weigh corrosive or hazardous materials.
7. The balance is adjacent to equipment that produces a magnetic field (e.g., a magnetic stirrer).
8. Direct sunlight strikes the balance.

In situations when the balance is located near equipment or systems that induce vibration, drafts, electromagnetic radiation, magnetic fields, or changes in temperature or humidity, the assessment should be conducted with those systems operating in order to duplicate a worst-case scenario.

### Operational Qualification

An operational qualification should be performed either by the user or by a qualified third-party vendor after the equipment has been installed.

As a minimum, the power should be turned on and the balance should be allowed to equilibrate according to the manufacturer's instructions (1–24 h, depending on the type of balance) before use. Depending on the balance, analysts should include the following procedures in the operational qualification:

1. Mechanical mobility of all moveable parts
2. Control of stable indication
3. Manually triggered or automatic adjustment by means of built-in weights

4. Operation of ancillary equipment
5. Tare function
6. Initial calibration

Several types of electronic analytical balances use built-in weights for manually triggered or automatic adjustment. This adjustment usually is applied to reduce the drift of the balance over time and to compensate for drifts caused by variations in the ambient temperature.

Calibration normally is performed as part of the operational qualification, but it also can be performed periodically thereafter. Calibration should be performed at the location where the balance is used in normal operation.

## Performance Qualification

*Table 1* provides a list of the most important balance properties that should be assessed during performance qualification. Depending on the risk of the application and the required weighing process tolerance, some of these tests may be omitted. Tests also can be omitted if there is evidence that the property in question has only minimal effect on the weighing performance. Any procedures used should be consistent with in-house standard operating procedures, applicable for the specific balance, and adequately justified. Performance qualification should be performed periodically as described in standard operating procedures, and the frequency of each of the individual tests can vary depending on the criticality of the property.

The weights that are used to perform the tests should be stored and handled in a manner that minimizes contamination. Before executing the tests, the technician should place the weights in the vicinity of the balance for an appropriate time to reach sufficient thermal equilibrium. If possible, tests should be carried out with a single test weight in order to minimize handling errors, but multiple test weights are permitted.

The tests should be recorded in such a manner that the data can be used to easily track balance performance and to assist in laboratory investigations as needed. Meaningful acceptance criteria can be set depending on the required weighing tolerance, i.e., the maximum allowed deviation permitted by specifications, regulations, etc., of a quantity to be weighed from its target value. Procedures should be in place to address test results that are outside acceptable ranges and to provide assurance that balance cleanliness and environment have not affected the result. Also, a procedure should be in place for removing a balance from operation when observed results fall outside acceptable ranges.

**Table 1. Suggested Performance Tests and Acceptance Criteria**

| Property | Definition | Examples | Acceptance Criteria |
|---|---|---|---|
| Sensitivity | Change in the displayed value divided by the load on the balance, which causes this change. | The test load at or sufficiently close to the capacity of the balance. | NMT 0.05% deviation from 1 (the sensitivity of a correctly adjusted balance), where ⟨41⟩ is applicable. For other uses, respective tolerance requirement divided by 2. |
| Linearity | Ability of a balance to follow the linear relationship between a load and the indicated weighing value. Nonlinearity usually is expressed as the largest magnitude of any linearity deviation within the test interval. | From 3 to 6 points over the range of the balance. | NMT 0.05% deviation where ⟨41⟩ is applicable. For other uses, respective tolerance requirement divided by 2. |
| Eccentricity | Deviation in the measurement value caused by eccentric loading—in other words, the asymmetrical placement of the center of gravity of the load relative to the load receiver. Eccentricity usually is expressed as the largest magnitude of any of the deviations between an off-center reading and the center reading for a given test load. | Performed in the center of gravity and the four quadrants (for rectangular platter shapes) or at analogous locations for other platter shapes. Test load usually should be 30% of the capacity of the balance or higher (refer to the manufacturer's manual for any possible upper limit). | NMT 0.05% deviation where ⟨41⟩ is applicable. For other uses, respective tolerance requirement divided by 2. |
| Repeatability | Ability of a weighing instrument to display identical measurement values for repeated weighings of the same objects under the same conditions, e.g., the same measurement procedure, same operator, same measuring system, same operating conditions, and same location over a short period of time. Repeatability usually is expressed as the standard deviation of multiple weighings. | 10 replicate weighings (using a test weight that is a few percent of the nominal capacity of the balance). | Requirement from ⟨41⟩ where applicable. For other uses, user specified requirements will apply. |

Sensitivity, linearity, and eccentricity all account for systematic deviations; i.e., they limit the accuracy of the balance (based on the definition of accuracy in *Validation of Compendial Procedures* ⟨1225⟩ and ICH Q2). In the International Vocabulary of Metrology (VIM) and documents of the International Organization for Standardization, this concept is referred to as trueness. Because deviations are largely independent from each other, it is not likely that all deviations occur simultaneously and have the same algebraic sign. Therefore the arithmetic addition of all individual deviations to assess the balance accuracy would constitute a rather conservative approach. A quadratic addition of the individual deviations is a more realistic approach. By allocating 50% of the weighing tolerance budget to the acceptance criteria of the individual properties, e.g., sensitivity, linearity, and eccentricity, analysts ensure adherence to the required weighing tolerance. Therefore, the acceptance criteria for the individual properties that account for the systematic deviations are set to weighing tolerance divided by 2. These properties—or a subset of them—also can be taken to fulfill the accuracy requirement described in ⟨41⟩. In this case the acceptance criteria thus allow a maximum deviation of 0.05% for sensitivity, linearity, and eccentricity. Repeatability preferably is tested with a test weight of a few percent of the balance capacity. At the lower end of its measurement range, the performance of laboratory

https://pharmacopeia.cn/v-about/

balances is limited by the finite repeatability, and limitations induced by systematic deviations normally can be neglected. Therefore, the whole weighing tolerance budget can be allocated to the acceptance criterion of the repeatability test.

For the sensitivity and linearity tests as described above, the analyst should use certified weights with an appropriate weight class (e.g., according to International Organization of Legal Metrology R111 or American Society for Testing and Materials E617, available from www.oiml.org and www.astm.org, respectively). [NOTE—If a differential method is used for the linearity test, certified weights may not be required.]

Depending on the acceptance criterion, it may be sufficient to consider only the nominal weight value of the test weights. If the nominal value of the test weight is considered, analysts should ensure that the maximum permissible error does not exceed one-third of the acceptance criterion. Alternatively, if the certified value of the test weight is considered, its calibration uncertainty should not exceed one-third of the acceptance criterion. If more than one weight is used to perform the test, the calibration uncertainties of the weights must be summed and the sum should not exceed one-third of the acceptance criterion. For tests such as eccentricity or repeatability, the use of certified weights is optional, but analysts must ensure that the mass of the weight does not change during the test.

The tests described above also can be included in formal periodic calibration in order to fulfill applicable cGMP requirements.

## Balance Checks

A balance check using an external weight helps ensure that the balance meets weighing tolerance requirements. The balance check is performed at appropriate intervals based on applicable standard operating procedures. The frequency of the balance check depends on the risk of the application and the required weighing tolerance. Checks with external weights can be replaced partially using automatic or manually triggered adjustment by means of built-in weights. When analysts perform the balance check with an external weight, the same acceptance criteria may apply as described in the sensitivity test above.

## Minimum Weight

The minimum net sample weight, in short, minimum weight, $m_{min}$, of an analytical balance can be expressed by the equation:

$$m_{min} = k \times s/\text{required weighing tolerance}$$

where $k$ is the coverage factor (usually 2 or larger) and $s$ is the standard deviation (in a mass unit, e.g., in mg) of NLT 10 replicate measurements of a test weight. If the standard deviation obtained is less than $0.41d$, where $d$ is the scale interval, the standard deviation is replaced by $0.41d$. The lower limit of $0.41d$ for the standard deviation results from the rounding error of the digital indication of a weighing instrument. The rounding error that is allocated to a single reading is calculated as $0.29d$. Note that a weighing always consists of two readings, one before and one after placing/removing the sample on/from the pan, with the difference between the two indications being the net sample weight. The two individual rounding errors are usually added quadratically, leading to $0.41d$. Taring the instrument after placing the tare container on the pan does not affect the rounding error as the zero indication is also rounded. The minimum weight describes the lower limit of the balance below which the required weighing tolerance is not adhered to. The equation above takes into account that the performance of analytical balances at the lower end of the measurement range is limited by the finite repeatability.

For materials that must be accurately weighed, ⟨41⟩ stipulates that repeatability is satisfactory if two times the standard deviation of the weighed value, divided by the desired smallest net weight (smallest net weight that the users plan to use on that balance), does not exceed 0.10%. For this criterion the equation above simplifies to:

$$m_{min} = 2000 \times s$$

If the standard deviation obtained is less than $0.41d$, where $d$ is the scale interval, the standard deviation is replaced by $0.41d$.

If not subject to the requirements of ⟨41⟩, the minimum weight value may vary depending on the required weighing tolerance and the specific use of the balance.

To facilitate handling, the test weight that is used for the repeatability test does not need to be at the minimum weight value but can be larger because the standard deviation of repeatability is only a weak function of the test weight value.

In order to satisfy the required weighing tolerance, when samples are weighed the amount of sample mass (i.e., the net weight) must be equal to or larger than the minimum weight. The minimum weight applies to the sample weight, not to the tare or gross weight.

Factors that can influence repeatability while the balance is in use include:

1. The performance of the balance and thus the minimum weight can vary over time because of changing environmental conditions.
2. Different operators may weigh differently on the balance—i.e., the minimum weight determined by different operators may be different.
3. The standard deviation of a finite number of replicate weighings is only an estimation of the true standard deviation, which is unknown.
4. The determination of the minimum weight with a test weight may not be completely representative for the weighing application.
5. The tare vessel also may influence minimum weight because of the interaction of the environment with the surface of the tare vessel.

For these reasons, when possible, weighings should be made at larger values than the minimum weight, i.e., the desired smallest net weight that the users plan to use on that balance should be larger than the minimum weight.

Official

https://pharmacopeia.com/

# OPERATION OF THE ANALYTICAL BALANCE

Select the appropriate balance for the quantity and performance needed. General chapter ⟨41⟩ provides requirements for balances used for materials that must be accurately weighed. The balance user should check the balance environment (vibration, air currents, and cleanliness) and status of calibration before use.

## Receivers

To ensure suitable performance in measuring the weight of a specimen, analysts should consider selection of a proper receiver for the material.

### GENERAL CHARACTERISTICS

All receivers must be clean, dry, and inert. The total weight of the receiver plus the specimen must not exceed the maximum capacity of the balance. With a properly maintained and adjusted laboratory balance, weighing uncertainty for small samples, i.e., net weights with a mass not exceeding typically a few percent of the capacity of the balance, essentially is determined by the repeatability. However, repeatability depends on the size and surface area of the weighed object. For this reason large or heavy receivers introduce a deviation from the conditions under which the repeatability was determined without considering the receivers. Therefore, either receivers of a low mass and small surface should be used (especially in cases when specimens of low weight are being measured) or the repeatability test should be performed with the receiver placed on the weighing pan as a preload. Receivers should be constructed from nonmagnetic materials in order to prevent magnetic interference with electronic balance components. Receivers should be used at ambient temperature in order to prevent the formation of air currents within the weighing chamber.

### SOLID SAMPLES

Receivers for weighing solid materials include weighing paper, weighing dishes, weighing funnels, or enclosed vessels, including bottles, vials, and flasks. Hygroscopic papers are not recommended for weighing because they may have a detrimental effect on the observed results.

Weighing dishes typically are constructed from a polymer or from aluminum. Antistatic weighing dishes are available for measuring materials that retain static electricity. Weighing funnels typically are constructed from glass or from a polymer. The design of this type of receiver combines attributes of a weighing dish and a transfer funnel, which can simplify the analytical transfer of a weighed powder to a narrow-necked vessel such as a volumetric flask. For solid samples that are volatile or deliquescent, analysts must weigh the material into an enclosed vessel. Where practical, analysts should use an enclosed vessel with a small opening in order to reduce sample weight loss from volatilization or weight gain from the adsorption and absorption of atmospheric water.

### LIQUID SAMPLES

Receivers for liquid samples typically are inert, enclosed vessels. For liquid samples that are volatile or deliquescent, analysts should use an enclosed vessel with a small opening, and the enclosure should be replaced rapidly following material transfer. Special precautions should be taken to be certain that the receiver and the enclosure are constructed from a material that is compatible with the liquid sample. The receiver and enclosure must have a seal that is sufficient to prevent leaks from a liquid that is of low viscosity or has low surface tension or a low boiling point.

## Types of Weighing

### WEIGHING FOR QUANTITATIVE ANALYSIS

The initial step for many quantitative analyses is to accurately weigh a specified amount of a sample. *General Notices, 6.50.20 Solutions* stipulates that solutions for quantitative measures must be prepared using accurately weighed analytes: i.e., analysts must use a balance that meets the criteria in ⟨41⟩. Errors introduced during the weighing of a sample can affect the accuracy of all subsequent analytical measurements.

### ADDITION WEIGHING

Addition weighings typically are used for solid samples or liquid samples for which volatility is not an issue. The receiver is placed on the balance. After the balance display stabilizes, the analyst should tare the balance; add the desired amount of material to the receiver; allow the balance display to stabilize; record the weight; and quantitatively transfer the material to an appropriate vessel or, if it cannot be guaranteed that the entire amount has been transferred, weigh the receiver again and note the weight difference.

### DISPENSE WEIGHING

Dispense weighing typically is used for weighing emulsions or viscous liquids such as ointments. In these situations it is not practical to weigh the material into a typical receiver. Accordingly, the analyst should tare the balance; place the sample on the balance in a suitable container (e.g., a bottle, tube, transfer pipet, or syringe) that has been wiped clean on the outside; record the weight after the balance display stabilizes; transfer the desired amount of sample to an appropriate receiving vessel, such

@2024 USPC

as a volumetric flask; and place the pipet or syringe back onto the balance. The difference in the two weighings is equal to the weight of the transferred specimen.

#### GRAVIMETRIC DOSING

Gravimetric dosing typically is used for sample and standard preparations or capsule filling. For such weighing the analyst places the volumetric flask, vial, or capsule shell on the balance; tares the balance after the balance display stabilizes; adds the solid or liquid components into the receiver by means of dosing units; and records the respective weights.

## Problem Samples

#### ELECTRICALLY CHARGED SAMPLES AND RECEIVERS

Dry, finely divided powders may be charged with static electricity that can make the powder either attracted to or repelled by the receiver or the balance, causing inaccurate weight measurements and specimen loss during transfer. A drift in the balance readings should alert the operator to the possibility that the material has a static charge. Commercially available balances with a built-in antistatic device can be used to remedy the problem. Such devices may use piezoelectric components or a very small amount of a radioactive element (typically polonium) to generate a stream of ions that dissipate the static charge when passed over the powder being weighed. Antistatic weigh boats, antistatic guns, and antistatic screens also are commercially available. The static charge depends also on the relative humidity of the laboratory, which in turn depends on atmospheric conditions. Under certain conditions, static charge is caused by the type of clothing worn by the operator and this charge can cause large errors in the weighing. Borosilicate glassware and plastic receivers have a well-known propensity for picking up static charge, especially at low relative humidity. The gloves used to protect the operator also may increase the potential for a static charge problem. Placing the container in a metal holder may help to shield the static charge, and antistatic gloves also can help to alleviate the problem.

#### VOLATILE SAMPLES

When weighing a liquid that has a low boiling point, analysts must receive the specimen in a vessel with a gas-tight enclosure of small diameter. The analyst then tares the vessel and enclosure, adds the desired amount of sample, and replaces the enclosure. After the balance display stabilizes, the analyst records the specimen weight.

#### WARM OR COOL SAMPLES

Samples that are warm or cool should be equilibrated in the laboratory, or the weight readings may be erroneous. With regard to warm samples, the apparent weight is smaller than the true weight because of heat convection. For example, a flask that is warmer than ambient air warms up this air, which then flows upward along the flask and reduces the apparent weight of the contents by viscous friction.

#### HYGROSCOPIC SAMPLES

Hygroscopic materials readily absorb moisture from the atmosphere and steadily gain weight if left exposed. Therefore, hygroscopic samples must be either weighed promptly or placed in a vessel with a gas-tight enclosure. For a gas-tight vessel, analysts should tare the vessel and enclosure, add the desired amount of sample, and replace the enclosure. After the balance display stabilizes, the analyst can record the specimen weight.

#### ASEPTIC OR BIOHAZARDOUS SAMPLES

The weighing of sterile or biohazardous samples should take place within the confines of a clean bench, biosafety cabinet, isolator, or similar containment device. Air flow within the hood potentially can cause balance instability, so after a balance has been installed under a hood, analysts should perform a rigorous qualification study with suitable weight artifacts (see ⟨41⟩) in order to determine the acceptability of the balance performance in this environment.

#### WEIGHING CORROSIVE MATERIALS

Many chemicals, such as salts, are corrosive, and materials of this nature should not be spilled on the balance pan or inside the balance housing. Extra care is essential when materials of this nature are weighed. Analysts should consider the use of sealed containers such as weighing bottles or syringes. In the event of a spill, requalification of balance may be necessary, depending on the nature of the spill.

## Safety Considerations When Weighing

During a weighing, the analyst may be exposed to high concentrations of a pure substance. The analyst must carefully consider this possibility at all times and should be familiar with the precautions described in the substance's Material Safety Data Sheet before weighing it. Hazardous materials should be handled in an enclosure that has appropriate air filtration. Many toxic—and possibly allergenic—substances present as liquids or finely divided particles. When weighing these substances, analysts should use a mask that covers the nose and mouth to prevent any inhalation of the substance, and they should use gloves to prevent any contact with the skin. [NOTE—The use of gloves is good practice for handling any chemical. If it is necessary

Official

https://pharmacopeia.cn/v29240/

to handle the container being weighed, the analyst should wear gloves not only for self-protection but also to prevent moisture and oils from being deposited on the weighed container.]

# ⟨1265⟩ WRITTEN PRESCRIPTION DRUG INFORMATION—GUIDELINES

The purpose of these guidelines—comprising format, content, and accessibility of prescription drug leaflets—is to help ensure that leaflets are useful. In this context, "useful" means that recipients receive, understand, and are motivated to apply written information about their medicines to achieve maximum benefit and minimize harm. Dispensers, prescribers, health care providers who counsel patients about their medicines, and the patients themselves are intended to be the primary beneficiaries for these guidelines.

## CRITERIA (FROM THE KEYSTONE ACTION PLAN[1])

Written prescription medicine information should be based on the following criteria:

1. Scientifically accurate,
2. Unbiased in content and tone,
3. Sufficiently specific and comprehensive,
4. Presented in an understandable and legible format that is readily comprehensible to consumers,
5. Timely and up-to-date, and
6. Useful.

## FORMAT GUIDELINES

1. Group all information from the same category, using brief, clear titles and bullets or subheadings as needed. Avoid symbols and subheadings not directly connected to the information they mark.
2. Be consistent in the placement and labeling of categories of information in all leaflets.
3. Provide information at the sixth-grade reading level or below, if possible (never above eighth-grade level). Do not exclude information to achieve a lower reading level.
4. Use simple, common, accurate terms (for example, use "noise in the ears", not "tinnitus").
5. Use direct language that avoids words with opposite meanings (for example, use "decrease blood pressure", not "increase low blood pressure effect").
6. Provide reasons for instructions (for example, "take with food to avoid upset stomach").
7. Emphasize the most important information. Clearly distinguish warnings from instructions or from other text that may be misinterpreted as warnings.
8. Accompany each pictogram, if used, with corresponding text placed close to the pictogram. Use the simplest pictograms possible. For pictograms intended to prompt patients to ask questions or inform health care providers, add text such as "Tell Doctor" or "Ask Pharmacist".
9. Make text readable by using 12-point or larger type, both uppercase and lowercase letters, an easy-to-read font (for example, a serif font), and adequate space between lines and paragraphs. To call attention to important information, use a larger, boldface type.
10. Evaluate format by performing tests of readability, comprehension, memory, problem solving, and behavioral efficacy and intention, using representative samples of the target population.

## CONTENT GUIDELINES

1. Provide enough detail to facilitate correct use, achieve maximum benefit, and minimize harm, including a statement that identifies activities (such as driving or sunbathing) that the patient should avoid.
2. Write text that is unbiased in content and tone and scientifically accurate. The uses described should be consistent with FDA-approved labeling or otherwise permitted by FDA, or should appear in federally recognized drug compendia. Distinguish unlabeled from labeled use.
3. For drugs sold under a brand name, provide both brand and generic names, and include a pronunciation guide for each.
4. Describe the drug and its dosage form. Include indications and contraindications, specific directions for use, what to do if a dose is missed, and what to do in the event of an overdose or poisoning.
5. Do not use abbreviations.
6. Indicate the intended type of benefit (for example, "cure", "prevention", "to help relieve symptoms"). Indicate how—and how soon—the patient should recognize the benefit and what to do if none is observed.
7. Give a balanced evaluation of risks and benefits.
8. List side effects, in order of severity, such as "serious", "most common", and other similar type groupings. It may not be appropriate to provide sufficient detail for the patient to be able to monitor serious or common side effects. Provide guidance to consult the doctor or pharmacist, and indicate that not all the side effects are listed.

[1] In December 1996, the "Action Plan for the Provision of Useful Prescription Medicine Information" was presented to the Secretary of Health and Human Services. The plan, commonly known as the "Keystone Plan," described certain criteria for written prescription medicine information. These criteria are described in detail in the action plan, which can be found at www.fda.gov/cder/offices/ods/keystone.pdf.

Official

https://pharmacopeia.com/

9. List sufficiently specific and comprehensive information that includes the provision of all important risk information. Patients should be advised to be sure to inform the provider about all the medicines they are taking.
10. Indicate the potential for therapeutic duplication if the drug is available under multiple names or over-the-counter, or if the active ingredient is contained in other products.
11. If known, include a statement concerning the safety of use in the presence of other conditions and during pregnancy or breast-feeding. Direct affected patients to discuss their condition with health care providers. If the safety of use during pregnancy or breast-feeding has not been established, say so.
12. State whether safety and efficacy have been established in pediatric, geriatric, and other special populations. Patients should be encouraged to discuss with their health care provider any recommendations for dosage adjustment.
13. Illustrate information with diagrams when appropriate. Label the diagram components (for example, device parts) if they are not obvious. The words on the label should be prominently placed thereon with such conspicuousness and in such terms as to render them likely to be read and understood by the ordinary individual under customary conditions of purchase and use.
14. Include the following:
    A. A statement that the product is to be used only by the person for whom it was prescribed,
    B. Storage information,
    C. A completeness disclaimer advising the patient to discuss this issue with the health care provider,
    D. The publisher of the leaflet and the date the leaflet was developed or revised,
    E. Sources of in-depth information and answers to questions, and
    F. Other relevant general statements.
15. The patient should be advised about risks of developing dependence on, or tolerance to, the medication.

## ACCESSIBILITY GUIDELINES

1. Write text that is relevant to the intended use of the drug.
2. Design the leaflets to be easy to recognize, consistent in format, and easy to store and retrieve.
3. Supplement the leaflets with oral counseling of patients, including children, the elderly, and caregivers.
4. Include a statement asking the patient to reread the leaflet.
5. Distribute the leaflets with all prescription medicines to consumers (namely, persons independently responsible for any aspect of medicine use or for giving medicines to others).
6. Produce leaflets in Spanish, English, or other languages; and establish criteria for producing them in other languages and for special populations (for example, children, visually handicapped) [NOTE—Ideally, prescription drug information leaflets would be customized for the patient's condition and for other relevant information (for example, gender, age, or physical limitations), and would be available in the patient's primary language. Currently, such customization is neither feasible nor practical, but it remains a goal.]

# ⟨1285.1⟩ HEMATOXYLIN AND EOSIN STAINING OF SECTIONED TISSUE FOR MICROSCOPIC EXAMINATION

## INTRODUCTION

Histologic methods involve the preparation of organs, tissues, or cells for microscopic analysis of constituent elements that have been exposed to particular chemistries or immunochemical staining procedures. Histologic methods have many goals, and are often used to evaluate native and processed therapeutic tissue-based products. For example, these methods can be used to establish the integrity of the tissue with regard to cellular content and extracellular constituents. Nuclear staining intensity and nuclear shape may be altered if tissue recovery or handling is compromised. Furthermore, extracellular structural and accessory components such as collagen, elastin, and glycosaminoglycans can be specifically stained so their presence and location can be determined.

Histologic methods are particularly useful for detecting trends in content (e.g., cell numbers and amounts of tissue constituents). Therefore, they have been valuable in the development and verification of tissue-processing methods intended to reduce or eliminate cellular content (decellularization detected by reduced nuclear staining, for example with hematoxylin) while maintaining extracellular matrix structure and components (e.g., retention of glycosaminoglycans or other carbohydrates assessed by persistence in Alcian blue staining).

Tissue histologic analysis typically begins with a routine staining procedure using hematoxylin and eosin (H&E) to detect cellular chromatin and cytoplasm and extracellular structures (e.g., collagen and muscle). Hematoxylin acts as a basic dye. In a metal complex it binds to acidic structures such as cellular nucleic acids (DNA or RNA), producing the blue–purple stain typically noted as nuclear staining. Additionally, in calcified tissues it forms a blue or purple precipitate. Eosin acts as an acid dye and stains basic materials red (muscle) to pink (collagen). Eosin staining is responsible for the detection of the cytoplasm and intracellular and extracellular proteins, but it does not allow identification of specific intracellular structures or proteins. H&E does not stain fat itself, but fatty areas can be identified by the staining of the stroma, yielding an outline of adipocytes.

H&E staining is often used to demonstrate the reduction of nuclei following tissue decellularization processes, but H&E staining also provides structural information. H&E staining reveals that Type I collagen fibrils have a particular arrangement and wave pattern depending on the tissue observed and the orientation of the specimen. Altered collagen fibril patterns, e.g., smearing and loss of fibrils, may suggest disruption of the native structure of the tissue. Decellularization methods, which can alter the structural integrity of tissue, may reduce the staining intensity of collagen. Alternatively, the staining intensity can be artificially increased if residual charged processing chemicals remain in the tissues. H&E staining can help identify noncollagen protein structures. For example, elastin fibers are not specifically stained by this method, but thick elastin fibers such as the internal elastic lamina of arteries are easily detected by their profound waviness and subintimal location shown by staining. A mineralized matrix (e.g., in bone) can be seen as dark red to purple (depending on the hematoxylin choice) granular staining within fields of structural protein fibers.

H&E staining is a starting point for more detailed histologic analysis. Differential staining of collagen (typically colored blue) is achieved with Masson Trichrome stain, and Verhoeff's Van Gieson and Movat Pentachrome stains highlight elastin (black). The other major components of connective tissues are the glycosaminoglycans, and these can be detected and to some extent differentiated with various cationic dyes such as Alcian blue in Movat's Pentachrome stain, for example.

More detailed compositional analysis of tissues and observations of the effects of decellularization methods require structure-specific probes. At the level of light microscopy, this specificity is provided by immunohistochemical staining using antibodies to targeted structural proteins and extracellular matrix constituents or by using labeled lectin probes to detect certain sugar structures. The latter are of particular utility for evaluating the removal of important xeno-antigenic epitopes.

The purpose of this chapter is to identify the factors that should be controlled to optimize the consistency of the results of tissue staining with H&E. In addition, the chapter provides a common H&E staining procedure.

## BASIC PRINCIPLES

Hematoxylin is oxidized to hematein, which complexes with a metal cation, binds to negatively charged groups, and stains basophilic substances such as nucleic acids. The most common cation for this application is aluminum (III), but iron (III) and tungsten also are important. Hematoxylin also stains calcium deposits. The most common metal used in hematoxylin staining is aluminum, and the resulting stain produces a blue color. This aluminum salt form of hematoxylin requires a pH >5 to form an insoluble blue aluminum hematein complex. The high pH is obtained in a bluing step using a weak alkali solution such as ammonium water. Because anionic materials often are used to process tissue (e.g., anionic detergents), these materials should be removed from the tissue first, or nonspecific hematoxylin staining may be seen.

Eosin is an acidic analine dye with affinity for cationic amino acids such as arginine and lysine in proteins. Cytoplasm, muscle, connective tissue, colloid, red blood cells, and decalcified bone matrix all stain pink to pink/orange/red with eosin. Eosin methods use solutions containing various proportions of water, ethanol, and acetic acid. The uptake of eosin in cells is promoted by higher eosin concentration, a higher proportion of water than ethanol, and the inclusion of acetic acid.

## PROCEDURES—POINTS TO CONSIDER

It is important to control the consistency and quality of the stain reagents and process. Each new lot of stains should be qualified with known control specimens to ensure consistent staining processes. Solution color should be monitored, and if colorless solutions become colored they should be discarded (especially the alcohols and xylene). Staining solutions can age,

@2024 USPC

and their staining effectiveness changes over time. Thus analysts should establish or assign a shelf life to critical staining reagents. Some reagents form precipitates or undergo overt color changes over time. Best practices indicate that such solutions should be replaced. Labeled expiration dates of commercial stains should be followed closely. If reagents are mixed in the laboratory, analysts should monitor their performance over time using control specimens to assess staining intensity and differentiation. Expiration dates should be added for each laboratory reagent. Best practices require that to the extent possible samples to be compared should be stained at the same time. To facilitate comparison, staining should be monitored and corrected if necessary. Regressive staining can be performed if overstaining with hematoxylin occurs. In this case, excess stain is removed with acid (e.g., 0.5% HCl in 70% ethanol) in a step called differentiation. Excessive hematoxylin staining can block eosin staining. Ideally, progressive staining, or real-time monitoring of the staining process to the desired intensity, should occur.

As with any tissue-staining method, H&E staining intensity may be affected by steps taken before the staining procedure, the chemicals used, and the conduct of the staining itself. Section thickness can affect the overall specimen depth and can influence the apparent stain. Inadequate removal of paraffin wax can prevent interaction of the aqueous solutions of the staining steps with the tissue. The color can be too strong if certain hematoxylin reagents are not diluted before use, if the stain is applied for too long, if the differentiation step is too short, or if the acid is too dilute. Weak staining can be the result of exhausted hematoxylin, short staining time, overdifferentiation, or low pH during the bluing step.

## SYSTEM SUITABILITY

Control tissue should be used during each run to ensure that all the reagents are working appropriately and the processing regime does not adversely affect staining. Untreated fresh tissue makes a good positive control, because there are no processing reagents that could affect the staining process. An appropriate negative control is an unstained sample from a previous lot that met all the product quality criteria of the H&E analysis. Controls are important because processing methodologies such as decellularization or cross-linking may positively or negatively affect the ability of the reagents to stain the tissue as expected and can contribute to lot-to-lot variability in staining intensity.

## QUANTITATION

A physical count of positively stained cells in a given area (cells/mm$^2$) is preferable to simply comparing a sample to a previously submitted visual reference, particularly for products that undergo a decellularization process that yields a greatly reduced (yet nonzero) number of positively stained cells. Many, though not all, samples of tissues that have undergone a process of cellular removal still have identifiable cellular debris after processing. It is difficult to compare these nonzero samples to a visual reference, so a standardized count per area is a better comparison of process effectiveness.

Software-based automated cell-counting systems that are available on many microscopy systems must be validated to confirm that the software appropriately counts cells and sample area. When the tissue has not been decellularized, there should be a high value of positive signals, and the system should be able to accurately differentiate that tissue from other samples with low cell counts. Validation is important when analysts attempt to quantify the number of cells in a given area on irregularly shaped samples because the algorithm used to estimate areas may have limitations when applied to these types of samples. Sample area should be measured accurately when there is a low cell count, because a large error in the denominator can cause a significant error in the reported cell density.

## EXAMPLE PROTOCOL

A common H&E method is described below. Analysts can follow this example after preparing and deparaffinizing tissue sample slides as described in *Preparation of Biological Specimens for Histologic and Immunohistochemical Analysis* ⟨1285⟩. This protocol is commonly used to study the effectiveness of tissue decellularization.

**Bluing reagent:** 3 mL of 28% ammonium hydroxide in 1 L of *Purified Water*

**Staining method:** After deparaffinizing tissue-containing slides, place the slides in a hematoxylin solution[1] for 1.5–3 min. [NOTE—Staining times can vary depending on hematoxylin brands (and type) and the tissues being stained, so optimization of staining time is required in this step. For this reason, laboratories should track the reagent sources to ensure consistency.] Rinse slides under running tap water for 0.5–3 min. If necessary, perform a differentiation step to remove excess stain so the desired element or structure is left stained by placing the slide in a clarifying solution[2] for 30–60 s followed by rinsing in tap water for 30–60 s. Next, place slides in *Bluing reagent* for 1–2 min. Dip slides 12 times in *Purified Water*. Rinse thoroughly in tap water for 0.5–2 min to remove the *Bluing reagent*. [NOTE—Insufficient rinsing affects subsequent staining because of a change in pH.] Next, place the slides in the following solutions for the specified times: 95% ethanol for 30 s to 1 min [NOTE—The time will vary depending on eosin type and components.] then place the slides in eosin solution[3] for 45 s to 3 min, 70% ethanol for 3 min, 95% ethanol for 3 min, and finally 100% ethanol for 3 min. [NOTE—Alcohol washing must be closely monitored to avoid excessive removal of eosin stain. Excessive removal of eosin from the extracellular matrix can be seen as pale pink staining.] Place slides in three changes of fresh xylene or xylene substitute for 1–3 min each. Place a couple drops of mounting medium on the slide, and apply the cover slip.

**Expected results:** Nuclei should be stained blue. Cartilage and calcium deposits should stain various shades of blue. Cytoplasm and other tissue constituents stain various shades of pink. Erythrocytes and eosinophilic granules stain bright pink to red.

## CONCLUSIONS

It is critically important to test and verify staining conditions for each new tissue being studied. Staining intensity may be altered by tissue treatment before processing. A notable example is the treatment of tissues to decellularize or antigenically modify them, because these procedures may affect tissue components and may alter the staining of the remaining constituents.

# ⟨1285⟩ PREPARATION OF BIOLOGICAL SPECIMENS FOR HISTOLOGIC AND IMMUNOHISTOCHEMICAL ANALYSIS

## INTRODUCTION

Histology and immunohistochemistry (IHC) are commonly used to visualize the cellular and biochemical constituents of tissues. Whether the attributes to be probed are detected based on chemical reactivities (histochemistry) or are detected using antibodies (IHC) or lectins with known specificities, the preparation of the specimen for staining is a critical phase of the analysis. Preparation typically involves (1) tissue fixation, (2) mounting the tissue in an embedding medium to permit sectioning that is sufficiently thin for the tissue to be viewed microscopically, and then (3) removal of any embedding medium before histochemical or IHC evaluation.

The purpose of this chapter is to identify factors that should be controlled to optimize the consistency of tissue staining results. The following sections address tissue fixation used to prevent degradation and to prepare the tissue for sectioning and staining. Since these methods are often used to characterize tissue-based therapeutic products and the adequacy of their process methods, USP sometimes includes visual tools to support those product monographs. USP Authentic Visual References (AVRs) are often histology images that have been prepared as described in this chapter and are used as reference standards associated with product monographs. The purpose of histologic analysis is to generate visual images that can be used either for illustration or as a visual reference. When used as AVRs, the image set should include representative images of both failed and passing samples at different magnifications. AVRs can be used to better clarify specifications and acceptance criteria related to, for example, cell content, collagen structure, or integrity.

## BASIC PRINCIPLES

The sample tissue must be properly and adequately treated or fixed to limit changes to the extracellular matrix elements or to specific constituents such as cells or proteins. Tissue fixation typically employs a chemical that can rapidly permeate the tissue to effectively cross-link proteins and limit degradation caused by either chemical or enzymatic action. Standard fixation methods typically use 10% neutral buffered histological-grade formalin and are adequate for most, if not all, histochemical analyses. Formalin fixation provides material suitable for IHC analysis provided that proper attention is paid to postfixation treatments (collectively known as antigen retrieval). Once tissue is properly fixed, it can be embedded.

The tissue is embedded in a medium that is sufficiently stiff to maintain sample geometry and the desired orientation for sectioning but is soft enough to be easily and rapidly cut through without distortion. The most common medium used is paraffin, although it is not suitable for nondecalcified hard tissues and other stiff materials (e.g., hard polymers or metals). Because paraffin is not water soluble, tissue generally is passed through a graded series of increasing concentrations of ethanol and finally into xylene (or a suitable substitute) in which the paraffin wax is soluble. Sufficient time is allowed for the paraffin to permeate the tissue, and then the block is sectioned to the desired thickness. Hard tissues commonly are embedded in hard plastics such as poly(methyl methacrylate).

After sectioning, the samples are floated on warm water with or without gelatin so they can be transferred to microscope slides. If the sections are to be used for IHC, it is recommended that gelatin not be used in the water because it can contribute significantly to background staining. Positively charged slides also are recommended to aid in sample retention throughout the IHC processing regime. The sections are allowed to dry in air, in a slide warmer, or in an oven at no more than 50°. Because most histochemical and IHC procedures are carried out under aqueous conditions, the paraffin within the mounted tissue sections must be removed. This is accomplished by reversing the xylene and alcohol rinses until the samples are rinsed in water immediately before staining.

The mounted sections are now ready for histochemical staining. If an immunological staining method is to be used, in most cases an antigen retrieval step will be necessary to break the protein cross-links formed by formalin fixation. Many procedures are available to accomplish this, and although heat treatment in acid vapor appears to be effective in recovering the reactivity of most targets in tissues, the ultimate choice may depend on the characteristics of the target to be evaluated.

## PROCEDURES—POINTS TO CONSIDER

### Fixation

The most common fixatives are aldehydes, alcohols, and oxidizing agents. Each has advantages and disadvantages depending on the particular purpose (see *Table 1*).

**Table 1. Attributes of Common Tissue Fixatives**

| Fixative Name | Mechanism | Advantages | Disadvantages | Notes |
|---|---|---|---|---|
| Formaldehyde (e.g., 10% neutral buffered formalin) | Cross-links protein | Minimal alteration of protein structure and antigenicity; good penetration | Buffered version is preferred to counteract oxidation of formaldehyde to formic acid, which tends to cause a brown artifact. | Unbuffered precipitates can form, and will be acidic (pH 3–4.6). |

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M7829_01_01
@2024 USPC

**Table 1. Attributes of Common Tissue Fixatives** *(continued)*

| Fixative Name | Mechanism | Advantages | Disadvantages | Notes |
|---|---|---|---|---|
| Glutaraldehyde (e.g., 0.25%–4%) | Cross-links protein | Morphology suitable for electron microscopy | Deforms α-helix structure of protein, so not good for IHC; slow penetration | Use with 2–3 µm thick sections. Opens structures such as blood vessels to improve access to all tissue surfaces and to prevent opposing surfaces from bonding to each other |
| Alcohols (e.g., methanol or ethanol) | Denature proteins | Best applied to cytologic smears; good penetration | Can cause tissue hardness and brittleness, making sectioning difficult | |
| Permanganates, dichromates, or osmium tetroxide | Oxidizing agents that cross-link proteins | Fixation of cytoplasm without precipitation; fixation of lipids, especially phospholipids | Causes substantial denaturation; uncommon | |
| Picrates | Oxidizing agents that cross-link proteins | Good retention of nuclear structure with limited tissue hardening | Explosion hazard; causes cell shrinkage | |

Tissue that is not appropriately fixed will not embed and section well, and subsequently will not stain well. Adequate fixation time is of primary importance in quality assurance. Fixatives usually are delivered at a 15:1 to 20:1 ratio of fixative volume to tissue mass. Alternatively, multiple changes of fixative can be used with agitation. It is important to expose tissues to fixatives for a sufficient time, making sure that the sample does not dry before or during this process. Even small tissue pieces may require 12–24 h of exposure time. Tissue handling also is important because areas that are physically gripped may not be fixed as rapidly as areas that are not gripped.

Typical concentrations for some fixatives are shown in *Table 1*. Note that if fixation concentrations are too high or if fixation time is too long, structural artifacts can form. The fixation temperature can be increased somewhat but not to the extent that will cause protein denaturation.

Buffers also are important for high-quality fixation. A pH range of 6–8 usually is best because it will most likely maintain the native tissue structure. Buffering must be sufficient to overcome acidification caused by hypoxia and to prevent black deposits of formalin–heme.

## Tissue Processing

### DEHYDRATION

Once the tissue is properly fixed, it is ready for dehydration and the embedding process. The most common dehydrants are alcohols, but sometimes acetone is used because it rapidly fixes the tissue (although it is a fire hazard). Tissues may be physically damaged if they are insufficiently dehydrated, often because of water contamination of ethanol wash solutions. After dehydration, the tissue is placed in a clearing agent before embedding. Some common clearing agents are the following: xylene, toluene, chloroform, methyl salicylate, limonene (a volatile oil found in citrus peels), or some commercial xylene substitutes.[1]

### EMBEDDING

Depending on the tissue type and subsequent staining protocol, there are several embedding and mounting-media options. Paraffin is most commonly used to embed tissues. Its density is similar to that of most tissues, which facilitates sectioning, and multiple paraffin types with different melting points and hardness can be evaluated if tissue sections do not cut smoothly. If very thin sections are needed or if harder tissues (e.g., bone) will be embedded, plastics are good options (e.g., methacrylate, glycol methacrylate, araldite resin, or epon). Once the mounting medium is selected, the specimen should be carefully aligned and oriented in the medium relative to the desired cutting plane. Tissues that are properly fixed and embedded, if stored appropriately, can stay in this form indefinitely before staining.

Tissues can be embedded manually or with automated systems. Some embedding systems have a chamber for keeping molds and samples hot and ready for embedding. They also may have a separate chamber to melt paraffin, an attached dispenser for pouring paraffin into embedding molds, and a separate cold plate to cool the recently embedded tissues. Both manual and automated station methods are essentially the same and are well accepted as tissue embedding methods. The only difference is that the latter are semi-automated so that the system is operational within an hour or less (i.e., paraffin is melted, heating chambers are warmed, and the cold plate is cooled). Manual methods are somewhat slower. Regardless of the system used, the integrity of the histological section must not be compromised.

### SECTIONING

When tissue blocks are ready for staining, sections are cut with a sharp knife or disposable blades. Paraffin-embedded tissue sections typically are 4–8 µm thick, but plastic-embedded tissues usually are 2 µm thick. The tissue sections are placed on slides and can be stored in this state. The slides are cleared again (to dissolve the paraffin) and are rehydrated before staining or IHC. In all cases analysts should be aware of the importance of each step in order to avoid producing artifacts (e.g., fixation-related shrinkage or nicks, folds, or tears in the tissue sections caused by improper microtome work or a knife that is too dull). Once the staining procedure is complete, analysts should apply sufficient mounting medium over the tissue sections in order to avoid entrapment of air bubbles when a cover slip is applied.

[1] For example, Clear Rite, Pro Par Clearant.

https://pharmacopeia.cn/

## Example Protocol

The following is an example of a fixation, paraffin-embedding, and processing method that is commonly used before hematoxylin and eosin (H&E) staining to study the effectiveness of tissue decellularization processes.

**Fixation solution:** 0.1 M sodium phosphate, pH 7, containing 10% formalin

**Paraffin:** Melt paraffin at 60° for 3 h before analysis. [NOTE—For proper infiltration and success in later steps, it is best to keep the *Paraffin* fresh (free of clearing agent) with frequent changes of paraffin (at least two changes). The temperature of the *Paraffin* must be NMT 2°–4° above its melting point; otherwise, the tissues exposed to overheated *Paraffin* will overharden.]

**Paraffin solution 1:** *Paraffin* and xylene (1:3) or a xylene substitute[2]

**Paraffin solution 2:** *Paraffin* and xylene (1:1) or a xylene substitute

**Paraffin solution 3:** *Paraffin* and xylene (3:1) or a xylene substitute

**Fixation and dehydration, clearing, and paraffin infiltration of the tissue (DCI):** Place each tissue sample (NMT 1 $cm^3$) in *Fixation solution* for a minimum of 6–8 h. The volume of *Fixation solution* should be NLT 15–20 times the volume of the tissue sample. [NOTE—When processing bone samples, thoroughly fix before decalcification and DCI. In this case, after fixation, rinse the sample with Purified Water, and place in a rapid decalcifier solution[3] for the recommended time. After decalcification, rinse the bone samples with Purified Water again, and place them back in the *Fixation solution*.] Place each tissue sample in an embedding cassette, and label the cassette with a pencil or histology pen. Place cassettes in the following series of solutions for 30 min each: 2 changes of 70% ethanol, 2 changes of 95% ethanol, and 3 changes of 100% ethanol. [NOTE—An optional approach is to transfer cassettes directly from 100% ethanol to 100% xylene for 3 changes. Place cassettes in *Paraffin* heated to 2°–4° above its melting point for 1–3 changes for NLT 90 min and NMT 180 min. Exposure to prolonged heat causes shrinkage and hardening of tissues. Avoid overnight treatment.] Next, place cassettes in the following series of solutions for 60 min each at 60°: *Paraffin solution 1, Paraffin solution 2,* and *Paraffin solution 3*.

**Tissue embedding:** [NOTE—This example is a manual method, but an automated embedding method can be substituted.] Move the container with the cassettes described above from the incubator into a 60° water bath to prevent the infiltrated paraffin from solidifying during the embedding procedure. [NOTE—For easier release later from the embedding molds, molds can be sprayed with a diluted mold-release concentrate.] Place a small amount of *Paraffin* into a room-temperature base mold. Using forceps, remove a tissue-containing cassette from the liquid *Paraffin*, and position the tissue section with the desired orientation in the mold before the *Paraffin* solidifies. [NOTE—If it is not positioned properly, the tissue sample can be placed back into the tissue cassette containing the liquid *Paraffin,* and then a new mold can be prepared and tissue positioning can be attempted again.] Once the tissue is in place, place the labeled portion of the tissue cassette onto the base mold, and add *Paraffin* to a level just below the lip of the cassette. Place the cassette mold assembly onto a frozen cold plate. When the *Paraffin* begins to solidify on top, transfer the assembly to an ice bath until the entire block is solidified (about 20 min). Once the *Paraffin* is solidified, carefully separate the base mold from embedded tissue without using excessive force. Store blocks at 4° until needed for sectioning. Blocks can be sectioned immediately, but it is advisable to wait at least 24 h for best results.

**Sectioning paraffin-embedded tissue:** Using an appropriate marker, label glass slides with a tissue-sample identifier. Select an embedded tissue block, and trim any excess wax remaining around the edges of the block. Fill a flotation bath with Purified Water, with or without gelatin (histology samples only), and warm to 36°–46°. Carefully place a new microtome blade into the blade holder. Ensure that the blade is locked into place. If available, select the manual or motorized mode of the microtome. Place the tissue block in the microtome cassette holder, and adjust its orientation using the adjusting screws until the block is correctly positioned vertically and horizontally in relation to the blade. Select the *trim* setting. [NOTE—The trim cut usually is set to 15–16 µm, but this can be increased if a large amount of trimming is necessary, or can be decreased if only a small amount of tissue is present in the block. In addition, blocks can be refrigerated or placed on ice before sectioning to keep them cool and firm.] Advance the block forward to the desired position. Once the block is positioned, start trimming or "facing" the block. After the tissue is visible in the sections, set an appropriate sectioning depth and begin collecting tissue sections. [NOTE—Routine H&E sections should be cut at approximately 6 µm, but the section thickness can be adjusted between 4 and 8 µm as necessary if there is difficulty obtaining good-quality sections.] Using forceps, transfer the sections to the tissue flotation bath. Gently place the ribbon of sections onto the water surface while gently pulling to eliminate any wrinkles from the ribbon. [NOTE—If the water in the flotation bath becomes too hot, the tissue sections will fragment. If this occurs, decrease the heat setting on the bath, and allow the water to cool before proceeding.] Next, separate one or two adjacent, intact, full sections from the ribbon with a sharp dissecting probe or forceps. Using a glass slide placed at approximately a 45° angle beneath the section, lift the sections onto the slide. Gently tap off the excess water, and allow the sample to dry. As needed, repeat the sectioning process for additional samples. After all slides have been prepared and before staining, allow the slides to air-dry for NLT 15 min or until no water droplets are visible. Remove the wax blocks from the microtome, and store appropriately.

**Deparaffinization and rehydration of histological slides:** Before staining, place slides with mounted tissue specimens in either Coplin jars, reagent buckets, or staining racks. Place slides in the following solutions for at least 3 min each: 3 changes of xylene (or a xylene substitute), then 100% ethanol, then 95% ethanol, then 70% ethanol, then 2 changes of Purified Water. Proceed with the desired staining procedure. [NOTE—Slides can be left in the water for several hours but then must be stained.]

## METHOD DEVELOPMENT AND VALIDATION: POINTS TO CONSIDER

Histological methods sometimes are used to demonstrate that cells within a tissue sample are still viable (e.g., when evaluating a cryopreservation method's performance). In other circumstances, the method is used to evaluate the absence of viable cells following a decellularization process. Each case presents specific validation challenges.

H&E staining provides a useful tool for determining whether significant quantities of cells are still viable after preservation. During method validation, immunohistological stains can be used to ensure that specific cell types are still present in the preserved samples. Testing samples for all expected cell types during the validation phase provides support for the less specific H&E staining (that will stain all cells and not just specific cell types) during routine monitoring.

When validating any histological method, analysts should demonstrate that different observers can detect the same quality (or quantity) of an object, tissue type, cell body, nucleus, etc., and that the characterization by different observers can be replicated in several specimens following the same process. Samples for evaluation may consist of multiple types of cells, extracellular matrix proteins, and glycosaminoglycans, or other components. Some of these components may be resistant to decellularization processes or may be difficult to stain. During assessment of method reproducibility, analysts should evaluate multiple samples throughout the sample to ensure that they are representative of the types of materials expected to be found in the matrix. In addition, because inadequate decellularization procedures may not remove all cells throughout the material, it is important to take samples from multiple locations in the tissue so that remaining cells are not underestimated. Intra-operator reproducibility also should be a part of the assessment because the relatively weaker signal from fewer positively stained cells may make visualization more challenging for some technicians. The method validation should use samples that underwent worst-case decellularization processing conditions as determined by statistical modeling to ensure that residual cells can still be identified and quantified in these marginal samples. Finally, the validation of the method should include control samples to confirm the suitability of the staining system (see *Hematoxylin and Eosin Staining of Sectioned Tissue for Microscopic Examination* ⟨1285.1⟩).

The histological assessment of decellularized tissue-based matrix products is one tool to characterize the matrix but cannot be the sole indicator of product quality. On the one hand, processing may generate decellularized matrix products that have no detectable cells but may not possess other critical quality attributes. On the other hand, tissue matrix products undergoing other decellularization processes may result in products with greatly reduced cellular content (although some cells may remain) that retain the necessary performance characteristics for that therapeutic purpose.

### Sample Selection for the Analysis of a Decellularization Process

Samples cannot always be taken from a random location within the product. For example, it is not practical to pull a sample from the center of a sheet of decellularized pericardium without creating a defect that would make the end product undesirable. If routine sampling plans require sampling from the edges or waste portion of a given matrix, analysts should conduct an initial validation study that confirms that such a sample is representative of the whole. This is important because the geometry of the matrix may affect the exposure of the matrix to the decellularization processing solutions. For example, if the tissue matrix is tubular, e.g., a nerve segment, and a sample is taken from the end for histological assessment, then this sample will have different exposure to solutions than a sample taken from the center of the nerve segment. Thus, the sampling may not represent a worst-case assessment, and the suitability of the sample should be determined by means of a validation study.

## CONCLUSIONS

This chapter outlines common steps to prepare tissue or organ specimens for light microscopic analysis following either staining or treatment with structure-specific probes. Each of these steps can produce specimen artifacts that either interfere with the observation or actually introduce structures that were not present in the original sample (e.g., certain well-known chemical artifacts). Therefore, proper attention and consistent execution of each step are critical factors in generating sections that reflect the character of the tissue and that stain in a reproducible manner.

# ▲⟨1381⟩ ASSESSMENT OF ELASTOMERIC COMPONENTS USED IN INJECTABLE PHARMACEUTICAL PRODUCT PACKAGING/DELIVERY SYSTEMS

1. INTRODUCTION
2. SCOPE
3. DESCRIPTION OF ELASTOMERIC COMPONENTS IN PACKAGING SYSTEMS
4. ELASTOMERIC COMPONENTS—MATERIALS OF CONSTRUCTION
    4.1 Thermoset Elastomeric Components
    4.2 Thermoplastic Elastomeric Components
    4.3 Surface Coatings and Treatments
    4.4 Compounds of Concern
5. ELASTOMERIC COMPONENTS—MANUFACTURING TECHNOLOGY AND STERILIZATION PROCEDURES
    5.1 Generic Manufacturing
    5.2 Sterilization Procedures
6. IDENTIFICATION TESTS
7. TEST REQUIREMENTS AND RESPONSIBILITIES
8. SUMMARY OF ⟨381⟩ PHYSICOCHEMICAL TESTS
    8.1 Test Samples
    8.2 Physicochemical Tests

## 1. INTRODUCTION

Risk to drug product quality may exist when elastomeric components come into direct or indirect contact with pharmaceutical products. Elastomeric components used in pharmaceutical packaging/delivery systems must be proven suitable for their intended use based on aspects of protection, compatibility, safety, and performance.

Tests and acceptance criteria applicable to elastomeric components used in packaging/delivery systems for injectables are referenced in conjunction with *Injections and Implanted Drug Products* ⟨1⟩.

*Elastomeric Components in Injectable Pharmaceutical Product Packaging/Delivery Systems* ⟨381⟩ presents a body of test procedures and acceptance criteria for elastomeric components employed in injectable product packaging/delivery systems. The biological reactivity tests and physicochemical tests provide baseline information on a component's suitability. The test methods and acceptance criteria are detailed in their description but lack an explanation as to their relevance to the composition of the elastomers. Due to the large and diverse nature of the pharmaceutical marketplace, it may not be intuitive to stakeholders as to the proper use and application of ⟨381⟩. Therefore, a primary purpose of this chapter is to communicate the key concepts that form the foundation of ⟨381⟩ and to establish and clarify its application and applicability.

Beyond the baseline requirements provided in ⟨381⟩, elastomers will need to be qualified for intended use commensurate with the level of risk to drug product quality. These evaluations would encompass studies for extractables and leachables. Recommendations for conducting these studies are found in *Assessment of Extractables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1663⟩ and *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩.

Finally, elastomeric component functional suitability as part of the finished product packaging/delivery system must be demonstrated. Relevant information is found in *Elastomeric Component Functional Suitability in Parenteral Product Packaging/Delivery Systems* ⟨382⟩ and *Assessment of Elastomeric Component Functional Suitability in Parenteral Product Packaging/Delivery Systems* ⟨1382⟩.

## 2. SCOPE

This chapter serves as a supplement to the elastomeric component baseline requirements in ⟨381⟩. This chapter seeks to 1) describe elastomeric components and their materials of construction for use in injectable pharmaceutical packaging/delivery systems; 2) provide a high-level introduction to elastomer chemistry, manufacturing technology, and the post-processing of components; 3) designate and expand on baseline requirements; 4) discuss identification testing; 5) discuss test requirements and responsibilities; and 6) provide a summary of required and recommended test methods.

## 3. DESCRIPTION OF ELASTOMERIC COMPONENTS IN PACKAGING SYSTEMS

Certain components used in pharmaceutical packaging/delivery systems must have elastic properties for the system to function properly. Elastomers are a unique family of polymers with properties including the ability to recover from being stretched or deformed beyond their original state. This allows components to be flexible, maintain a seal, and be able to reseal after puncturing. In the following sections, typical elastomer materials, compositions, and physical attributes are summarized.

@2024 USPC

Various compounding ingredients, including curing systems, are required to produce optimal elastomeric performance. In thermoset elastomers, the physical attributes will depend on polymer cross-linking, achieved during the vulcanization process. The cured polymer will produce a chemical reaction and by-products that will impact the chemical makeup of the elastomeric formulation. The compounding ingredients, reaction by-products, and post-processing steps, such as sterilization, will influence the outcome of the component's chemical characterization.

Given the complex nature of packaging systems and their manufacturing and development processes, multiple testing procedures are needed to establish their suitability for use with a specific pharmaceutical product. The logical manufacturing and development process for packaged drug products—starting with the packaging system's materials of construction, continuing with the packaging system itself, and ending with the packaged drug product—forms the basis of the following three-stage approach to packaging/delivery systems qualification:

- **Component screening:** The baseline requirements for biological reactivity and physicochemical testing described in this chapter.
- **Controlled extraction studies:** Studies as described in ⟨1663⟩ to create extractables profile(s) of particular injectable pharmaceutical packaging/delivery systems, packaging components, or materials of construction.
- **Pharmaceutical product assessment:** Actual-case measurement of confirmed leachables in the injectable pharmaceutical product in the packaging/delivery system intended for the commercial market. (For additional information, see ⟨1664⟩).

Assessment of elastomeric component functionality is performed within the context of the intended product packaging system. (For additional information, see ⟨382⟩ and ⟨1382⟩.)

# 4. ELASTOMERIC COMPONENTS—MATERIALS OF CONSTRUCTION

## 4.1 Thermoset Elastomeric Components

### 4.1.1 THERMOSET COMPOSITION (TYPICAL)

A thermoset elastomer is a polymer system in which the elastomeric properties are derived from chemical cross-linking that is irreversible. This cross-linking is created between a curative (cross-linking agent) and a polymer (elastomer) when the materials are subjected to heat and pressure. In thermoset elastomers de-cross-linking is not possible without destruction of the material. The ingredients that typically are part of the thermoset elastomeric (rubber) formulation are shown in *Table 1*.

**Table 1. Thermoset Elastomeric Components: Typical Elastomeric Ingredients**

| Ingredient | Function |
|---|---|
| Polymers (elastomers) | Provide elastic properties after curing |
| Curatives (cross-linking agents) | Form cross-links to provide elasticity and strength |
| Fillers/extenders | Impart hardness, modulus/deformation, strength, reinforcement |
| Processing aids | Impart flexibility, fatigue resistance, mold flow |
| Antioxidants/antiozonants | Provide stabilization, i.e., protection against UV, oxygen, ozone |
| Plasticizers | Aid processing by providing flexibility, hardness |
| Dyes/coloring materials | Impart color |

### 4.1.2 POLYMER TYPES AND ATTRIBUTES

Typical polymers used in elastomeric components for packaging/delivery systems for injections, along with characteristic physical attributes and component examples, are shown in *Table 2*. Different types of elastomers may be combined in a single formulation in order to combine physical attributes.

**Table 2. Typical Elastomers for Thermoset Elastomeric Components**

| Elastomer | Physical Attributes | Typical Components |
|---|---|---|
| Isobutylene/isoprene copolymer (butyl) (IIR); Brominated isobutylene isoprene (BIIR); Chlorinated isobutylene isoprene (CIIR); Brominated isobutylene para methylstyrene terpolymer (BIMS) | Gas barrier; Aging resistance | Stoppers, plungers, lined seals |
| Natural polyisoprene (NR);[a] Synthetic polyisoprene (IR) | Good coring and reseal behavior; Abrasion resistance; Higher gas permeability | Stoppers, plungers for single-use syringes, septa, needle shields, tip caps |
| Styrene butadiene rubber (SBR) | Higher gas permeability | Needle shields, tip caps |
| Ethylene propylene diene monomer rubber (EPDM) | Chemical resistance; Aging resistance | O-rings |
| Acrylonitrile butadiene rubber (nitrile) (NBR) | Chemical resistance (e.g., mineral oils) | Stoppers, plungers, gaskets, O-rings |
| Polychloroprene (neoprene) (CR); Epichlorohydrin (ECO/CO) | Chemical resistance | O-rings, gaskets |

**Table 2. Typical Elastomers for Thermoset Elastomeric Components** *(continued)*

| Elastomer | Physical Attributes | Typical Components |
|---|---|---|
| Polysiloxane (VMQ, PMQ, PVMQ) | Heat resistance | Stoppers, plungers, tubing, gaskets, O-rings |

[a] NR must be labeled appropriately per 21 CFR §801.437; see www.fda.gov/downloads/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm070929.pdf.

## 4.2 Thermoplastic Elastomeric Components

### 4.2.1 THERMOPLASTIC COMPOSITION (TYPICAL)

A thermoplastic elastomer (TPE) is a polymer system with a different nature. Elasticity is incorporated in a different way (see below), and, more importantly, thermoplastic elastomers have a thermal behavior that is comparable to plastics. Thermoplastic elastomers when heated lose their elasticity and become deformable like a plastic. Cooled down again, they regain their elasticity. This cycle can be repeated. Unlike thermoset elastomers, the elastic behavior of thermoplastic elastomers is reversible.

TPEs, like thermoset elastomers, owe their elasticity to a polymer network that has a certain degree of structure. However, for thermoset elastomers, the structure occurs through chemical cross-linking with covalent bonding, whereas TPEs use a different mechanism. For example, in styrenic block copolymers, hard polystyrene blocks serve as physical cross-links in a three-dimensional network of softer chains of a different polymer such as polyisoprene or ethylene/butylene copolymer.

In a different class of thermoplastic elastomer named thermoplastic vulcanizates, a hard plastic phase and a soft elastomeric phase are present. The hard phase can use material such as polyolefin, while the soft phase is a thermoset elastomer phase with a high degree of chemical cross-linking. The curing of the elastomer phase is done in a process known as “dynamic vulcanization”. During this process, chemical cross-linking takes place during the mixing of the elastomer with the vulcanization system and other ingredients, such as polyolefin. Additional ingredients that may be present in TPEs are fillers, antioxidants, antiozonants, and plasticizers.

## 4.3 Surface Coatings and Treatments

After manufacturing, elastomeric components may not fulfill all the properties that are required for their application. An additional coating or surface treatment may be necessary. The most common surface treatment is siliconization, which is used to overcome the inherent tackiness of components and to provide lubricity. Tackiness will negatively impact component processing (e.g., sterilization, machinability at filling) and may introduce permanent component deformation. Chlorination is a less frequently used surface treatment. In this treatment, the component surface is exposed to chlorine, resulting in non-tacky and somewhat lubricious parts. In order to provide non-tackiness and lubricity, but at the same time reduce extractable levels (i.e., barrier effect), components may be covered, on part of their surface or on their entire surface, with lubricious barrier materials that are applied either by coating or by film lamination. Polymeric coatings and surface treatments are shown in *Table 3*.

**Table 3. Surface Coatings, Films, and Treatments for Elastomeric Components**

| Coating or Treatment | Physicochemical Effect | Typical Components |
|---|---|---|
| Silicone: silicone oil or emulsion, cross-linked silicone oil | Non-tackiness, lubricity | All components |
| Chlorination | Non-tackiness | Small, thin-walled components |
| Coating deposited by chemical vapor deposition | Barrier, non-tackiness, lubricity | Stoppers, plungers |
| Fluoropolymer coating | Barrier, non-tackiness, lubricity | Stoppers, plungers |
| Fluoropolymer lamination [ethylene tetrafluoroethylene (ETFE), fluorinated ethylene propylene (FEP)] | Barrier, non-tackiness, lubricity | Stoppers, plungers |

## 4.4 Compounds of Concern

Elastomeric components are made of various materials of construction. Some of these materials may raise quality or safety concerns. For example, *Table 4* lists several ingredients in elastomeric components that are carcinogens. Whenever possible, use of elastomeric components containing these ingredients should be avoided. It is recommended that the user evaluate the presence of such materials in components, either by direct use or by use in the manufacturing processes of the materials of construction. An overview of such materials, together with the associated concerns, is shown in *Table 4*.

**Table 4. Elastomeric Components: Compounds of Concern**

| Compound of Concern | Source | Risk |
|---|---|---|
| Latex | Associated with compounds containing dry natural rubber or derivatives | Associated with anaphylaxis in individuals allergic to natural rubber latex proteins |
| Materials of animal origin | Fatty acids and their metal salts used as processing aids or slip agents in polymers | Potential sources of transmissible spongiform encephalopathies (TSEs) in pharmaceutical products before manufacturing[a] |

**Table 4. Elastomeric Components: Compounds of Concern** *(continued)*

| Compound of Concern | Source | Risk |
|---|---|---|
| 2-Mercapto-benzothiazole (MBT) | Vulcanization accelerator used in the production of elastomers | Potential carcinogen |
| *N*-Nitrosamines | Associated with the use of certain secondary amines in the cure system | Potential carcinogens |
| Phthalates [e.g., orthophthalates such as bis(2-ethylhexyl) phthalate (DEHP)] | Used as a plasticizer or softener in polymers | Associated with developmental, reproductive, and endocrine health effects |
| Polycyclic aromatic hydrocarbons (PAHs) | Associated with carbon black (colorant or reinforcing agent) | Potential carcinogens |

[a] When tallow is derived from TSE-relevant starting material, a rigorous manufacturing process should eliminate or reduce any TSE risk.

**Latex:** Contact with elastomers or packaging/delivery systems containing natural rubber latex, dry natural rubber, or synthetic derivatives of natural rubber latex has been associated with allergic reactions, including anaphylaxis, in individuals allergic to natural rubber latex proteins. There is no one threshold level of exposure that can be considered safe; factors include the exposure route and the immune status of the individual. Information regarding suitable labeling can be found in the FDA Guidance for Industry *Recommendations for Labeling Medical Products to Inform Users that the Product or Product Container is not Made with Natural Rubber Latex* (December 2, 2014).

**Materials of animal origin:** Pharmaceutical products having raw materials derived from animal sources have a risk of transmissible spongiform encephalopathies (TSEs). Cattle infected with bovine spongiform encephalopathy (BSE) can transmit to humans in the form of Creutzfeldt-Jakob disease (CJD) and the variant (vCJD). This disorder is caused by a prion (protein) that causes the brain to be porous or spongy. Manufacturers should use materials from "non TSE-relevant animal species" or non-animal origin where possible to minimize the risk. When tallow is derived from TSE-relevant starting material, a rigorous manufacturing process should eliminate or reduce any TSE risk.

**2-Mercapto-benzothiazole (MBT):** 2-Mercapto-benzothiazole (MBT) is used as a non-volatile vulcanization accelerator in the production of elastomers. MBT reacts with zinc oxide and sulfur to cross-link elastomers. It can be bonded in the vulcanizate or may be present as a substance incorporated in the polymer. The amount of free MBT in the final product will be dependent on the vulcanization conditions.

***N*-Nitrosamines:** *N*-Nitrosamines are organic nitrogen-containing compounds that, under certain reaction conditions, are yielded as reaction products of nitrosating agents (e.g., certain oxides of nitrogen and nitrosatable secondary amines). Most secondary amines, but not all, may lead to carcinogens. There are 6 *N*-nitrosamines of concern that are listed in *Orally Inhaled and Nasal Drug Products* ⟨1664.1⟩.

**Phthalates:** Phthalates are a group of chemicals (orthophthalates and terephthalates) used in many polymer products to make plastics more flexible or as polymer-solvating agents. Phthalate esters are prepared by the esterification of phthalic anhydride with alcohols (C1/C2-C13). They are broadly divided into two distinct main groups with very different applications, toxicological properties, classification, and legal requirements. Orthophthalates used in food packaging are being reviewed by the FDA due to concerns for reproductive and endocrine health effects. More information can be found in the US *Federal Register* proposed rules (Vol. 83 No. 220, November 14, 2018).

**Polycyclic aromatic hydrocarbons:** Polycyclic aromatic hydrocarbons (PAHs), also known as polynuclear aromatic hydrocarbons (PNAs), are organic compounds with two or more fused aromatic (benzene) rings and are found as contaminants in oils used in elastomeric formulations and in carbon black used as a colorant or reinforcing agent. Carbon black is a material produced by the incomplete combustion of heavy petroleum products (i.e., ethylene cracking or coal tar). There are different types of carbon black and those with lower surface-area-to-volume ratios will have fewer PAHs absorb onto the surface during the manufacturing process. The PAHs are firmly bound to the carbon black surface under normal handling and use. They can only be extracted from the surface of the carbon black under rigorous laboratory conditions with strong solvents at elevated temperatures. There are 17 PAHs of concern that are listed in ⟨1664.1⟩.

# 5. ELASTOMERIC COMPONENTS—MANUFACTURING TECHNOLOGY AND STERILIZATION PROCEDURES

## 5.1 Generic Manufacturing

### 5.1.1 THERMOSET ELASTOMERS

The overall process of manufacturing thermoset elastomers consists of an elastomeric compound held in a heated mold under pressure. During this process, the elastomer is "cured" by undergoing a chemical reaction resulting in an elastic polymer network. The basic steps in manufacturing such components for pharmaceutical use are as follows:

- **Weighing of elastomeric ingredients:** Portions of the various ingredients are weighed according to instructions that reflect the elastomeric compound formulation.
- **Mixing:** The weighed portions of the various materials of construction are homogeneously mixed.
- **Preforming:** The mixed elastomer is brought into a physical shape that allows easy handling in the subsequent step.
- **Molding:** Elasticity is introduced and the components are shaped by the curing reaction. The products are not individually shaped but are attached to a web.
- **Die-trimming:** The components are separated from the web by die-trimming.

https://pharmacopeia.com/

- **Washing, lubrication, and drying:** The components are brought into their final state of microbiological and particulate cleanliness before packing. Lubrication, most often in the form of siliconization, typically is combined with washing and drying.
- **Packing:** The components are packed in suitable packaging material.

#### 5.1.2 THERMOPLASTIC ELASTOMERS

TPEs are processed like plastic materials. They are injected, as a hot mixture, into a cooled mold. Unlike thermoset elastomers, a thermoplastic elastomer does not involve curing agents during molding. TPE components are not attached to a web, so they do not need die-trimming. Co-injection of a plastic material with a TPE is a way to create a two-material component, where the TPE part has a sealing and/or resealing function.

### 5.2 Sterilization Procedures

Elastomeric components for injections undergo sterilization as individual components prior to the filling process and then may be sterilized a second time as part of an assembled packaging system after filling. Sterilization of an individual component may be done using ethylene oxide, ionizing radiation, or steam; method selection is dependent on the elastomeric formulation and system design. For example, depending on the irradiation dose, some elastomeric formulations may not withstand ionizing radiation. Sterilization of the filled packaging system is usually done using steam. The desired outcome is a sterile component with no change to its critical parameters such as material chemical profile (extractables), functional performance, or drug product compatibility. For guidance on sterilization procedures, refer to the following suite of chapters: *Sterilization of Compendial Articles* ⟨1229⟩, *Steam Sterilization by Direct Contact* ⟨1229.1⟩, *Gaseous Sterilization* ⟨1229.7⟩, and *Radiation Sterilization* ⟨1229.10⟩. For products regulated as medical devices (e.g., unfilled syringes or infusion administration sets), different standards and requirements may apply.

**Ethylene oxide sterilization:** Ethylene oxide (EtO) can be used to sterilize elastomeric components, but the method has the drawback of requiring an outgassing time period to allow the levels of residual compounds to fall below the regulatory limits. Most EtO sterilization processes involve three different stages, which are preconditioning, sterilization, and degassing. The preconditioning stage includes a dwell time, under controlled temperature and humidity, which may decrease the resistance of microorganisms to inactivation and reduce the sterilization cycle time. Sterilization is completed by the introduction of EtO gas followed by an aeration phase that removes residual EtO. The aeration phase also allows time for removal of the common EtO degradants, ethylene chlorohydrin and ethylene glycol, from the elastomer. The degassing time required depends on factors such as the composition and size of the elastomeric part.

**Ionizing radiation sterilization:** Ionizing radiation can use either electron beam (e-beam) or gamma radiation. Cobalt 60 is a frequently used source of gamma rays, which are very penetrating. An e-beam produces accelerated electrons, which do not have the ability to penetrate materials to the same depth achieved by gamma rays. The energy provided by these two methods is sufficient to deliver a sterilizing dose but is also capable of exciting and dissociating polymer bonds. The free radicals produced within polymer structures initiate a series of complex chemical reactions (e.g., chain scission or cross-linking) that may continue for a period of time after irradiation is completed. Inhibitors and stabilizers can be added to polymer formulations and are designed either to absorb energy or react with the free radicals. Even so, not all elastomeric formulations are deemed to be suitable for radiation sterilization.

**Steam sterilization:** Steam sterilization is typically performed in an autoclave under saturated steam conditions. Commonly used cycles are 121°–122° for 30–60 min. The components are dried following sterilization, not only to remove surface water but also to remove residual moisture that has entered the matrix of the elastomer. Drying procedures need to be optimized based on a number of factors including the length of the sterilization cycle, the elastomeric formulation, and the elastomer size and shape. Particular care should be taken when the elastomeric components are to be used to seal a lyophilized or powder-filled product, as residual moisture in the component can migrate into the formulation over time.

## 6. IDENTIFICATION TESTS

Components are made of a wide variety of elastomeric materials and optional polymeric coatings. For this reason, it is beyond the scope of ⟨381⟩ to specify identification tests that encompass all possible component presentations. However, it is the responsibility of the component supplier and the drug product manufacturer to verify the component's elastomeric formulation and any coating or laminate material used according to suitable identification tests. Examples of some of the analytical test methodologies that may be used include specific gravity, percentage of ash analysis, sulfur content determination, Fourier-transform infrared spectroscopy–attenuated total reflectance (FTIR–ATR) test, chromatography of an extract, UV absorption spectrophotometry of an extract, or infrared absorption spectrophotometry of a pyrolysate.

## 7. TEST REQUIREMENTS AND RESPONSIBILITIES

Elastomeric components provided by a supplier to a drug product manufacturer may demonstrate compliance with specific (e.g., biological and/or physicochemical) acceptance criteria as required by the drug product manufacturer in accordance with requirements established by the manufacturer for storage and/or delivery of a unique drug product. Processing such as sterilization may be performed on finished elastomeric components by the supplier prior to delivery to the drug product manufacturer, or by the drug product manufacturer before use, as agreed upon by both the supplier and the drug product manufacturer.

https://pharmacopeia.com/

For elastomeric components that are subsequently processed or sterilized by the drug product manufacturer after receipt from a supplier, the drug product manufacturer is responsible for ensuring that the components are compliant with appropriate acceptance criteria required for storage and/or delivery of a unique drug product after the application of such processing and/or sterilization conditions (i.e., in their ready-to-use state). This is of particular importance if elastomeric components are processed under conditions that may impact the biological, physicochemical, or functionality characteristics of the component.

## 8. SUMMARY OF ⟨381⟩ PHYSICOCHEMICAL TESTS

### 8.1 Test Samples

Elastomeric components are comprised of multiple materials that have unique attributes for each configuration, application, and change resulting from any treatment that occurs after formation (post-processing). This can be a challenge for establishing elastomeric baselines due to multiple combinations of materials and post-processing treatments by the component manufacturer and the drug product manufacturer.

Elastomeric components may be classified into two types: Type I and Type II. Type I elastomeric components meet the strictest requirements and are preferred because they have lower levels of extractables. Type I elastomers, however, may not exhibit sufficient elasticity to be suitable for special uses (e.g., multiple piercing, which requires reseal capacity and lower fragmentation rates). In such cases, the solution consists of using elastomers that do not respect all Type I physicochemical acceptance limits because they have properties that allow the component to meet sealability and fragmentation requirements. An allowance is made for Type II elastomeric components to meet less stringent alternative acceptance criteria for physicochemical testing. Some Type II components may fail to pass *Biological Reactivity Tests, In Vitro* ⟨87⟩ requirements but will meet *Biological Reactivity Tests, In Vivo* ⟨88⟩ requirements, thus complying with biological reactivity requirements.

Test samples described in ⟨381⟩ are to mimic the finished, processed component intended for the final product and its packaging/delivery system. It is the drug product manufacturer who is ultimately responsible for the quality and safety of the finished pharmaceutical product. Therefore, the drug product manufacturer is responsible for ensuring component conformance to the baseline requirements of ⟨381⟩.

### 8.2 Physicochemical Tests

**Appearance (turbidity/opalescence):** This is a nonspecific test for all the extractable species in an elastomeric formulation that are not soluble in an aqueous solution. A high turbidity is the indication of a high extractable potential. Species promoting turbidity have numerous origins in an elastomeric formulation, including fatty-acid derivatives, residues of curing systems, and oligomers from the elastomer.

**Color:** This is a nonspecific test indicative of the presence of extractable species in an elastomeric formulation that have the capacity of attributing color to an aqueous solution. Species that cause color may have several origins in an elastomeric formulation. Aqueous solutions are common in pharmaceutical packaging/delivery systems.

**Acidity or alkalinity:** This is a nonspecific test indicative of the acidic, basic, or buffering power of the aqueous extractables from the elastomeric formulation. High values in the acidity/alkalinity test may need to be evaluated in conjunction with the specifics of a drug solvent vehicle and anticipated acceptance criteria for the pH of the drug product.

**Absorbance:** This UV spectrum test of an aqueous extract from an elastomeric formulation is indicative of the unsaturated or aromatic character of the chemical species extracted. Unsaturated compounds in the extracts may originate from many raw materials and additives of an elastomeric formulation such as antioxidants and curing or dying agents.

**Reducing substances:** This is a nonspecific test. Extracted species from an elastomeric formulation with potential reducing power may originate from most raw materials of an elastomeric formulation (polymers, curing systems, antioxidants, etc.).

**Volatile sulfides:** This test is specific for elastomeric formulations containing sulfur. Sulfur and sulfur precursors are often used as components of curing systems for elastomers.

**Ammonium:** This test is specific for elastomeric formulations with nitrogen-containing raw materials. Ammonium ions can be generated during the curing process. Thiurams and thiazoles are examples of nitrogen-containing curing systems used.

    4.5 Plunger Functional Suitability Tests
    4.6 Tip Cap and Needle Shield Functional Suitability Tests
5. CONCLUSION

## 1. INTRODUCTION

This chapter contains information and guidance to assist in the functional suitability assessment of elastomeric components as part of packaging/delivery systems intended for parenteral dosage forms contained in *Elastomeric Component Functional Suitability in Parenteral Product Packaging/Delivery Systems* ⟨382⟩. Such components include primary packaging/delivery system components that are partially or completely made of elastomeric material. Excluded from this chapter are products and their packaging that are regulated as medical devices (e.g., unfilled syringes, infusion administration sets, delivery systems for drug-eluting stents). The proper selection and design of functional suitability assessment studies is based on sound and justifiable scientific principles provided in ⟨382⟩, *1. Introduction*.

## 2. EARLY PACKAGING/DELIVERY SYSTEM SELECTION AND DEVELOPMENT: FUNCTIONAL SUITABILITY ASSESSMENT CONSIDERATIONS

Early in the packaging/delivery system selection and development process, the final packaging/delivery system and its components may not be fully defined and functional suitability requirements may not be established. This is especially true if the packaging/delivery system or the drug product is novel to the drug product applicant. At this phase of the product life cycle, functional suitability assessments are performed to better understand packaging/delivery system performance and/or to screen potential elastomeric component and container candidates. To that end, *Table 1* lists elastomeric component functional suitability tests in standards published by the International Organization for Standardization (ISO). The list should not be considered all-inclusive. The most recent standards should be referenced.

The terms "standards" and "recognized standards" used throughout this chapter and ⟨382⟩ refer to those published by ISO.

Although not mandated, testing components and/or closure packaging/delivery systems according to such standards may provide useful information, especially during early product packaging/delivery system development. Other relevant internationally recognized standards deemed scientifically appropriate may be used instead of, or in addition to, those listed in *Table 1*. Standard test data may be made available by elastomeric component or packaging/delivery system suppliers.

[a] Single-use device: A single-use device, also referred to as a disposable device, is intended to be used on one patient during a single procedure. It is not intended to be reprocessed (cleaned, disinfected/sterilized) and used on another patient.

## 3. FINAL PRODUCT PACKAGING/DELIVERY SYSTEM FITNESS-FOR-INTENDED-USE SUITABILITY ASSESSMENT

Evidence of the elastomeric component's ability to satisfactorily function as part of the final packaging/delivery system according to its intended product use is required to support commercial market approval of a finished drug product. Internationally recognized standards, such as those listed in *Table 1*, can provide a useful benchmark when designing appropriate elastomeric component functional suitability assessment studies. However, the drug product applicant is advised to exercise caution before prescriptively adopting standardized tests. Such tests may not provide a complete or adequate assessment of the elastomeric component's ability to meet the final packaging/delivery system's product-specific functional demands and instead should be considered a precursor to design verification and validation of the final finished combination product. Standardized tests may not be adequate or appropriate in specific situations for many reasons, for example:

https://pharmacopeia.com/

- The final packaging/delivery system components may differ in design or dimension from the description in the standard.
- The manner in which the final packaging/delivery system's components are processed, reprocessed, and/or assembled may differ from the description in the standard.
- The manner in which a liquid, such as a diluent, must be added to the packaging/delivery system for final dosage form preparation (such as for lyophilized product reconstitution, powdered product constitution, product dilution, or admixture) may differ from the description in the standard.
- The manner in which the packaged product is to be accessed at the time of use may differ from the description in the standard. Differences may include needle or spike design, material, or lubricity; needle puncture speed; and the number of penetrations per closure.
- The standard's test procedure or analysis method may provide an inadequate measure of packaging/delivery system functional suitability given the specific rigorous demands placed on the final packaging system. For instance, bench test conditions may not sufficiently mirror the rigors imposed on the marketed product during actual storage, distribution, and usage conditions.
- The test method may lack sufficient sensitivity or precision to provide an adequate measure of packaging/delivery system functional suitability. For example, a container-closure seal integrity test that relies on dye ingress observation may be too insensitive to provide an accurate picture of a lyophilized dosage form package's ability to meet the maximum allowable leakage limit demanded by the finished product packaging/delivery system.
- The standard test's acceptance criterion may not reflect the functional performance demanded of the final packaging/delivery system for the particular intended use. For example, the maximum allowable needle penetration force for a closure dictated by a standard may result in damage to the penetration needle supplied with the intended delivery device.
- The standard test's sample size may not reflect the reliability demanded of the final packaging/delivery system. A larger sample size will be expected in design verification and validation of the final packaging/delivery system.

Therefore, the drug product applicant is tasked with developing a body of elastomeric component functional suitability assessment tests that logically and most appropriately assess the final packaging/delivery system. Challenges placed on the final product's packaging/delivery system during testing should mimic challenges the product is likely to encounter through storage/distribution, product expiry, and clinical in-use condition. These testing challenges should provide clear and definitive measures of packaging/delivery system performance.

## 4. GENERAL CHAPTER ⟨382⟩ BACKGROUND AND GUIDANCE

Chapter ⟨382⟩ offers drug product packaging/delivery system fitness-for-intended-use functional suitability assessment procedures and acceptance criteria that are reflective of current best practices. These best practices take into consideration all the recognized ISO standards in *Table 1* as well as USP tests and guidances (e.g., *Biological Reactivity Tests, In Vitro* ⟨87⟩ and *Biological Reactivity Tests, In Vivo* ⟨88⟩). Specific sources for the various tests are detailed in the following sections. These tests are not intended to be exhaustive. The drug product applicant may require additional tests to adequately assess the component's functional suitability as part of a particular packaging/delivery system.

Re-evaluation of functional suitability may be required when changes occur in components, processes, or even the commercialized product itself during its life cycle. The functional suitability of a drug product packaging/delivery system is the responsibility of the drug product applicant.

The following sections contain guidance and background information relevant to tests in ⟨382⟩.

### 4.1 Test Samples

The following relates to ⟨382⟩, *3. General Test Requirements, 3.1 Test Samples*. Functional suitability of elastomeric components cannot be tested for in isolation from the intended packaging/delivery system. Furthermore, a component's functional performance assessment outcome can be affected by the design, mating interfaces, processing, and assembly of that packaging/delivery system. For example, closure processing parameters and vial package sealing forces directly impact parenteral vial packaging integrity results. Plunger break-loose and extrusion forces are directly related to the design, material of construction, and lubricity of the syringe barrel.

Test samples employed for each functional suitability test are to mirror the components and packaging/delivery system of the intended product as closely as possible, because component functionality is connected to the packaging/delivery system. Components are to be prepared, processed, and assembled as defined for the final product packaging/delivery system, especially if such steps are believed to have a potential impact on component functionality.

The following examples are offered as illustration:

- Components are to be washed, lubricated, and sterilized according to intended product protocol.
- Components are to be laminated or coated according to the requirements of the intended product packaging/delivery system.
- Vial and bottle closures are to be optimally capped onto vials in a manner reflective of the intended finished product packaging/delivery system.
- Syringe/cartridge barrels are to be prepared and lubricated according to the requirements of the intended pharmaceutical product.
- Syringe/cartridge plungers are to be inserted into syringe barrels according to production practices (e.g., by use of a vent tube or vacuum insertion). Manual placement can be utilized for feasibility assessment.
- Cartridge line seal crimping pressure is to be reflective of the intended finished product packaging/delivery system.

Some tests, such as ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.1 Fragmentation*, state that the test samples are to be filled with water. However, in cases where package contents can influence test outcome, such as ⟨382⟩, *6. Plunger*

@2024 USPC

*Functional Suitability Tests, 6.1 Plunger Break-Loose and Extrusion Forces* tests, it is recommended that test samples be filled with product or a product proxy so that the test outcome better reflects packaging/delivery system intended use. Alternatively, content material that brackets the characteristics of multiple products may be chosen.

Some flexibility in test sample preparation and content is permitted if the variation is judged to have little or no impact on test outcome. With appropriate justification, test samples may bracket relevant parameters of packaging/delivery system design, intended interfaces, dimensional analysis, component processing, package assembly, and product contents. Bracketing may be employed to allow a functional suitability assessment program that addresses a wider spectrum of packaging/delivery systems and/or products.

The selection, design, preparation, assembly, and contents of test samples should follow sound scientific principles so that the final product packaging/delivery system can be comprehensively evaluated for functional suitability.

## 4.2 Test Sample Population Size

As described in ⟨382⟩ *3. General Test Requirements, 3.2 Test Sample Population Size*, test sample quantity should provide a reasonable measure of confidence of the packaging/delivery system elastomeric component functionality. Current recognized standards inform the test sample population sizes specified in chapter tests. For this reason, sample sizes vary across test categories and even among package types within a test category. For example, ⟨382⟩*, 5. Needle and Spike Access Functional Suitability Tests, 5.1 Fragmentation* vial system tests require 12 test samples (as per ISO 8362-2, 8362-5, and 8871-5), whereas bottle system tests require 10 test samples (as per ISO 8536-2 and -6). In the case of fragmentation tests, it was deemed important to respect the historical particulate findings generated using these varied sample population sizes. On the other hand, ⟨382⟩*, 5. Needle and Spike Access Functional Suitability Tests, 5.3 Needle Self-Sealing Capacity* tests require 30 test samples regardless of the packaging/delivery system to ensure more meaningful leakage findings even though recognized standards require fewer samples.

Test sample population sizes cited in chapter test methods represent minimal test sample population size requirements but may be inadequate depending on risk assessments and whether the data generated will be attribute or variable. Sample population sizes that are larger than those specified in test procedures are encouraged to provide greater assurance of packaging/delivery system performance and to minimize the risk of product failure during commercial use.

## 4.3 Packaging/Delivery System Integrity Tests

The verification of packaging/delivery system integrity is required according to ⟨382⟩*, 4. Packaging/Delivery System Integrity Tests*. All components that are intended to seal or affect container closure must adequately protect and contain the packaging/delivery system contents. In this context, all such components are termed closures. All closures are required to ensure adequate system integrity; therefore, all packaging/delivery systems within the scope of the chapter are required to meet an appropriate system integrity functional suitability assessment. This section does not apply to closures after they have been breached by a needle, spike, or other access device.

Packaging/delivery system integrity refers to the ability of a packaging/delivery system to keep product contents in, and to keep detrimental environmental contaminants out. All packaging/delivery systems for parenteral products closed with elastomeric components are required to demonstrate integrity, as defined by the level of protection necessary for product quality maintenance. All systems with elastomeric closures mechanically fitted to the container demonstrate some gaseous leakage past the seal interface, even when optimally assembled. Leaks of concern for sterile product packaging/delivery systems are those that pose an unacceptable level of risk to relevant product physicochemical, biological, and microbiological quality attributes.

Specifically, all parenteral product packaging/delivery systems must: 1) prevent microbiological ingress to ensure that product sterility is met; and 2) prevent product escape or entry of external liquid or solid matter to ensure that relevant product physicochemical quality attributes are met. In addition, some products require the maintenance of package headspace content in a manner that ensures relevant product physicochemical quality attributes are met and/or allows for ease of product access by the end user. As some packaging/delivery systems employ more than one closure, and each closure may provide a different level of product protection, different integrity tests may be required to effectively evaluate the inherent integrity of the various closure types.

See *Package Integrity Evaluation—Sterile Products* ⟨1207⟩, as well as its subchapters, for further guidance on the concepts of inherent package integrity and maximum allowable leakage limit, and for guidance on the proper selection, development, validation, and utilization of appropriate leak test methods.

## 4.4 Needle and Spike Access Functionality Tests

Information in ⟨382⟩*, 5. Needle and Spike Access Functional Suitability Tests* applies to packaging/delivery system closures that allow for drug product access by hypodermic needle, spike, or other closure penetration device. Packaging/delivery systems intended for parenteral products that permit dosage form access by insertion of a closure piercing device are required to allow for safe and effective product access, without damaging the packaging/delivery system or the drug product and without risking harm to either the patient receiving the medication or the individual accessing and/or administering the product.

Traditionally, needle and spike access functionality tests have not accounted for the possibility of an additional closure penetration commonly performed to introduce liquids into the product packaging/delivery system for lyophilized product reconstitution, powdered product constitution, product admixture, or product dilution. Closure penetration practices for dosage form preparation vary widely. The piercing device employed for dosage form preparation may be very different in size or design from the needle or spike used for subsequent product access and withdrawal. There is little published information on the impact of such initial closure penetrations on closure performance or product quality. To address this gap, needle and spike

@2024 USPC

access functional suitability tests have been expanded to incorporate a first closure piercing for products requiring final dosage form preparation in addition to the closure piercing(s) for product access and withdrawal.

Tests dictate that all piercings be performed using the dosage form preparation piercing device(s) and/or the product access piercing device(s) intended or recommended by the drug product applicant. For example, if the intent is to provide or to specify a needle or other piercing device with the marketed product for a given purpose, then this same item or a facsimile is to be used. If a piercing device will neither be specified nor provided (i.e., not designated), the procedures cite dosage form preparation and drug product access devices to be used for the tests. Drug product access needles/spikes cited align with current reference standards. Dosage form preparation needles cited in the procedures are unique to USP.

The following tests are included in this functional suitability assessment category.

## FRAGMENTATION

See ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.1 Fragmentation*. Also called coring, fragmentation is a measure of the packaging/delivery system's tendency to fragment or core when penetrated by a dosage form preparation piercing device (if applicable) and by a product access piercing device. If injected, such closure fragments may pose a health risk to the patient.

The penetration tests largely align with fragmentation tests in ISO standards in the piercing devices used and the number of piercings per test sample. Specifically, *Procedure A* in ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.1 Fragmentation, Vial and bottle systems* was informed by ISO 8362-5 and 8871-5. *Procedure B* was informed by ISO 8536-2 and -6. The ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.1 Fragmentation, BFS systems* test method was informed by ISO 15759. *Procedure A* of ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.1 Fragmentation, Cartridge systems* was informed by ISO 13926-3 and *Procedure B* was informed by ISO 11608-3.

Unlike ISO tests, an extra initial piercing option representing a dosage form preparation piercing is included in the vial and bottle systems as well as the BFS systems test procedures.

Also unlike ISO tests, fragmentation count analysis is to be performed according to *Particulate Matter in Injections* ⟨788⟩, *Method 2 Microscopic Particle Count Test*, with noted modifications. Modifications include allowances for microscope magnification range adjustment and the use of the linear graticule for particle sizing. Test procedures require particle sizing based on the longest linear dimension of the particle.

Acceptance criteria are defined according to the quantity of detected particles ≥150 µm in the longest linear dimension. Smaller particles are not reported. Recognized standards define fragmentation acceptance criteria according to the number of particles visibly detected, i.e., particles ≥50 µm (e.g., ISO 8871-5). ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.1 Fragmentation* has adopted the same particle quantity limits, as per the recognized standards, but counted particles are ≥150 µm, sized microscopically, defined by the longest linear dimension. This change was based on more recent data suggesting visibly detected particles are closer to 150 µm in size, as per *Visible Particulates in Injections* ⟨790⟩.

## PENETRATION FORCE

See ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.2 Penetration Force*. Also called penetrability, penetration force is the maximum force necessary to penetrate the closure using a dosage form preparation piercing device (if applicable) and a product access piercing device. Penetration force tests also confirm the ability of the closure to remain in place without being forced into the container during piercing.

Test procedures and acceptance criteria were informed by current reference standards. In some cases details were modified so all packaging/delivery systems could be tested similarly. Details are included below.

*Procedure A* and *Procedure B* of ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.2 Penetration Force, Vial and bottle systems* evaluate the penetration force required for a dosage form preparation hypodermic needle and for a dosage form access hypodermic needle, respectively. *Procedure C* evaluates the penetration force required for spike access. ISO standard vial package closure penetration tests do not specify the needle insertion rate or the use of a mechanical testing machine (ISO 8362-2, 8362-5, 8871-5). Standard bottle spike penetration force tests specify use of a mechanical testing machine, operated at an insertion rate of 200 mm/min with a load cell accuracy of ±2 Newtons (N) (ISO 8536-2 and -6). For consistency among chapter tests, the vial and bottle systems tests specify the use of a mechanical testing machine operated at the penetration rate of 200 mm/min with a data acquisition rate of NLT 100 Hz for both vials and bottles penetrated by either needles or spikes.

*Procedure A* and *Procedure B*, which use a needle for penetration, require a load cell accuracy of ±0.25 N in anticipation of results less than 10 N. *Procedure C*, which uses a spike, anticipates higher penetration forces, therefore, a load cell accuracy of ±2 N is specified, similar to the corresponding ISO standards.

There exists no published data or ISO standard for dosage form preparation penetration force for vial and bottle systems; therefore *Procedure A* does not include quantitative acceptance limits. The end user is responsible for establishing a limit appropriate for the system and its intended use.

The penetration force acceptance limit for BFS systems is also not specified. The penetration force limit in ISO 15759 only evaluates the penetration force through the closure, not the force required to penetrate the closure combined with the underlying plastic layer in a fully assembled BFS system. For this reason, the end user is responsible for establishing a limit that is appropriate for the system and its intended use.

The penetration force acceptance limit for plastic systems of no more than 200 N is the highest for all package types. This high value is informed by ISO 15747 and includes the friction force between the spike and the access port tube.

## NEEDLE SELF-SEALING CAPACITY

See ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.3 Needle Self-Sealing Capacity*. Also called reseal capacity, injection port tightness, or in-use leakage tests, this term applies to product packaging/delivery system closures required to ensure adequate package integrity during in-use conditions of multiple breaches by a needle(s). Such systems include

Official

https://pharmacopeia.com/

multiple-dose product packaging/delivery systems, as well as systems with closures that must be penetrated more than once to permit dosage form preparation followed by penetration(s) for product access and administration.

Test samples are challenged prior to packaging/delivery system in-use integrity verification by exposing the closures to worst case (i.e., the most challenging) piercing conditions anticipated for the intended product. In cases where the largest gauge piercing device(s) and/or the maximum penetration quantity conditions are undefined, ⟨382⟩ lists challenge conditions to be employed, similar to self-sealing test requirements corresponding to recognized standards.

The ⟨382⟩ test requires a minimum of 30 test samples for all packaging/delivery system types. This quantity is greater than the specification in ISO's standards for resealability tests. However, the requirement for 30 test samples does align with the requirements of ⟨382⟩, *4. Packaging/Delivery System Integrity Tests*. A smaller quantity was viewed to be less likely to yield meaningful leakage information.

No leak test procedure is mandated for self-sealing capacity. Tests described in corresponding recognized standards may be consulted. However, such tests may not accurately or appropriately measure the integrity of the compromised closure for the intended product and its use. Therefore, the reader is referred to *Package Integrity Evaluation—Sterile Products* ⟨1207⟩ and its subchapters for guidance in test method selection, development, validation, and utilization.

SPIKE RETENTION AND SEALABILITY CAPACITY

See ⟨382⟩, *5. Needle and Spike Access Functional Suitability Tests, 5.4 Spike Retention and Sealability Capacity*. This test is a measure of a closure system's ability to be fully penetrated by a spike (without pushing the closure into the container); to block visible evidence of liquid product leakage between the spike and the closure during the product-dosing time period; and to retain the spike during this time period.

Test samples are to be challenged by exposing the closures to worst case (i.e., the most challenging) piercing conditions anticipated for the intended product. In cases where the spike piercing device is undefined, utilize the device described in the corresponding ISO standards. Note that the ⟨382⟩ test sample size and test conditions are similarly based on recognized standard procedures for the respective packaging/delivery system categories.

## 4.5 Plunger Functional Suitability Tests

Information in ⟨382⟩, *6. Plunger Functional Suitability Tests* applies to packaging/delivery systems that incorporate a plunger (also called a piston), namely cartridge systems and syringe systems. This section include tests to evaluate plunger break-loose and extrusion forces as well as plunger seal integrity.

Packaging/delivery systems designed to allow for product elution via a plunger are required to allow for complete, safe, and effective product delivery without damaging the system and without risking harm to either the patient receiving the medication or the individual accessing and/or administering the product. The plunger is also required to ensure adequate product containment from the time the product is filled until product delivery to the patient is complete.

PLUNGER BREAK-LOOSE AND EXTRUSION FORCES

See ⟨382⟩, *6. Plunger Functional Suitability Tests, 6.1 Plunger Break-Loose and Extrusion Forces*. This test evaluates plunger break-loose force (also known as the initiating force), which is the force required to initiate the movement of the plunger. It also evaluates plunger extrusion force (also known as the sustaining force), which is the force required to sustain the movement of the plunger to expel the content of the syringe or cartridge. This test allows an analysis of the ease with which product delivery may be performed.

Many variables can affect these forces. For example, product characteristics of fluid viscosity, density, and fluid surface tension can directly impact break-loose and extrusion forces. These forces are also influenced by the interference fit between the plunger and the barrel, the plunger rib design and quantity, the lubrication of the plunger and the inner surface of the barrel, the fit of the plunger rod into the threaded plunger, the needle internal diameter, the inside diameter of the syringe or cartridge, and the target injection time. The use of connecting devices with the test sample can significantly influence forces such as extrusion forces.

Furthermore, it is noteworthy that break-loose force can increase over time to an unacceptable level at which point it is difficult to initiate plunger movement by hand. If the plunger is operated by a spring, the break-loose force required may be greater than the capability of the spring. The drug product applicant is advised to consider this possibility when designing drug product shelf-life stability assessment studies. Finally, component processing can also impact plunger function. For example, an irregular extrusion force, or one that rises significantly towards the syringe nozzle, can indicate non-homogeneous lubrication of the barrel due to improper application or degradation.

The performance requirements of the packaging/delivery system should consider the intended use of the syringe or cartridge. For example, if the product is to be manually delivered, break-loose force, extrusion forces, and range of possible rates of delivery should accommodate the skill set of the population responsible for product administration. If the product is to be delivered using an automatic pen injector, forces must be appropriate for the delivery system hardware.

In conclusion, a wide number of variables can impact break-loose and extrusion force results. The many combinations of products, packaging/delivery systems, and intended uses influence acceptable functional performance criteria. Therefore, a single test method cannot be defined, nor can acceptance criteria be specified, for all relevant packaging/delivery systems, products, and intended-use applications. The user is responsible for following the generic test method outlined in ⟨382⟩ and for establishing meaningful quantitative acceptance criteria that best represent the demands of the specific product packaging/delivery system.

PLUNGER SEAL INTEGRITY

See ⟨382⟩, *6. Plunger Functional Suitability Tests, 6.2 Plunger Seal Integrity*. This test is designed to apply a fixed force to the plunger of a sealed syringe or cartridge containing liquid product in order to detect leakage past the plunger. *Procedure A* applies to manually operated prefilled and single-use syringe systems. This procedure and acceptance criteria were informed by ISO 7886-1. *Procedure B* applies to non-manually operated prefilled syringe systems that function as part of an auto-injector system such as a spring-driven or power-driven delivery device. This procedure and acceptance criteria were informed by ISO 11040-8. *Procedure C* is specifically for cartridge systems used for dental local anesthesia products and was informed by ISO 11040-2 and -3. *Procedure D* is for all cartridge systems, excluding those for dental local anesthesia products. The procedure and acceptance criteria were informed by ISO 13926-2 and -3. For all procedures, satisfactory plunger seal tightness will not permit visible leakage of liquid product past the rear rib or final seal of the plunger when forces simulating product delivery are applied. Inspect the primary components (syringe and plunger) prior to the insertion of the plunger to avoid trapping liquid between the plunger ribs and the container. For cartridge containers that are also closed with a stopper or septum (without a needle), acceptance criteria also require the absence of visible leakage past this closure.

### 4.6 Tip Cap and Needle Shield Functional Suitability Tests

⟨382⟩, *7. Tip Cap and Needle Shield Functional Suitability* tests examine the functional suitability of tip caps and needle shields. These components are intended to protect the needle or nozzle (Luer end) of the syringe, allow for nozzle/needle sterilization, and maintain the sterility of the contents of the syringe container. The functional suitability tests examine the forces required to remove the tip cap or needle shield prior to dose administration. *Procedure A* measures the axial force used to pull off needle shields and tip caps. *Procedure B* is a torque test that measures the force use to unscrew and remove the Luer lock rigid tip caps. A packaging/delivery system is satisfactory if the force needed to remove the component allows for the manual removal of the tip cap or needle shield with relative ease but prevents the accidental loss of these components during storage or transit.

When selecting acceptance criteria, the user should consider the various factors that can influence removal forces. For example, processes applied to the components pre- and post-assembly, such as lubrication and sterilization, can impact test results. Other factors include elastomeric component age, age of the assembled system, and possibly finished product storage conditions.

The procedures and acceptance criteria in ⟨382⟩, *7. Tip Cap and Needle Shield Functional Suitability* were influenced by ISO 11040-4 and -8.

## 5. CONCLUSION

In summary, the functional performance of elastomeric components is to be evaluated in a manner that ensures the elastomeric component is suitable. Although this chapter's scope does not include functional suitability tests relevant to other components of the packaging/delivery system, or to all aspects of the system itself, such tests are nevertheless important. Consideration should be given to the full scope of packaging/delivery system functional demands inherent in the manufacture, safety, use, and marketability of the intended product. To this end, the applicant may seek direction in other relevant packaging/delivery system guidances and standards. Determination of a suitable elastomeric component requires that the applicant employ a science- and risk-based approach to accomplish a thorough and complete functional suitability assessment verifying the entire packaging/delivery system's fitness for intended use.▲ (USP 1-Dec-2020)

REFERENCES

## 1. INTRODUCTION

The phenomena observed when photons [i.e., an electromagnetic (EM) wave] strike or interact with a small object (a particle or a molecule) and thereby change direction is called light scattering (LS).

In static light scattering (SLS), the inevitable short-term temporal fluctuations in scattering intensity due to Brownian motion are averaged over a range of time scales from several hundredths to several tenths of a second. SLS measures the time average intensity of scattered light from particles in a suitably prepared sample; the detector signal is, therefore, time independent or "static".

In SLS, the scattered light is detected and measured as a function of the angle between the detector and the incident beam direction. Light scattering can be either at a single fixed angle, as in low-angle light scattering (LALS) or right-angle light scattering (RALS); or over a range of angles, as in multi-angle light scattering (MALS).

SLS provides information about molecular weight, particle size, particle shape, and molecular interactions.

This chapter provides guidance and procedures for LALS and MALS. These SLS methodologies are based on the Rayleigh approximation of classical Mie scattering theory. In these scattering methods, the particles are assumed to be present in solution (or gas) and free to move; thus, the particles are inherently in an unordered state. Other scattering phenomena such as reflection, refraction, and diffraction require the scattering particles to be highly ordered and are out of the scope of this text.

## 2. THEORY

SLS techniques are based on measurement(s) of the scattered light intensity ($I_S$) itself, as opposed to indirect measurements (e.g., inferring the scattered intensity from the attenuation of transmitted light).

In order to obtain a measure that relates the material itself to the scattering intensity, independent of equipment characteristics, one defines the Rayleigh ratio, $R(\Theta)$, for the sample under investigation (*Equation 1*):

$$R(\theta) = \frac{I_S(\theta) r^2}{I_0 V_S(\theta)} \qquad (1)$$

$R(\Theta)$ is defined as the scattered intensity per unit solid angle, scattering volume ($V_S$), and incident intensity ($I_0$) that is in excess of that scattered by solvent alone, and $r$ is the distance of the scattering volume from the detector.

*Figure 1* shows that the scattering of light on the particle changes the wave vector from $k_{incident}$ to ~$k_{scatter}$. For sufficiently small particles, only the direction, but not the wavelength, changes as a result of the collision. Hence, the length of the wave vector $\vec{k}$, remains unchanged.

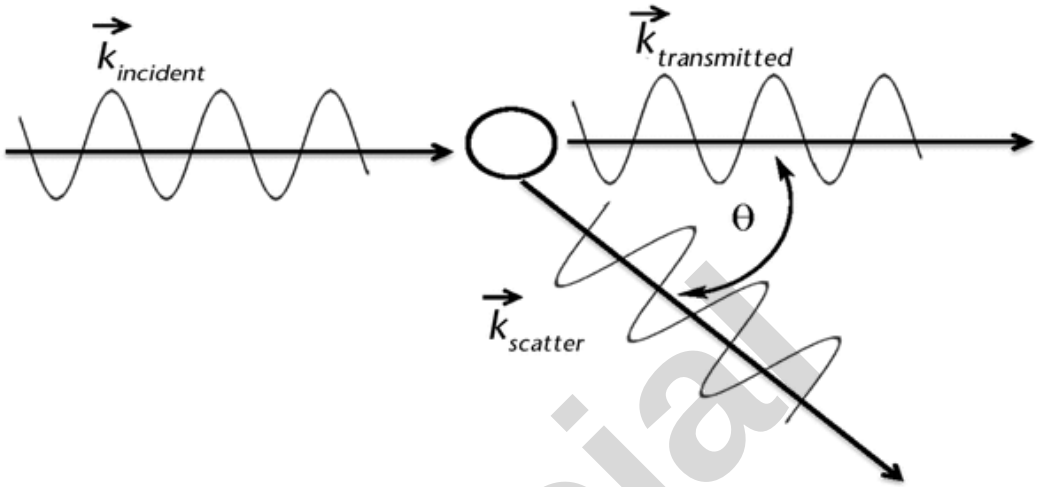

Figure 1. Scattering of light at an angle Θ.

As the EM wave interacts with the electron orbits of the constituent molecules, the orbits are perturbed periodically at the same frequency as the electric field of the EM wave. The oscillations of bound and free charges in turn generate EM waves inside and outside of the particle.

Although Maxwell's equations for an EM light wave interacting with a sphere completely describe these interactions, proper boundary conditions for electric and magnetic fields are needed to find the exact solutions for these equations, along with the values of the quantities of interest. Moreover, such solutions are difficult to find.

One of the rare exact solutions for the scattering of a plane wave by a uniform sphere is obtained from the Mie theory of scattering (*1*). Mie theory has no size limitations; it converges to the limit of geometric optics for large particles. Mie theory, therefore, may be used to describe most spherical particle scattering systems. However, difficulties in finding exact solutions for the wave equations have led to the development of approximate methods of solving the scattering problem. One class of these approximations, known as Rayleigh scattering theory, describes light scattering by particles that are small compared to the wavelength of the light (*2*,*3*). Due to the complexity of the Mie scattering solution, the Rayleigh scattering theory is generally preferred, if applicable.

When the scattering particles are much smaller than the wavelength of the light (approximately 1/20 of the wavelength or less), they are considered to be at the Rayleigh scattering regime. The EM field acting on the particle in the Rayleigh scattering regime is effectively homogenous. This is a very important approximation for biomedical optics because many of the structures from which cell organelles are built (e.g., the tubules of the endoplasmic reticulum, cisternae of the Golgi apparatus) fall into this category.

Therefore, the time for penetration of the electric field is much shorter than the period of oscillation of the EM wave. The particle behaves like a dipole and therefore radiates (scatters) light isotropically, i.e., at an equal intensity in all directions relative to the direction of the incident light. With larger particles and/or shorter wavelengths, the scattered light begins to exhibit additional interference effects from other atoms within the molecule.

In addition, the scattered light has the same wavelength as the incoming light, a process referred to as elastic scattering. Moreover, the intensity of the scattered light is independent of the particle size.

At the Rayleigh limit, the Rayleigh ratio is transformed to *Equation 2*:

$$\frac{K^* \times c}{R(\theta)} = \frac{1}{M_w \times P(\theta)} + 2A_2 \times c \qquad (2)$$

The variables are defined as follows:

$R(\Theta)$ = Rayleigh ratio

$K^*$ = optical contrast parameter = $[4\pi^2 n_0^2 (dn/dc)^2]/(\lambda_0^4 N_A)$ and $K^* = K \times (dn/dc)^2$ where $K$ is a constant, $K = \frac{4\pi^2 n_0^2}{\lambda_0^4 N_A}$

Status: Currently Official on 05-Jan-2024
Official Date: Official as of 01-Dec-2019
DOI Ref: 62d7l
DocId: GUID-95009428-314D-4936-B74A-8845C0D245F8_2_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M12337_02_01
@2024 USPC

[NOTE—$K^* \neq 0$ only when $n \neq n_0$, i.e., $dn/dc \neq 0$. Modern instruments rely on laser light, and the incident light is polarized. For unpolarized light, the constant factor 4 is replaced with 2.]

$P(\Theta)$ = form factor = $1 + (16\pi^2/3\lambda^2)(r_g^2)\sin^2(\theta/2)$ captures the decrease in scattered intensity resulting from interference between individual scattering centers within a large molecule. At a small $\Theta$, $P(\Theta) \approx 1$, because $\sin^2(\theta/2) \rightarrow 0$.

$A_2$ = second virial coefficient; describes interactions between molecules. In an ideal system/solution, $A_2 = 0$ (i.e., there are no interactions between molecules) and the intensity of scattered light will increase linearly with the concentration. Because interactions between molecules become rarer at lower concentrations ($c$), at the limit $c \rightarrow 0$ it is reasonable to assume that $A_2 = 0$.

$M_w$ = weight-average molecular weight of the analyte/solute

$r_g$ = radius of gyration, the equivalent spherical particle radius. At the Rayleigh limit, $r_g << \lambda_0$, for example in the case of visible light in which $\lambda_0 > 400$ nm, then $r_g < 15$–$20$ nm. This is true for folded proteins with $M_w < 5 \times 10^7$.

$c$ = analyte concentration

$\lambda$ = relative scattering wavelength: $\lambda = \lambda_0/n$

$\lambda_0$ = incident wavelength

$n$, $n_0$ = real refractive indices of the particle and solvent [refractive index (RI) in the absence of absorption]

$dn/dc$ = the differential RI (concentration) increment, i.e., the change of $n$ with the analyte concentration, needs to be known in advance. It should be determined separately, either from literature data or experimentally. It has a constant value for many proteins in water-based buffers and for polysaccharides:

- Proteins = 0.18–0.20 mL/g
- Polysaccharides = 0.14–0.15 mL/g

For glycosylated proteins, $dn/dc$ may not be the same for all glycoforms.

$N_A$ = Avogadro constant

# 3. APPLICATIONS

## 3.1 Low-Angle Light Scattering Determination of Molecular Weight

Depending on the experimental conditions, it is possible to further simplify *Equation 2*, thereby making it amenable to practical applications. In particular, at small scattering angles, $\Theta \rightarrow 0$, $P(\Theta) \rightarrow 1$. Therefore, at small angles, scattering is independent of $\Theta$. This observation forms the basis of LALS. Note that measurements at $\Theta = 0$ are impractical because the incident (laser) light would interfere with the measurement.

### 3.1.1 MEASUREMENTS AT LOW CONCENTRATION

Further, at the limit of low concentrations, the term $A_2 \times c$ approaches 0. *Equation 2* then simplifies to *Equation 3*, as shown below:

$$R_{LS}(\theta) = K_{LS} \times c \times M_w \times (dn/dc)^2 \qquad (3)$$

A prerequisite prior to applying the above equation is an accurate determination of the value of $dn/dc$, which is dependent on both the solvent and the sample/analyte. The value of $dn/dc$ can be determined experimentally by measuring the RI of the sample in a known solvent at various concentrations. The slope of the regression line of $n$ versus $c$ is then $dn/dc$.

For example, for a protein or complex that contains no carbohydrate, $dn/dc$ is constant (often $\approx 0.185$ mL/g) and nearly independent of the amino acid composition of the protein. However, it is advised to measure the actual $dn/dc$ for each material in order to obtain an accurate result.

### 3.1.2 MEASUREMENTS AT MULTIPLE CONCENTRATIONS

When data are available at several concentrations, the second virial coefficient, $A_2$, may be determined (see *Equation 2*).

To determine the molecular weight, $M_w$, from measurements at different concentrations and at low angles [at which $P(\Theta) \approx 1$], use *Equation 2*:

$$\frac{K^* \times c}{R(\theta)} = \frac{1}{M_w} + 2A_2 \times c \; (s)$$

By extrapolating the function $\frac{K^* \times c}{R(\theta)}$ to zero concentrations, the linear regression yields $M_w$ as well as $A_2$:

$$Intercept = 1/M_w \; Slope = 2 \times A_2$$

However, the molecular weight obtained by this approach is very sensitive to the molecular polydispersity of the sample as well as interference by impurities.

@2024 USPC

#### 3.1.3 COMBINATION WITH OTHER DETECTION TECHNIQUES

Determination of $M_w$ by LALS stipulates that $dn/dc$ is known. To this end, the RI increment, $dn/dc$, has to be measured for several different concentrations to generate a plot of $dn/dc$ versus $c$, the $y$-intercept of which is $dn/dc$. Alternatively, when $dn/dc$ is constant, the slope of the regression line of $n$ versus $c$ is $dn/dc$. Determination of $dn/dc$ is facilitated by the coupling of LALS with an RI detector, and *Equation 4* is used for the RI signal, as shown below:

$$R_{RI}(\theta) = K_{RI}cM_w(dn/dc) \qquad (4)$$

Combining *Equation 3* and *Equation 4* leads to *Equation 5*, as shown below:

$$M_w = K'(LS)/(RI) \qquad (5)$$

where $K' = K_{RI}/[K_{LS}(dn/dc)]$ is the instrument calibration constant. The molecular weight $M_w$ is then derived from the ratio of the *LS* versus the *RI* signal. This assumes that $dn/dc$ is constant.

When $dn/dc$ is no longer constant, for example in the case of carbohydrate-containing proteins, an additional detector is needed. For samples detectable by UV, a wavelength is chosen at which ε for the carbohydrate but not the protein part is = 0. Then the ε in *Equation 6* below is effectively that of the protein:

$$UV = K_{UV}C\varepsilon \qquad (6)$$

The value of the specific refractive increment, $dn/dc$, can then be assumed to be proportional to $(RI)A/(UV)$. The outputs of the three detectors, designated *LS*, *RI*, and *UV*, respectively, are related to the molar mass of a sample according to *Equation 7*, as shown below:

$$M_w = \frac{K_{RI}^2}{K_{LS}K_{UV}} \times \frac{(LS)(UV)}{\varepsilon(RI)^2} \qquad (7)$$

ε is a material but not an equipment constant and usually must be determined separately.

### 3.2 Multi-Angle Light Scattering

In MALS, measurements are made at multiple angles (at least three). To obtain the values of the three unknowns on the right-hand side of *Equation 2* ($M_w$, $A_2$, and the mean square radius, $r_g^2$), measurements of $R(\Theta)$ at three different angles are needed in order to obtain three independent expressions of *Equation 2*. The number of angles at which measurements are made (i.e., the quantity of data collected) determines the precision (reproducibility) as well as the accuracy of the measurement.

By measuring the angular dependence of the signal, it is possible to calculate the molecular size ($r_g$) from the initial slope (at small angles) of the angular dependence in *Equation 8*, as shown below:

$$\frac{d_y}{d_x} = \frac{16\pi^2 n_0^2 r_g^2}{3\lambda_0^2 M_w} \qquad (8)$$

where $n_0$ is the RI of the solvent, $r_g$ is the root mean square radius (radius of gyration, molecular size), $\lambda_0$ is the vacuum wavelength of the laser, and $M_w$ is the molecular weight.

In addition, measuring the signal over multiple angles provides information on the three-dimensional shape of the analyte, either by using non-linear regression analysis or graphically by using Zimm plots (*4*).

### 3.3 Combination of Light Scattering with Size-Fractionation Techniques

A more robust approach to molecular weight determination is based on pre-fractionation of poly-disperse protein mixtures or analytes into “slices” of uniform molecular weight. The coupling of fractionation and detection techniques affords more information than either method can provide on its own.

Size-fractionation techniques include size exclusion chromatography (SEC), field-flow fractionation (FFF) techniques, and other separation modes. By applying light scattering in combination with another concentration detector such as RI or UV, a more complete description of the molecular weight distribution can be realized.

*Figure 2* shows an example of this for a sample of Dextran with a known molecular weight of approximately 40 kDa. The diagonal line shows the molecular weight across the SEC curve, and the entire distribution can be used to calculate molecular weight moments; the most obvious one is $M_p$, which is the molecular weight at the peak of the distribution. In addition, three other parameters can be calculated:

1. Number-average molar mass:

$$\overline{M_n} = \frac{\Sigma n_i M_i}{\Sigma n_i} = \frac{\Sigma c_i}{\Sigma c_i/M_i}$$

2. Weight-average molar mass:

Official

Do Not Distribute
Status: Currently Official on 05-Jan-2024
Official Date: Official as of 01-Dec-2019
DOI Ref: 62d7l
DocId: GUID-95009428-314D-4936-B74A-8845C0D245F8_2_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M12337_02_01
@2024 USPC

$$\overline{M_w} = \frac{\Sigma n_i M_i^2}{\Sigma n_i M_i} = \frac{\Sigma c_i M_i}{\Sigma c_i}$$

3. *Z*-average molar mass:

$$\overline{M_Z} = \frac{\Sigma n_i M_i^3}{\Sigma n_i M_i^2} = \frac{\Sigma c_i M_i^2}{\Sigma c_i M_i}$$

The value of $n_i$ is the number of molecules with molar mass $M_i$, and $c_i$ is the weight concentration of molecules with molar mass $M_i$ (as determined by the RI detector).

In the case of 40 kDa Dextran, the measured parameters are shown in *Table 1*, along with a calculation of the polydispersity ($I_p = M_w/M_n$).

**Table 1. Measured Molar Mass Parameters for 40 kDa Dextran**

| Parameter | Value |
|---|---|
| $M_n$ | 29,420 |
| $M_p$ | 34,650 |
| $M_w$ | 40,760 |
| $M_z$ | 55,960 |
| $I_p$ (= $M_w/M_n$) | 1.385 |

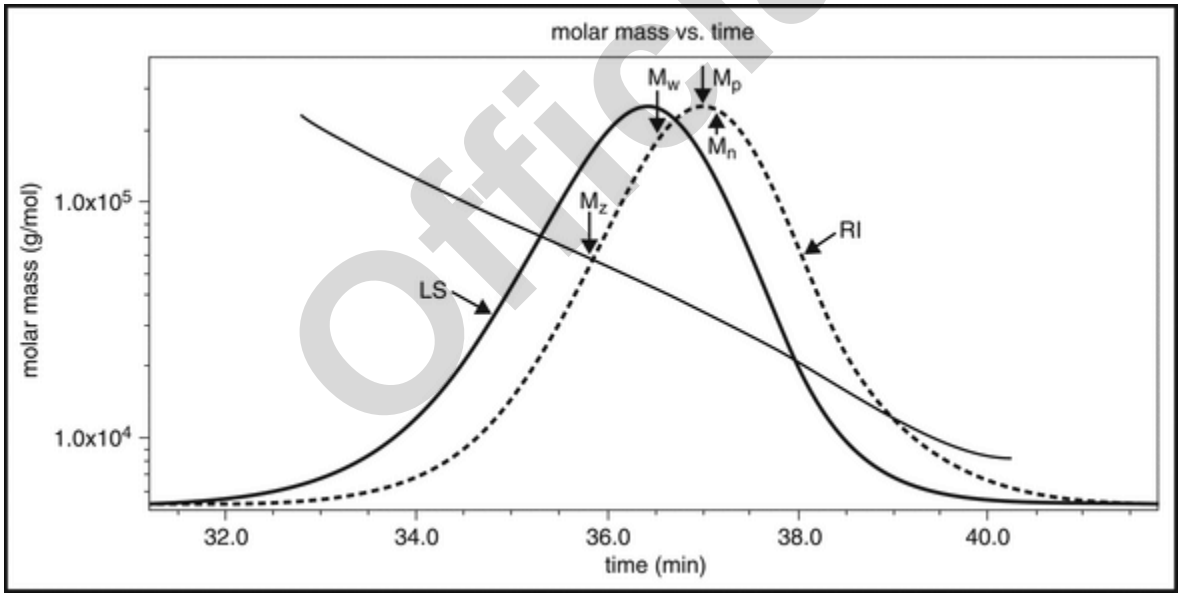

Figure 2. Molecular weight distribution for 40 kDa Dextran.

## 4. INSTRUMENTATION

Modern light scattering spectrometers use laser light because of the following advantages that lasers offer over conventional light sources:

- Reliability
- Beam collimation
- Single wavelength (scattering depends on the wavelength of the scattered light)
- Equipment durability and compactness

*Figure 3* shows a typical setup for the measurement of SLS. A monochromatic light source (i.e., a light source emitting light of only one wavelength; usually a laser) shines light on the sample. The intensity or the power of the scattered light is being measured at a known scattering angle Θ by a detector.

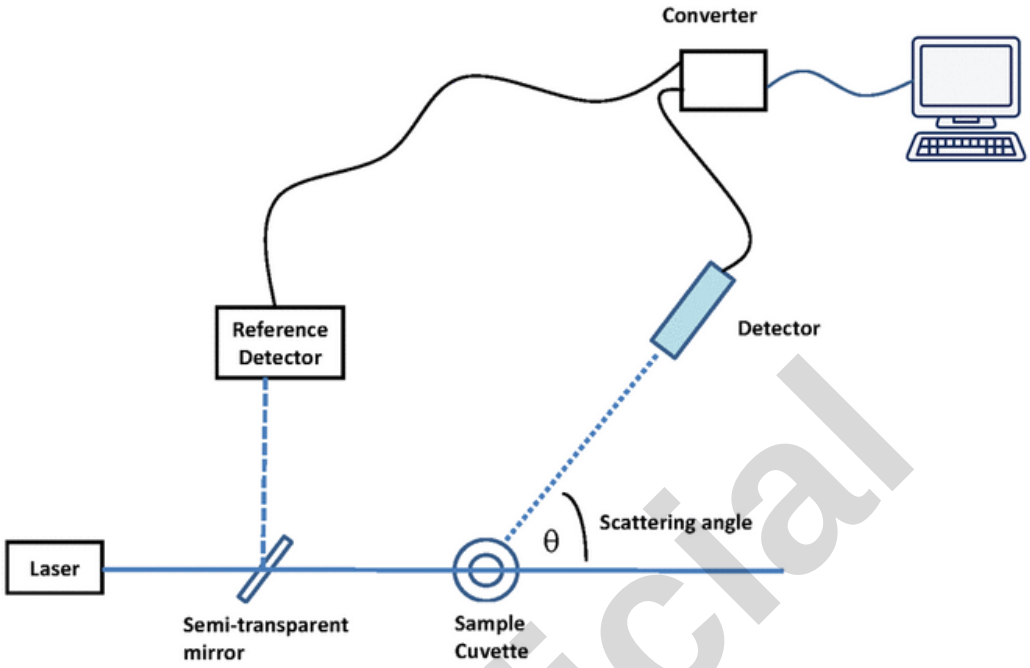

Figure 3. A typical setup of a static light-scattering instrument.

Historically, the measurements at different angles were made using a scanning photometer (single detector, variable angle). More recently, photometers containing a fixed array of 3–18 detectors have come into use.

## 5. LOW-ANGLE LIGHT SCATTERING VERSUS MULTI-ANGLE LIGHT SCATTERING

A major advantage of LALS is the exact measurement of high molecular weights (>10 million g/mol) without the principle-related errors that often occur with extrapolations, which are necessary for measurements at higher angles (but not with the use of many angles).

The major drawbacks of LALS when compared to MALS are as follows:

- **Higher noise:** Low angles are always noisier than high angles. Although using in-line filter(s) removes the scattering effects of debris from the low-angle data, it also removes much of the signal. Further, the measurement precision is roughly proportional to the square root of the number of detectors.
- **Less information:** Multi-angle data are needed to solve the Rayleigh equations.
- Inability to obtain information on molecular shape (see *3.2 Multi-Angle Light Scattering*).

LALS techniques and systems may be preferred for their simplicity and have been optimized to deal with their inherently lower information content (e.g., linearization strategies of multi-concentration data such as Zimm plots). Low-angle systems will be much cheaper and less dependent than the more complex equipment and (proprietary) fitting algorithms used in multi-angle systems. Finally, with the use of additional coupled simple detector systems such as RI and UV, the determination of molecular weight using LALS is a feasible, robust option.

A combination of the simplicity of LALS with the improved signal-to-noise ratio of higher scattering angles, offered by modern detectors, is achieved when performing measurements at $\Theta = 90°$, the angle with the highest signal-to-noise ratio. Also, except for proteins of high molecular weight, there will be no significant angular dependence of the scattering with this configuration. However, for high molecular weight proteins, the light scattering signal has to be corrected with a viscosity detector, which requires making additional theoretical assumptions that are difficult to verify for routine applications.

## 6. PRACTICAL CONSIDERATIONS

Many SLS experiments, particularly those aimed at elucidating properties of proteins and other polymers in solution, will fall into the Rayleigh–Gans–Debye (RGD) scattering regime. *Table 2* summarizes the governing equations for four typical experimental situations: 1) low-angle scattering at a low concentration, which provides information on the molecular weight of the sample; 2) low-angle scattering at multiple concentrations, which provides information on molecular weight and solution non-ideality; 3) multi-angle scattering at a low concentration, which provides information on molecular weight and molecular size; and 4) multi-angle scattering at multiple concentrations, which provides information on molecular weight, molecular size, and solution non-ideality.

**Table 2. Most Common Governing Equations**

| | Low Concentration | Multiple Concentrations |
|---|---|---|
| Low-angle light scattering (LALS) | $\frac{K^*c}{R(\theta)} = \frac{1}{M_w}$ Output: $M_w$ only | $\frac{K^*c}{R(\theta)} = \frac{1}{M_w} + 2A_2c$ Output: $M_w$ and $A_2$ |
| Multi-angle light scattering (MALS) | $\frac{K^*c}{R(\theta)} = \frac{1}{M_w}\left(1 + \frac{q^2 r_g^2}{3}\right)$ Output: $M_w$ and $r_g^2$ | $\frac{K^*c}{R(\theta)} = \frac{1}{M_w}\left(1 + \frac{q^2 r_g^2}{3}\right) + 2A_2c$ Output: $M_w$, $r_g^2$, and $A_2$ |

Additional considerations:

- To obtain a reliable estimate for the excess Rayleigh ratio, one must use a calibration standard to obtain an "absolute" scattered intensity. Pure organic solvents (e.g., toluene) can be used for this purpose. It is important to note that the Rayleigh ratio of the solvent is a function of wavelength of the incident light. Alternatively, one can calibrate the system using a standard of known molecular weight (e.g., bovine serum albumin).
- For the above RGD equations to hold, samples must not absorb light in the wavelength range of the incident beam. Because laser light in the visible range is most common, samples should be colorless. If the samples are colored, more advanced data analysis techniques are required. Otherwise, the results will be unreliable.
- Likewise, cuvettes in the instrument systems with removable cuvette should not absorb light in the wavelength range of the incident beam. Care should be taken to ensure that the cuvette is free from smudges, scratches, or any other optical defect that could interfere with the measurement.
- Scattered intensity depends on the molecular size. Very small levels of large particles can dominate the signal and compromise the measurement. Samples should be appropriately prepared to minimize contamination from environmental or other sources. Sample preparation may include filtration, centrifugation, or other appropriate separation techniques. Care should be taken to ensure that the method of sample preparation itself does not introduce experimental artifacts (e.g., the analyte of interest adsorbing to a filter membrane). It is good practice to examine samples by dynamic light scattering to verify the absence of large contaminating species prior to conducting SLS measurements.

# ▲⟨1430.2⟩ ANALYTICAL METHODOLOGIES BASED ON SCATTERING PHENOMENA—LIGHT DIFFRACTION MEASUREMENTS OF PARTICLE SIZE

1. INTRODUCTION
2. THEORY
3. INSTRUMENTATION
4. APPLICATIONS
5. METHOD DEVELOPMENT
6. METHOD VALIDATION STRATEGY
7. DATA INTERPRETATION AND REPORTING

## 1. INTRODUCTION

Light scattering measurements may be used for the determination of particle size distributions because light scattered from particles has an angular dependence on the size of the particles. In principle, this application makes use of the same phenomenon as the low-angle light scattering (LALS) and multi-angle light scattering (MALS) techniques. The difference in the particle size measurement method lies in the higher spatial or angular resolution needed for the detection of scattered light. Light diffraction measurements allow for the derivation of a full-size distribution, with moderate to high resolution, rather than a single characteristic size. Specialized instrumentation and software have been developed for the specific needs of this application. Additional details on method and instrument requirements are provided in *Light Diffraction Measurement of Particle Size* ⟨429⟩.

Light scattered by particles in the near-forward direction is analogous to diffraction of light through an aperture. As this application makes use of the full pattern of diffracted light, it is properly described as light diffraction. It is also often referred to as laser diffraction due to the almost universal use of laser light sources.

The range of application, speed, minimal sample restrictions, and ease of use has made this the most broadly applied and commonly used technique for particle size analysis. Distributions with a resolution on the order of 100 independent channels are common. Measurements can be performed in seconds or less. Depending on the instrument configuration, the method is applicable to sizes ranging from about 0.01 µm to greater than 3000 µm. Particles may be measured in almost all matrices through which light can be transmitted, including liquids, gases, vacuums, and, potentially, solids.

The discussion in this chapter will focus on the application of laser light diffraction to materials of pharmaceutical interest. This still covers a wide range of materials, including excipients, active pharmaceutical ingredients (APIs), intermediates, starting materials, raw materials, in-process formulations, and drug products. Materials may be liquid, solid, inorganic, organic, crystalline, amorphous, single- or multi-phase, and combinations of these materials.

## 2. THEORY

The complete description of light scattering by spheres is given by the Mie theory, which is based on the solution to Maxwell's equation for the interaction of light with an optically homogeneous sphere. This accounts, not only for light diffracted by the particles, but also for light passing through the particles, i.e., refracted light. The Fraunhofer model represents a special case of the Mie theory that does not account for refraction. The assumptions here are that the refractive index (RI) of the particle material relative to the matrix and the absorptivity are high, so that effectively no light passes through. It also assumes that particles are large relative to the wavelength of the incident light. Thus, it is most properly applicable to particles greater than several micrometers for visible light sources. Though the Fraunhofer model can be applied when these conditions are not met, it can produce known artifacts and errors. However, it can still be useful as a default when the RI is unknown. The errors are often negligible for larger particles. A more detailed description of the Mie and Fraunhofer models can be found in ISO 13320:2009—*Particle size analysis—Laser diffraction methods*.

Some limitations in Mie theory are that it assumes (among other conditions) that particles are spheres with smooth surfaces and that they are optically homogeneous. These conditions are not generally met for most real particles of pharmaceutical materials. An additional complication is that most measurements are performed with the particles in motion. Thus, non-spherical particles may present a range of aspects to the incident light axis during the measurement, in effect appearing as multiple particles. Consequences of these deviations from theory are discussed in *7. Data Interpretation and Reporting*.

RI includes both real and complex components. The real component is commonly determined by either a microscopy method (Becke line technique) or from the RI of solutions of known concentration.

In the Becke line technique, particles are immersed in oils of known RI and observed with transmitted light. As the focus is moved above the plane of the particle, a bright ring may be observed moving into the region of higher RI, i.e., either into or away from the particle boundary. Using different oils, the particle RI may be determined well within the needed accuracy. Using polarized light, the RI of the individual crystalline axes may also be determined. In that case, an averaged value may be used in the Mie model.

In the solution method, an Abbe refractometer is used to measure the RI of a solution for which the concentration of the material is known. Extrapolating the solution RI, from a series of known concentrations of the material, to that of the pure substance yields a good approximation. This may require knowledge of the true density of the material.

https://pharmacopeia.com/

The imaginary component of the RI is the absorptivity value for the wavelength of light used in the light diffraction measurement. For most non-colored materials, this will be very low. This value is not typically measured.

For both components, the values should be considered as initial approximations. Although the Mie model results are not especially dependent on the chosen values, it can sometimes yield unrealistic results. The sensitivity of the measurement to small changes in the assumed values should be assessed. This requires only the recalculation of an existing measurement using different RI values. Final RI and absorbance values should be chosen to avoid being too near an area of high sensitivity. The resulting size distributions should always be evaluated to assure that they realistically represent the sample.

## 3. INSTRUMENTATION

Instrumentation consists of light source(s), a measurement region, optics to collect the scattered and unscattered light, multi-element detector(s), and necessary hardware and software for the computations. Often more than one light source may be used. Light sources are usually lasers, though not always. Sources of different wavelengths are mainly used to extend the size range, especially to better handle samples in the submicron region.

The measurement region is where the sample is measured. Depending on the specific application, this is typically in a well-defined position relative to the detector and optics, and comprises windows that physically contain the sample dispersion. Associated sample dispersion equipment is also part of the instrument. (An exception would be for instruments specifically designed for sprays or on-line use.)

The detectors must provide adequate spatial resolution needed to best define the diffraction pattern. To best resolve the variations in diffraction patterns in the applicable size range, most elements are within a relatively low forward angle. Additional detectors at wider angles are often incorporated to extend the range to smaller sizes. Depending on the instrument design, different lenses may be used for specific size ranges. This is not common with the reverse Fourier configuration.

Further descriptions and illustrations of common instrumentation configurations are shown in ⟨429⟩ and ISO 13320.

## 4. APPLICATIONS

In principle, the light diffraction technique may be applied to any particulate system that allows for sufficient transmission of light: solid in liquid, liquid in liquid, gas in liquid, solid in gas, and liquid in gas. However, it is most commonly applied to solids dispersed in either liquids or gas (air), and to sprays of liquids or solids in air.

For solid powders, dispersion in either liquid or gas both offer advantages and disadvantages. Dispersion in liquids generally allows better control of the degree of dispersion of the material, which is important for understanding the desired characteristics of the powder. It also offers the advantage of being able to sample the dispersion's particles from the instrument dispersion outflow for observation by microscopy. Microscopy permits observation of the particles in the same state they exist during the light diffraction measurement. Obtaining particles from a dry dispersion as they exist in the dispersion would be difficult, if not impossible.

Disadvantages of liquid dispersion include possible changes in the material characteristics due to dissolution or flocculation. Selection of the dispersant system, including use of surfactants, is critical to developing a suitable method.

The advantages of dry or air dispersion of solid powders include the absence of solubility concerns and minimal sample preparation. A significant disadvantage is decreased control of particle dispersion. Though a range of dispersion energy can be applied by controlling the shearing air pressure, there is typically a reduced ability to separate deagglomeration from particle fracture processes. The occurrence of artifacts appearing as larger particles has also been observed, possibly due to material flaking from the surfaces of the dispersion unit. Larger sample sizes may also be needed.

Dry dispersion also requires adequate filtration and containment of the vacuum exhaust. Highly potent or toxic materials may not be suited for this analysis.

The use of dry dispersion is most appropriate for materials used in a similarly dispersed state, for example, the analysis of liquid or powder sprays from drug products and devices.

## 5. METHOD DEVELOPMENT

The fundamental step in starting the development of a method is to define the desired state of dispersion for the sample. Almost all powder samples will exhibit some degree of agglomeration. Attractions due to dispersion or van der Waals forces, electrostatics, or physical attachment, etc., are present in any sample. The strength of the attachments varies widely and depends on the particles' size, composition, and prior processing.

The terms agglomerate and aggregate will not be defined here. Within the scope of pharmaceutical materials, there can be an essentially continuous range of particle association strengths. Agglomerates or associations can range from those that are very weak and easily disrupted with minimal agitation, to those that are very strong and physically bound particles. Hence, the terms agglomerate and aggregate are sometimes used interchangeably, depending on the process used to create the material.

It is critical that the intended use of the particle size information be understood to determine the appropriate degree of dispersion. For example, measurement of primary, i.e., fully deagglomerated particles may be more informative for understanding the particle formation process or inherent dissolution behavior of a powder. Alternatively, including agglomerates in the measured distribution may be more useful for understanding issues of content uniformity and powder flow. A good understanding of the intended use of the material and expected forces encountered during further processing will help to determine the appropriate dispersion. Optical microscopy is an important tool to characterize the sample dispersion.

A typical dispersion study (assuming a solid in liquid dispersion) would first consist of analyzing a suspension created with minimal dispersion energy, e.g., by stirring or vortexing. Subsequent analyses of the suspension are performed after application of increasing dispersion energy, e.g., with added sonication times. If this is not possible with a single preparation, multiple preparations may be used. At each stage, the stability of the sample should be examined, e.g., with a stirring study. Comparing

Official

https://pharmacopeia.com/

the resulting distributions with consideration of the sample behavior and supporting microscopy reveals the suitability of the dispersion conditions.

For dry dispersions, analyses using different shear air pressures and feed rates are done. This is often referred to as an air pressure titration study.

Once the intended state of dispersion is determined, method development will focus on how to best achieve and maintain that state reproducibly and reliably. For powders, dispersion either in air or a liquid is necessary. For liquids, the dispersant must support the dispersion of the particles to the desired extent, with no dissolution or other physical change or re-agglomeration. Though dissolution is not an issue for air or gas dispersion, achieving the proper degree of dispersion may be a greater issue.

The amount of incident light scattered or absorbed by the sample, expressed in terms of obscuration, transmittance, or optical concentration range of the sample, is related to the sample concentration and serves as a convenient proxy for relative concentration. It is expected that this will affect the measured size, though a range of values where the sensitivity of the results is low should be possible. This is generally a function of the overall instrument design and not material-specific. The lowest concentration must be sufficient to minimize the effects of noise, and the upper limit is needed to minimize the effects of multiple scattering. Suitable ranges may be recommended by the instrument manufacturer. Restricting the range may improve reproducibility.

## 6. METHOD VALIDATION STRATEGY

Chapter ⟨429⟩ provides guidance to demonstrate the required accuracy and precision for the instrument and methods of the laser light diffraction technique.

The International Council for Harmonisation (ICH) guidelines on method validation do not fully account for characterization methods such as particle size analysis. However, the fundamental concerns about method precision and robustness still apply.

As described in *Validation of Compendial Procedures* ⟨1225⟩, precision should be addressed by assessing repeatability and intermediate precision. Additional assessments of reproducibility could include multiple instruments and laboratory location.

The robustness assessment should address the sensitivity of the method to other likely sources of variation and should establish a range of acceptable conditions. Factors to consider will depend on the type of dispersion. For liquid dispersions, in addition to the classic stability considerations, this should include an assessment of the stability of the dispersion in the instrument over potential analysis times. Sample concentration, as indicated by obscuration, is an important factor, as it is most likely to have some effect. Other typical factors could include stability of the predispersion, recirculation or stir rate, dispersion energy, equilibration or stir time before initiating the measurement, and measurement time. For dry dispersion, measurement time, sample amount, air pressure, and feed rate to achieve target obscuration may be most important. These factors may be examined using an experimental design. For example, two or more factors could be evaluated by using high and low values at about the nominal value and determining the main effects.

Overall, the greatest sources of variations in the light diffraction technique are the sample properties, the sample preparation, and sampling. These far exceed any variations in the measurement process.

Given the fundamental aspects of the measurement process and the technique-dependent definition of size, the assessment of the accuracy is not simple. Comparison to an orthogonal technique is not always possible, especially given the different effects the particle shapes may have. A subjective assessment using optical or electron microscopy is recommended to compare the range of particle sizes observed with the reported light diffraction results.

## 7. DATA INTERPRETATION AND REPORTING

The ease of acquiring particle size distribution information by light diffraction belies potential pitfalls in its interpretation. Other than for perfect spheres, the concept of accuracy in describing the size of a single particle, much less a collection of varied particles, is elusive. The chosen optical model, particle shapes, and optical properties of the sample all influence the results of the measurement.

Calculations are based not on the sizing of any single particle but rather on the average diffraction pattern from the ensemble of particles passing through the measurement region over time. During this time, the particles can present multiple orientations.

The calculated size distribution is also not directly calculated from the diffraction pattern. Rather it is the result of comparing the cumulative theoretical patterns of individual size fractions, calculated using the chosen optical model, to the measured diffraction pattern. The relative proportions of the individual size are varied until the resulting calculated pattern best matches the measured one.

Thus the size distribution of a sample is best described as the size distribution of spheres with defined optical properties that produces a diffraction pattern equivalent to that of the sample. Interpreting the measured size distribution in terms of specific physical dimensions, e.g., length or width, is a mistake. Doing so has important implications for the interpretation of the reported size distribution, especially when considering the effects of particle shape on the results.

In some cases, the distribution of the modeled spheres may be restricted to a certain defined shape, e.g., a normal, log-normal, or Rosin–Rammler distribution. This was more common during the early stages of the instrument development, when computational abilities were more limited. This approach is not commonly used today, though the option may be available in the instrument software.

Because of how the results are derived, the particle size distribution from light diffraction measurement is best considered as the cumulative fraction of volume (or mass, assuming a uniform density) that is less than the defined sizes. This cumulative distribution is the basis for deriving the most commonly used statistics. These include percentile sizes such as ×50 and ×90 (the sizes for which 50% and 90%, respectively, of the sample volume are less than), as well as size quantiles such as Q10 (the fraction less than 10 µm). These are derived easily by interpolation from the cumulative distribution. For other statistics, such as various mean sizes, central values of the individual size bins must be assumed.

In plotting particle size distributions, if represented as a scatter plot, it should be realized that it is more properly considered as a histogram, with the relative height of each band representing the volume fraction within the size band, i.e., between the upper and lower limit. Unless the bins are evenly distributed on the size scale, the distribution density function versus size is what should actually be plotted. The distribution density is the volume fraction divided by the width of the size bin. This allows for the properly proportioned representation of a distribution when the size bands are of different widths. It will also permit measurements from different sources, with different numbers of bins to be overlaid on the same plot. One caution is that this quantity will change if the scale basis of the size axis is changed, e.g., from linear to logarithmic.

Further descriptions of particle size distribution statistics can be found in ISO 9276-1:1998—*Representation of results of particle size analysis—Part 1: Graphical representation* through ISO 9276-6:2008—*Representation of results of particle size analysis—Part 6: Descriptive and quantitative representation of particle shape and morphology*.▲ (USP 1-Dec-2019)

1. INTRODUCTION
2. APPLICATIONS
3. THEORY
    3.1 Correlation Function Analysis
4. INSTRUMENTATION
5. MEASUREMENT
    5.1 Factors That Affect the Measurement
    5.2 Sample Preparation
    5.3 Test Procedures
    5.4 Data Interpretation
6. ADVANTAGES AND LIMITATIONS
7. ADDITIONAL SOURCES OF INFORMATION

## 1. INTRODUCTION

Dynamic light scattering (DLS)—also referred to as quasi-elastic light scattering (QELS)—is a nondestructive, light-scattering technique for particle characterization of colloidal dispersions, biological solutions, and solutions of macromolecules. DLS has also been referred to in the literature as photon correlation spectroscopy (PCS), which is one of the DLS measurement methods such as frequency analysis and cross-correlation spectroscopy. It is often used for measuring average particle diameter and the broadness of the size distribution of submicron-sized particles that are dispersed in a liquid and are free from the influence of sedimentation. Compared to other light-scattering techniques, DLS can provide size information in the nanometer (nm) range, which is out of the primary range of static light scattering (e.g., laser diffraction). In addition, DLS can also provide information on the stability of suspensions/emulsions as it is highly sensitive to aggregation and to the behavior of suspensions/emulsions under different dispersing conditions.

## 2. APPLICATIONS

Typical applications for particle sizing by DLS include those measuring any particle dispersed in a liquid (suspensions or emulsions) that is influenced by Brownian motion. These applications include, but are not limited to:

- Measuring micronized water insoluble active pharmaceutical ingredients (APIs) for injectable, oral, or other use
- Measuring droplet size of oil in water emulsions where the API is dissolved in the oil
- Monitoring liposome formation to ensure a desired size is attained
- Monitoring the quality and uniformity of a suspension used in a coating process, such as time-release coatings
- Monitoring the size of macromolecules, such as proteins or protein conjugates
- Any additional step in a process or finished product where a suspension is used

## 3. THEORY

The application of DLS applies the concept of random motion of particles in a colloidal system, commonly referred to as Brownian motion, in the particle size measurement. Dispersed particles scatter incident light proportional to the radii and inversely proportional to the light wavelength, indicating that the large particles scatter much more light than the small particles, and the short wavelength light is scattered stronger than the long wavelength light from the same particle. If the diameter of the particle is less than 1/10th of the wavelength of the incident light, the scattering is commonly referred to as Rayleigh scattering. However, if the particles are greater than 1/10th of the wavelength of the incident light, then the scattering process can be described by the Mie theory. In that case, the scattering is angle dependent and the scattered light is more intensely concentrated toward the direction of the incident light.

As the particles scatter light in DLS, the time-dependent fluctuations of the intensity of the scattered light resulting from random motion of the particles is measured. The fluctuations of intensity in scattered light are correlated with short decay intervals ($\tau$). One of the approaches to mathematically describe the time variation of such a random motion is the application of the correlation function. For monodisperse systems, the intensity autocorrelation function (ACF) is expressed as a mono-exponential function [$G(\tau)$] as shown in *Equation 1*:

$$G(\tau) = 1 + be^{-2D_t q^2 \tau} \quad (1)$$

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M12339_02_01
@2024 USPC

where $b$ is a constant, depending upon the instrument and settings of optics; $D_t$ is the translational diffusion coefficient; and $q$ is the scattering vector.

The scattering vector is further expressed as shown in *Equation 2*:

$$|q| = 4\pi n_0/\lambda_0 \cdot \sin(\theta/2) \quad (2)$$

where $n_0$ is the refractive index (RI) of the medium, $\lambda_0$ is the light wavelength in a vacuum, and $\theta$ is the scattering angle.

The intensity autocorrelation function [$G(\Pi)$], often expressed as $G_2(\tau)$, is expressed as a function of the field correlation function, $G_1(\tau)$, as shown in *Equation 3*:

$$G_2(\tau) = 1 + G_1(\tau)^2 \quad (3)$$

In DLS, a correlation is generated where raw correlation function (RCF) is plotted against delay time ($\tau$) as shown in *Equation 4*:

$$\text{RCF} = G_2(\tau) - 1 = G_1(\tau)^2 \quad (4)$$

$D_t$ is calculated by data analysis of the autocorrelation function using *Equation 1*.

The diffusion coefficient ($D$) is then related to the radius ($R$) of the particles by means of the Stokes–Einstein equation as shown in *Equation 5*:

$$D = k_B T/6\pi\eta R \quad (5)$$

where $k_B$ is the Boltzmann constant, $T$ is the absolute temperature, and $\eta$ is the viscosity of the dispersion medium. The size of spherical particles is calculated from the Stokes–Einstein equation if the viscosity of the medium is known at a given temperature. As can be seen from *Equation 5*, temperature is an important factor impacting the diffusion coefficient both directly ($T$ in the numerator) and indirectly as viscosity ($\eta$ in the denominator) is an inverse function of temperature. The particle size determined by DLS is the apparent hydrodynamic radius, $R_h$(app), and can change with the particle concentration ($c$) as shown in *Equation 6*, where $D(c)$ indicates that the measured diffusion coefficient is a function of $c$:

$$R_h(\text{app}) = \frac{k_B T}{6\pi\eta D(c)} \quad (6)$$

## 3.1 Correlation Function Analysis

Intensity correlation functions are commonly normalized so that $G(\infty)$ equals 1. Normalization of autocorrelation coefficient results in a baseline limit of 1 for $G(\infty)$ for monochromatic light, with an upper correlation limit of 2 for $G(0_0)$.

The time dependence of the fluctuation intensity is typically evaluated by employing a digital correlator. Each data point in the measured intensity correlation function is the average of the multiples of the number of photons counted in one sampling time and another sampling time with an interval between these two sample times called delay time. The entire intensity correlation function is formed by varying the delay time. Correlation is high at short delay times, and, as particles diffuse over time, correlation reduces to 0. The exponential decay of the correlation function is a characteristic feature of the diffusion coefficient.

The $z$-averaged decay rate ($\Gamma$) and the polydispersity index (PI) are commonly obtained by fitting a polynomial of third degree to the logarithm of the intensity correlation function per the cumulant method.

The decay rate is directly related to the diffusion coefficient ($D$) as shown in *Equation 7*:

$$\Gamma = q^2 D \quad (7)$$

where $q$ is the modulus of the scattering vector.

The cumulant analysis determines the mean diameter and a distribution width only. For polydisperse samples, more complex methods such as the CONTIN method are required in order to determine the size distribution function. Modern dynamic light scattering instruments perform cumulant analysis and size distribution function analysis automatically. The quality of the result, however, depends significantly on the quality of the data and the constraint settings of the fitting procedure.

The area under each peak of the intensity particle size distribution is proportional to the relative scattering intensity of each group of particles. The scattering intensity is weighted by molecular weight and radius; thus, the intensity distribution is more skewed toward the larger particles. Therefore, a change of the intensity to a mass or volume distribution can be achieved by means of the Mie theory. The underlying assumptions are as follows:

1. All particles exhibit an equal and uniform density.
2. The particles are spherical.
3. No inaccuracy exists in the intensity particle size distribution.

Although the first two assumptions can be applicable, the third assumption is not accurate due to the ineffective correlogram fitting in the DLS method, indicating that, no matter how monodisperse a sample is, the particle size distribution as measured by the DLS method will have intrinsic polydispersity and will not have a single band distribution.

Historically DLS studies were usually performed at an angle of 90°, which required very dilute samples to avoid multiple scattering phenomena and to have enough scattering intensity. With current instruments, it is now possible to perform DLS measurement on higher concentrated samples, up to 40% (w/v), with the advancement of backscatter technology.

The DLS technique provides size and polydispersity information at relatively low to moderate concentrations. At a high concentration DLS measurements become more challenging. These issues have been resolved to a great extent by the recent advancements in DLS backscattering and 3-D cross-correlation. Backscattering measurements allow detection of scattered light at a higher angle (typically 160°–180°), which is measured close to the cuvette wall. In 3-D cross-correlation technology, the sample is analyzed by two detectors simultaneously at the same scattering vector. Such measurements allow cross-correlating the signals from both detectors and, thereby, suppressing the contribution of multiple scattering.

Dynamic light scattering is typically used for measurements in the submicron range, although this technology may measure particle size up to a few microns. The upper size limit of DLS depends on sample density, implying that the upper limit of measurement is the point where the sedimentation of the particles overcomes the diffusion process. The lower limit of particle size measurement depends on the excess scattered light produced by the scattering particles relative to that produced by the suspension medium. In addition, sample concentration, relative RI of the particle and medium, laser power and wavelength of light, and detector configuration will affect the lower size limit measured by DLS. The major advantages of this method include its nondestructive nature, small amount of sample requirement, and ease of sample preparation. The accuracy of results determined by DLS may be compromised by sample contamination during the sample preparation. In addition, air bubbles and silicone droplets may be erroneously regarded as particles, leading to inaccurate results. Measurements of nonspherical particles can also be a challenge for DLS and may lead to inaccurate estimates since DLS assumes that particles are spherical and the diffusion is only translational. Nonspherical particles, especially very large and dissymmetrical (rod-like shape) ones, have also a rotational diffusion component in addition to the translational one. The rotational diffusion component introduces a time-dependent anisotropic effect to the measured fluctuations of the scattered light, which results in inaccurate size estimates. Lastly, the accuracy of the results of DLS measurements is affected also by changes in temperature and viscosity of samples.

## 4. INSTRUMENTATION

The instrumentation generally comprises a laser as the light source, sample holder or cell, suitable optics, detector, correlator or spectrum analyzer, and a computation unit. Several configurations of signal detection and analysis are possible (see *Figure 1*).

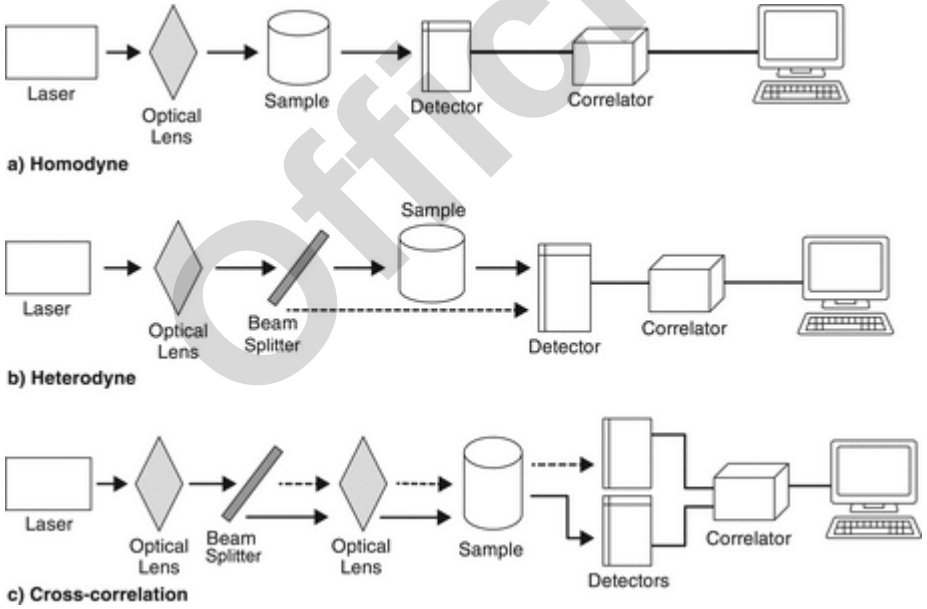

Figure 1. Typical optical arrangement for DLS.

Homodyne detection uses only the light scattered from the incident beam. In heterodyne detection, a portion of the incident beam is mixed with the scattered light as a reference. A cross-correlation arrangement involves the combination of two simultaneous homodyne measurements.

A laser light source provides a monochromatic, coherent light source to illuminate the sample. The laser is generally polarized with the electric field component perpendicular to the plane of the incident and scattered light paths, usually vertically.

The sample is contained in a holder or cell, which must be capable of maintaining the temperature of the sample to within ±0.3°.

Optics focus the beam to define the measurement region and collect the scattered light for analysis. These may be external to the sample cell or, with fiber optics, may be inserted into the sample dispersion. A polarizing analyzer may be included to maximize transmission of the vertically polarized light.

Scattered light collected by the optics is measured by a detector capable of responding to the temporal fluctuations of the light intensity and providing an output proportional to the intensity. The detector is positioned at a fixed angle relative to the incident light, generally between 90° and 180° (side scattering and backscattering). Some instruments that include the optics to perform zeta potential determination allow for size to be determined by DLS using a forward-scattering angle, such as 10°–15°.

@2024 USPC

The time-dependent signal from the detector is processed by the correlator or spectrum analyzer. Further computations are then carried out to determine the results: the average hydrodynamic diameter and the PI or the particle size distribution depending on the analysis methods used.

Further details about the recommended instrumentation and possible configurations may be found in ISO 22412:2017—*Particle size analysis—Dynamic light scattering (DLS)* or in *Particle Size Analysis by Dynamic Light Scattering* ⟨430⟩.[1]

As the measurement depends on first principles, including knowledge about the suspending fluid, there is no calibration required. However, proper instrument function should be confirmed periodically using suitably characterized standard particles. Standards may be available from the instrument vendors or from a national standards organization such as the National Institute of Standards and Technology. Requirements for the instrument suitability are specified in ⟨430⟩.

## 5. MEASUREMENT

### 5.1 Factors That Affect the Measurement

**Concentration:** The concentration must be sufficiently high to maintain constant time-averaged intensity but at the same time very low to prevent multiple scattering and/or particle–particle interaction.

**Measurement duration:** The typical measurement time is from 1–10 min.

**Multiple scattering:** At high concentrations, scattered photons may undergo multiple scattering, which results in a correlation function that decays faster and results in an apparent smaller particle size. Therefore, sample concentrations should be low enough that the optical paths remain to avoid multiple scattering.

**Particle–particle interaction:** In order to obtain an accurate measurement, the signal from all scattering particles freely experiencing Brownian motion within the scattering volume need to be measured. However, it may be difficult to always ensure the above requirement since at certain concentrations a portion of the scattering particles may be subjected to a constrained Brownian motion.

**Sample preparation:** It is absolutely critical to avoid large particles, commonly called “dust”, to avoid inaccurate signals and erroneous particle size measurements.

**Size range:** The size range commonly determined by DLS is 2–2000 nm. The instrument optics and engineering determine the lower size limit, while the upper limit is determined by the sedimentation and number fluctuations due to the limited number of large particles in a small scattering volume.

**Stray light:** Stray light must be minimized under all conditions.

**Temperature and Viscosity:** Temperature and viscosity of the sample must be controlled within a certain range in order to have an accurate measurement and reliable results.

### 5.2 Sample Preparation

As DLS monitors the intensity fluctuations in the light scattered from the sample due to the Brownian motion observed, different liquid environment conditions will affect the observed particle size. The conditions include: pH, conductivity, surfactants, or other chemicals or materials dissolved in the base liquid. This is why size data from DLS will differ from microscopic images taken with scanning electron microscopy or transmission electron microscopy. Microscopic characterization of nanomaterials involves drying the sample and placing it under vacuum while DLS requires the material to be dispersed in a liquid. DLS will give information on how the nanomaterial will behave in a liquid and report this behavior in terms of size.

It is best practice to analyze a sample suspension that is as close as possible to the concentration and conditions where the suspension will be used. In cases where the sample may be too concentrated, it is important to 1) perform dilutions with the same base liquid and 2) perform the dilution by mass. The solvents/buffers used as base liquid must be properly filtered. This will ensure that the DLS results are repeatable and that the data from any subsequent samples analyzed will be comparable. If the dilution is not performed in this manner or is performed differently each time, the results may become unreliable.

### 5.3 Test Procedures

The test procedures in a typical DLS instrument take into consideration the following aspects:

1. **Type of cell/cuvette:** Typically plastic or glass. (Quartz is not necessary unless specified by the manufacturer and is reserved for work in the ultraviolet light range, whereas most DLS instruments operate in the visible light range.)
2. **Temperature setting:** Typically controlled by a Peltier thermoelectric controller.
3. **Equilibration time:** If the sample is not at room temperature prior to analysis or if the temperature setting is set higher or lower than room temperature, it is important to allow the suspension temperature to equilibrate.
4. **Accumulation time:** The number of accumulations represents the number of individual measurements of the light fluctuations to build the ACF. Increasing the number of accumulations increases resolution and quality of the ACF, while decreasing the number of accumulations decreases analysis time. Most manufacturers have a recommended accumulation time that is a balance of resolution and analysis time.
5. **Selection of base liquid:** This is the base liquid with no particles present. In most cases, this is simply water. It is not necessary to add pH or salt concentration information since these characteristics are considered additives or conditions of the water that will have a negligible effect on viscosity and RI.

[1] This chapter will be published in a future *Pharmacopeial Forum* (*PF*) issue.

DOI: https://doi.org/10.31003/USPNF_M12339_02_01
@2024 USPC

6. **Sample ionic strength optimization:** To obtain a particle diameter close to its real dimension the PCS measurement has to be performed at a suitable ionic strength supplied by the presence of sufficient electrolyte (e.g., by a monovalent salt). A conductivity of greater than 1 millisiemens/cm is generally recommended. The stability of the suspension has to be closely monitored during the ions' addition to avoid the colloidal system collapse when the measurement is performed.
7. **Number of repetitions:** This is the number of times to repeat the analysis on the different aliquot from the same sample.

Additional procedures, calculation algorithms, and other items can be added based on the availability of the features by the instrument manufacturer.

### 5.4 Data Interpretation

The primary size result reported by DLS is the average hydrodynamic diameter (cumulant average or *z*-average) and the polydispersity index (PI). The PI is a measure of the broadness of the size distribution. For monodispersed materials, these two values are sufficient to evaluate the size of the particles.

For polydisperse systems, it is possible to calculate a particle size distribution using a Laplace inversion of the ACF and distribution algorithms. In practice, the general acceptance criteria for a Laplace inversion is that the PI is less than 0.7. The typical size distribution algorithms available are CONTIN and non-negative least squares (NNLS). Other algorithms may be available from the instrument manufacturer. The primary output for the size distribution data is an intensity weighted distribution. Number and volume-weighted distributions can be calculated from the intensity distribution. However, converting to number distribution should be done with caution.

Due to the low resolution of DLS and the error from the mathematical conversion, the values of $D_{10}$, $D_{50}$, and $D_{90}$ should not be used to describe the distribution results.

## 6. ADVANTAGES AND LIMITATIONS

DLS gives size information in the nanometer range, which is difficult to achieve using some other particle analyzing techniques. DLS also gives information on the stability of a suspension as well as interactions with the liquid environment, as the size determined is the hydrodynamic diameter.

DLS is not a very high-resolution technique for broad size distributions. The presence of any larger particles will influence the size calculation at the smaller end of the distribution. In some cases, filtration of the aliquot under analysis may be needed to ensure aggregates, agglomerates, or large particles are removed.

The assumption is made that the particles in the suspension are only in Brownian motion and no other influences. If the particles are actively flocculating or settling, this motion can be detected and the instrumentation will assume that it is Brownian motion and give inconsistent results. This is why the upper size limit is dependent on the density of the particles and the viscosity of the liquid. It is not always correct to assume that using a higher viscosity liquid will limit settling and yield better results because this will also limit Brownian motion.

# ▲⟨1430.4⟩ ANALYTICAL METHODOLOGIES BASED ON SCATTERING PHENOMENA—ELECTROPHORETIC LIGHT SCATTERING (DETERMINATION OF ZETA POTENTIAL)

1. INTRODUCTION
2. THEORY
3. INSTRUMENTATION
4. APPLICATIONS
5. DATA ANALYSIS
    5.1 Calculation of Electrophoretic Mobility
    5.2 Calculation of Zeta Potential
6. DATA INTERPRETATION
7. ADDITIONAL SOURCES OF INFORMATION

## 1. INTRODUCTION

Zeta potential is a parameter that is primarily used to characterize the stability of suspensions and emulsions. It can also be used to study surface morphology and adsorption on particles and other surfaces in contact with a liquid. Zeta potential is indirectly determined by the appropriate theoretical models from experimentally determined parameters, such as electrophoretic mobility. Electrophoretic light scattering (ELS) is the most general and common way to determine zeta potential of colloidal systems.

## 2. THEORY

A suspension of particles that has a given electrokinetic charge is placed in a cell that has a pair of electrodes placed apart at a known distance. A potential of known strength is generated between the electrodes and, by electrophoresis, results in the particles migrating toward the electrode of opposite charge. To detect and quantify this migration, particles are illuminated by a laser and the Doppler shifts of the scattered light from particles are recorded. The difference between the frequencies of the incident light and the scattered light is used to determine the velocity and direction of the particle migration. The particle velocity is then used to calculate the electrophoretic mobility by taking into account the strength of the electric field. Then, taking into account the viscosity and permittivity of the base liquid, the electrophoretic mobility is used to calculate the zeta potential.

## 3. INSTRUMENTATION

ELS, zeta potential instruments are light-scattering instruments that have either a reference beam optics alignment (most common) or a cross-beam optics alignment (less common). An example of a typical small-angle, light-scattering, zeta potential instrument (from ISO 13099-2:2012[1]) is shown in *Figure 1*.

Official

The cross-beam optical alignment instruments differ from the reference beam instruments in the fact that the laser beam is split into two beams of equal intensity that cross symmetrically (at a fixed angle between them) enter the sample cell from the same side.

A typical zeta potential measurement instrument is comprised of the following components:

1. A sample cell to contain the test suspension between two electrodes so that an electric field can be applied.
2. A suitable laser to illuminate the particles within the sample.
3. A suitable detector to capture the scattered light and the frequency shifts in the scattered light when the electric field is applied.
4. A software and computer system to process the collected scattering data and compute the mobility and zeta potential using appropriate models and algorithms.

The primary experimental technique used to determine zeta potential of colloidal systems is ELS. In this technique, a suspension is placed between two electrodes and an electric field is generated causing the ions and charged particles to migrate toward the oppositely charged electrode. When a laser is focused on the sample, this migration causes a Doppler shift in the frequency of the light scattered by the solution. An intensity or spectrum analysis of the shift in frequency is used to determine the electrophoretic mobility of the particles. Electroosmosis, the migration of the liquid along the sides of the cell flowing in the opposite direction from the particle migration, may affect the electrophoretic mobility measurement. A mechanism to correct for electroosmosis is often used during the measurement.

In cases where the Doppler shift is very small, the frequency analysis may not have enough resolution to determine the change. In such cases, phase analysis light scattering-based systems (PALS) can be used to perform the phase analysis of the shift. A typical schematic example of a PALS-based instrument is shown in *Figure 2*.

|---|---|
| 1. Laser | 5. Mirror |
| 2. Beam splitter | 6. Variable attenuator |
| 3. Pair of mirrors | 7. Scattering detector |
| 4. Sample cell with electrodes | 8. Computer |

The primary advantage of PALS is that it has higher resolution and can therefore detect very small Doppler shifts. This is typically needed for suspensions in nonpolar solvents or in aqueous solvents of high ionic strength in order to reduce Joule heating of the electrode surface. Elevated temperatures can cause changes in solution viscosity, which convolutes the measurement. Additionally, sample degradation can occur in some cases. The reported result from PALS is only the mean value of electrophoretic mobility. It does not provide any distribution information. Some current implementations combine PALS and spectrum analysis to obtain distribution information.

## 4. APPLICATIONS

In general, ELS is used to characterize the charge distribution (or average charge) and stability of suspensions and emulsions. ELS has been used widely for characterizing colloidal systems where it is important to control their stability (e.g., flocculation of submicron materials suspended in a liquid). Examples include preparations of pharmaceutical suspensions and emulsions where flocculation could affect appearance, efficacy, and bioavailability. In biological applications and in the biotechnology industry, ELS was used early on to characterize the surface properties of cells. More recently, the biopharmaceutical industry has adopted ELS measurements during development of formulations for the evaluation of degradation pathways and the characterization of compositional variants.

## 5. DATA ANALYSIS

### 5.1 Calculation of Electrophoretic Mobility

The ELS method is used to determine the electrophoretic mobility (μ) by measurement of the Doppler frequency shift (Δω) of the scattered light in an applied electric field (*E*) using either *Equation 1* (for the reference beam optical alignment) or *Equation 2* (for the cross-beam optical alignment):

$$\mu = \frac{\Delta\omega\lambda}{4\pi n E \sin\left(\frac{\theta}{2}\right)\sin\left[\left(\frac{\theta}{2}\right)+\xi\right]} \qquad (1)$$

$$\mu = \frac{\Delta\omega\lambda}{4\pi n E \sin\left(\frac{\theta'}{2}\right)} \qquad (2)$$

Δω = Doppler frequency shift
λ = laser wavelength in vacuum

https://pharmacopeia.cn/v29240/

$n$ = refractive index of the medium (or base liquid)
$E$ = electric field strength
$\theta$ = angle between the incident light and the scattered light
$\xi$ = angle between the scattered light and the orientation of the electric field
$\theta'$ = angle between the two beams

## 5.2 Calculation of Zeta Potential

For non-conductive spheres, zeta potential ($\zeta$) is commonly calculated using an extension of the Henry equation for its relationship with electrophoretic mobility ($\mu$) (*Equation 3*).

$$\mu = \frac{2\zeta\varepsilon}{3\eta_0} f(\kappa\alpha) \qquad (3)$$

$\varepsilon$ = dielectric permittivity of the medium (or base liquid)
$\eta_0$ = viscosity of the medium (or base liquid)
$\kappa$ = reciprocal of the Debye double-layer thickness
$\alpha$ = sphere radius
$f(\kappa\alpha)$ = a monotonic function varying from $f(\kappa\alpha) = 1$, as $\kappa\alpha \to 0$, to $f(\kappa\alpha) = 3/2$, as $\kappa\alpha \to \infty$

When $\kappa\alpha >> 1$, typical for large particles in aqueous suspensions, $f(\kappa\alpha) = 3/2$ in the above formula, leading to the Smoluchowski equation (*Equation 4*).

When $\kappa\alpha << 1$, typical for small particles in organic liquids, $f(\kappa\alpha) = 1$ in the above formula, leading to the Hückel equation (*Equation 5*).

$$\zeta = \frac{\eta_0\mu}{\varepsilon_r\varepsilon_0} \qquad (4)$$

$$\zeta = \frac{3\eta_0\mu}{2\varepsilon_r\varepsilon_0} \qquad (5)$$

Thus, depending on the nature of the particles and suspending medium, zeta potential ($\zeta$) is calculated from the electrophoretic mobility ($\mu$) utilizing either the Smoluchowski equation (*Equation 4*) or the Hückel equation (*Equation 5*).

The Smoluchowski equation is used when large solute particles (the hydrodynamic radius is large compared to the thickness of the electrical double layer) are probed, whereas the Hückel equation is preferred when small solute particles (the hydrodynamic radius is small compared to the thickness of the electrical double layer) are probed.

# 6. DATA INTERPRETATION

Zeta potential, expressed in units of millivolts (mV), is primarily used to characterize the physical stability of a suspension/emulsion. An unstable suspension may result in flocculation and sedimentation, and an unstable emulsion may collapse and result in phase separation. In general, as the absolute value of zeta potential decreases in magnitude, the suspension may become less stable and vice versa. The stability evaluation must be performed in conjunction with other relevant techniques. Although the relative stability change of the suspension may be indicated by changes in the value of the zeta potential, there is no direct link between zeta potential and absolute stability. Moreover, multiple determinations of different lots or preparations may be necessary to make general conclusions regarding the stability of different suspensions.

Although zeta potential is commonly used to quantitatively characterize the stability of a suspension, it is not intended to be the sole indicator of stability. Typically, zeta potential data are coupled with other quantitative or qualitative characterization techniques to monitor and characterize suspension stability, such as monitoring appearance or turbidity over time.

Zeta potential is also relative to the composition of the suspension. Typically, there is no distinct value of zeta potential that can be used as a threshold of stability.

It is important to note that zeta potential is a characteristic of a suspension, and not just of the particles. This includes the particles and the surrounding liquid environment with any ions or chemicals present in equilibrium. If care is not taken, performing multiple dilutions may alter this environment and change the zeta potential. It is also important to note that since the measurement relies on the migration of particles in an electric field, performing repeat measurements (NMT 3–5 depending on the sample) on the same aliquot may cause a shift in the zeta potential. If significant change is observed, an orthogonal method may be used to verify the integrity of the sample. Also note that a change of the zeta potential of a suspension may also change the observed hydrodynamic particle diameter by dynamic light scattering.

## 1. INTRODUCTION

Small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) make up a sub-family of small-angle scattering (SAS) diffraction techniques suitable for probing the size, shape, ordering, and interactions of molecules and molecular assemblies on length scales that are typically from around 1 nanometer (nm) to a few hundred nm. This size range overlaps with the lower range probed using the laser light diffraction technique (see *Analytical Methodologies Based on Scattering Phenomena—Light Diffraction Measurements of Particle Size* ⟨1430.2⟩).

Because these length scales are much larger than inter-atomic distances, in crystallographic terms SAS is considered low-resolution diffraction. Nonetheless, it is an extremely useful and versatile technique capable of providing structural information complementary to cryogenic transmission electron microscopy (cryo-TEM), high-resolution nuclear magnetic resonance (NMR), and analytical ultracentrifugation.

SAS differs from dynamic light scattering (DLS; see *Analytical Methodologies Based on Scattering Phenomena—Dynamic Light Scattering* ⟨1430.3⟩) in that it is a direct probe of size and shape.

### 1.1 Applications

SAS is routinely performed on solids, liquids, and dispersion samples (both aqueous and nonaqueous). Some types of SAS have been used to study foams.

In terms of pharmaceutical applications, SAS has been used to study topical creams, intravenous emulsions, hydrogels, polymer-drug conjugates, proteins, enzymes, and antibodies (*1*–*5*). Some types of SAS are particularly well suited to studying the physical chemistry underlying formulation problems.

SAS can be used in various applications to evaluate the size, shape, and ordering of molecules. For example, SAS can provide information on the size and dispersity of droplets, macromolecules, micelles, liposomes, nanoparticles, crystalline domains, and pores (including in mixtures of these and other multi-phase systems). With regard to shape, SAS can be used to determine the shape of micelles and nanoparticles; the tertiary structure of proteins, enzymes, and antibodies (using SAS-constrained modeling); and the conformational distribution of adsorbed layers. Finally, examples of the use of SAS to assess molecular order include determining the core-shell structure of micelles and sterically stabilized nanoparticles, the bilayer structure in liposomes, and the liquid crystalline structure (e.g., lattice parameters, space groups).

## 2. TYPES OF SAS

SAS is a specialized, but nonetheless highly useful and versatile, technique. Although a detailed discussion of SAS is beyond the scope of this chapter, the intention of this chapter is to raise awareness and then direct the reader to authoritative sources for further information.

SAS is most commonly performed using light [small-angle light scattering (SALS)], X-rays (SAXS), or neutrons (SANS). It is the wavelength of these different radiation sources, and the way that the radiation interacts with the atoms in a sample, that determines what type of information is obtained in a particular SAS experiment. Importantly, data from all of these variants of SAS can be analyzed using common formulae and software packages. *Table 1* summarizes some of the key aspects of the different types of SAS.

**Table 1. Key Aspects of Different Types of Small-Angle Scattering**

| | SALS | Lab-SAXS | Synchrotron-SAXS[a] | SANS[a] |
|---|---|---|---|---|
| Radiation scattered by | Electrons | Electrons | Electrons | Nuclei |
| Radiation velocity (m/s) | $3 \times 10^8$ | $3 \times 10^8$ | $3 \times 10^8$ | $10^2$–$10^3$ |
| Accessibility | Laboratory | Laboratory | Synchrotron source | Neutron source |
| Relative brilliance | Medium | Medium | High | Low |
| Wavelengths (nm) | 400–700 | 0.07–0.23 | 0.06–0.33 | 0.15–2.5 |
| Length scales probed (nm) | 250–25,000 | ≤1–350 | 0.1–2500 | 0.2–1000+ |
| Impact of dust contamination | Significant | Negligible | Negligible | Negligible |
| Effect of hydrogen (H)/deuterium (D) substitution | None | None | None | Large |
| Radiation/heat damage | Negligible | Possible | Very likely | Negligible |
| Absolute intensity calibration | Possible | Possible | Possible | Routine |
| Sample volumes (mL) | 0.05–5 | 0.007–0.1 | 0.0001–0.5 | 0.1–5.5 |
| Study optically opaque samples | No | Yes | Yes | Yes |
| Typical container materials | Glass, quartz | Polyimide (Kapton), polycarbonate, beryllium, silica/quartz, silicon nitride | Polyimide (Kapton), polycarbonate, beryllium, silica/quartz, silicon nitride | Silicon, silica/quartz, aluminum, titanium, vanadium, copper silicon nitride |

[a] Access to national and international large facilities is usually obtained through competitive peer review, but experimental time for successful proposals is then free, provided that the results are placed in the public domain. Where this route of access is unsuitable, for example, for commercial customers who require confidentiality or a guarantee of experimental time, a range of paid industrial access mechanisms will typically be available.

Official

## 3. BASIC THEORY

When a beam of radiation is directed at a sample, a fraction of the beam will be transmitted, a fraction will be absorbed (and in some experiments may then be re-radiated), and the remainder will be diffracted through a range of angles, Θ. In a typical SAS experiment, $0.01° < \Theta < 10°$; this value of Θ is different from that in wide-angle and classical crystallographic diffraction experiments, where $\Theta > 10°$. On some instruments, it may be possible to record the small- and wide-angle data concurrently.

Radiation scattered through the same angle but originating from different points in the sample may then superimpose constructively or destructively at the detector to construct a "scattering pattern". This reflects spatial fluctuations in the refractive index (RI) (SALS), electron density (SAXS), or scattering length density (SANS) of the sample, which in turn arise from differences in the size, shape, and order of the constituent molecules.

The length scale, *d*, of the spatial fluctuations that may be accessed in a SAS experiment is determined by Bragg's Law:

$$d = \frac{\lambda}{2\sin(\theta)}$$

where λ is the wavelength. Experimentally, it is more typical to express this in terms of (the modulus of) a quantity called the "scattering vector", *q*:

$$q = \frac{4\pi n}{\lambda}\sin(\theta) = |q| = |k_s - k_i|$$

from which it follows that:

$$d = \frac{2\pi n}{q}$$

where $k_i$ and $k_s$ are the incident and scattered wave vectors and *n* is the RI of the medium. Conveniently, for neutrons and for X-rays, *n* may be assumed to be unity. Note that *q* is an inverse length scale. The geometry of a SAS experiment is illustrated in *Figure 1*.

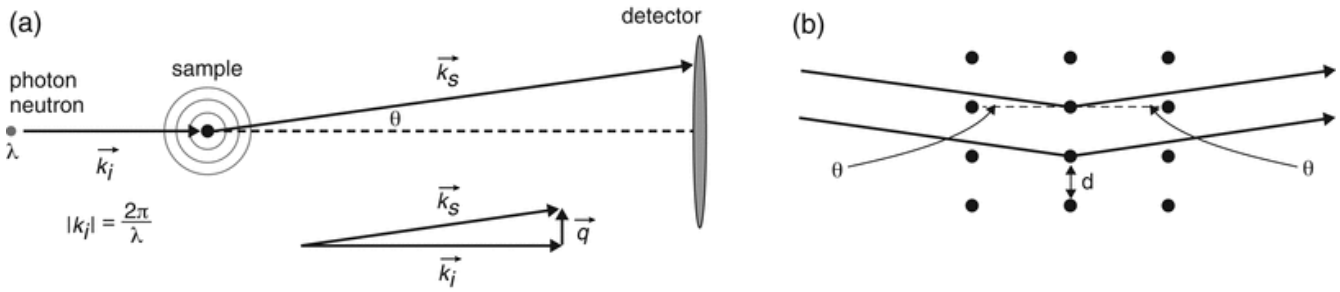

Figure 1. (a) The geometry of an SAS experiment, where $k_i$ and $k_s$ are the incident and scattered wave vectors and $q$ is the resultant scattering vector. (b) Schematic representation of diffraction from atoms in a sample.

The number of photons/neutrons of a given wavelength, scattered through a particular angle, that arrive at a detector pixel in a unit time, $N(\lambda,q)$, may be expressed as:

$$N(\lambda,q) = N_0(\lambda)\Delta\Omega\ \eta(\lambda)T_r(\lambda)V_S I(q)$$

where $N_0$ is the incident flux of photons/neutrons, $\Delta\Omega$ is the solid angle element defined by the size and distance of the detector pixel from the sample, $\eta$ is the detector efficiency, $T_r$ is the transmission of the sample (i.e., 1 – absorbance), $V_S$ is the volume of the sample illuminated by the beam, and $I(q)$ is the scattering function. Note that the first three terms are instrument-specific, whereas the last three terms are sample-dependent. The scattering function, the quantity determined in an SAS experiment, is given by:

$$I(q) = \Phi V(\Delta\rho)^2\ P(q)S(q) + B$$

where $\Phi$ is the volume fraction of the scattering objects in the sample (e.g., the volume fraction of nanoparticles in a dispersion); $V$ is the volume of one scattering object; $\Delta\rho = (\rho_{object} - \rho_{matrix})$ is the contrast of the sample (discussed below); the form factor $P(q)$ describes how the scattering is modulated by the size, shape, and dispersity of the scattering objects; the structure factor $S(q)$ describes how the scattering is modulated by interactions; and $B$ is a residual background signal normally taken to be $q$-independent. $P(q)$ has a value between 0 and 1. As $\Phi \rightarrow 0$, so $S(q) \rightarrow 1$.

For a solute in solution:

$$\Phi V = \frac{cM}{N_A\delta^2}$$

where $c$ is the mass concentration of the solute, $M$ is its formula weight, and $\delta$ is its bulk density. The objective of an SAS experiment is to extract information from $P(q)$ and/or $S(q)$. How this is achieved is discussed later. However, every component in the sample, including the container, will contribute to the overall scattering from the sample. So in addition to obvious background correction measurements (e.g., empty container; container + solvent), it is often useful to manipulate the various other individual contributions.

## 4. CONTRAST MATCHING

From the discussion in the preceding section, it is apparent that if the contrast term is zero, there will be no SAS. This condition is known as "contrast matching" and is potentially extremely useful because it permits the simplification of the scattering from complex multi-component samples and the study of individual components.

In SALS, contrast matching requires that two or more components have the same RI. The reader may have experienced this phenomenon when washing a glass in a bowl of water; the glass can seem to disappear because the glass and the water have similar RIs. In many experiments, however, RI matching of the components in a sample is often difficult to achieve in a useful manner. Some SALS and DLS instruments, however, use index-matching baths around the sample cell to reduce scattering from the outer wall of the cell.

In SAXS, contrast matching requires that two or more components have the same electron density. Because the electron density of a molecule is strongly influenced by the atomic number of the elements it contains, contrast matching a molecule with a heavy atom, such as a cationic surfactant, to an aqueous medium is not possible unless an additional solute is added to bolster the electron density of the medium. However, this course of action may change the pristine characteristics of the analyte and its chemical environment.

Contrast matching is more useful in SANS. Here, contrast matching is achieved if two or more components have the same scattering length density, $\rho$:

$$\rho = \frac{\delta N_A}{M}\Sigma_i b_i$$

where $b_i$ is the (bound) "coherent neutron scattering length" of nucleus $i$, and the other variables are as defined previously. The summation only needs to be performed over the empirical formula for a component.

Scattering length density calculators can be found online or as tools in some SAS analysis programs. A compendium of neutron scattering lengths is available online (*6*).

An example of a calculation for poly(ethylene oxide),–[$CH_2$-$CH_2$-O]$_n$–:

$$C_2H_4O,\ M = 44\ \text{g/mol},\ \delta = 1.127\ \text{g/cm}^3,\ b\ \text{in cm}$$

$$\rho = \frac{1.127 \times 6.023 \times 10^{23}}{44} \times \{(2 \times 6.646 \times 10^{-13}) + (4 \times -3.739 \times 10^{-13}) + 5.803 \times 10^{-13}\}$$

$$\rho = 0.64 \times 10^{10}\text{cm}^{-2} \text{ or } 0.64 \times 10^{-6}\text{Å}^{-2}$$

Importantly, because they depend on the neutron–nucleus interaction, scattering lengths are isotope-dependent. The same calculation for perdeuterated poly(ethylene oxide), for example, would yield $\rho = 6.46 \times 10^{-10}$ cm$^{-2}$.

[NOTE—It is a coincidence that this value appears to be 10 times the hydrogenous value.]

Thus, D–for–H exchange offers significant opportunities for exploiting contrast matching in soft-matter SANS experiments. *Table 2* lists some illustrative scattering length densities. These may sometimes be found expressed in the equivalent but non-SI units of $10^{-6}$ Å$^{-2}$.

**Table 2. Neutron Scattering Length Densities of Pharmaceutically Relevant Molecules**

| Molecule | $\rho(10^{10}\text{cm}^{-2})$ | Molecule | $\rho(10^{10}\text{cm}^{-2})$ | Molecule | $\rho(10^{10}\text{cm}^{-2})$ |
|---|---|---|---|---|---|
| $H_2O$ | –0.56 | $H_{25}$–sodium dodecyl sulfate (SDS) | 0.33 | Lipids | 0.1–0.4 |
| $D_2O$ | 6.37 | $D_{25}$–SDS | 5.83 | Proteins | 2.2–2.6 |
| $H_8$–toluene | 0.94 | $H_{60}$–Triton ×100 | 0.57 | Carbohydrates | 2.7 |
| $D_8$–toluene | 5.66 | $H_{31}$–dodecyldimethylamine oxide (DDAO) | –0.20 | DNA | 4.0 |
| Perfluorodecalin | 4.21 | $H_{39}$–deoxycholate Na | 0.66 | RNA | 4.5 |

Several useful characteristics of scattering length densities are evident in the table. First, they can be positive, negative, or, in principle, zero. Second, different classes of biological molecules span a wide range of scattering length densities. Lastly, it is usually possible to find a solvent, or preferably a mixture of solvents, that will contrast match any solute. So, for example, DNA can be contrast matched in a mixture of 34.1% $H_2O$: 65.9% $D_2O$ by volume, and a perfluorodecalin-in-water emulsion would not scatter neutrons if the oil was dispersed in a mixture of 31.1% $H_2O$: 68.9% $D_2O$ by volume. It is even possible to make an $H_2O$:$D_2O$ mixture that does not scatter (i.e., $\Delta\rho = 0$). *Figure 2* shows how contrast matching could be used in a SANS study.

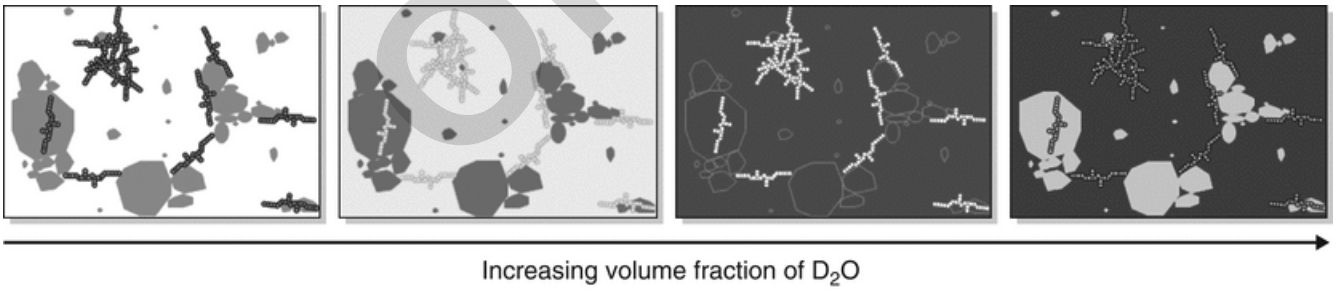

Figure 2. Schematic illustration of how contrast matching might be used in a hypothetical SANS study of a dispersion containing polymer/surfactant and drug particles. The scattering from all four figures would be different. The first and last would differ only in overall intensity, but the form of the scattering from these would differ from the forms of the second and third figures, which highlight different components of the sample.

When calculating scattering length densities, it is important to use as accurate a value as possible for the bulk density, $\delta$. However, sometimes determining $\delta$ can be problematic for deuterated compounds. In such instances, a useful rule of thumb for solvents and relatively simple molecules is $\delta_D = \delta_H \times 1.1$. Also, it is important to remember that $\delta$ is temperature-dependent.

Molecules containing hydroxyl groups, carboxylic acid groups, and even some amine groups will readily exchange those functional protons for deuterons when exposed to $D_2O$. This means that the scattering length density of some molecules can be pH-dependent; proteins are an obvious example. Some scattering length density calculators include a degree of exchange parameter to compensate for this pH dependence.

## 5. INSTRUMENTATION

The components of a SAS system (see *Figure 3*) are common across the different forms of the technique.

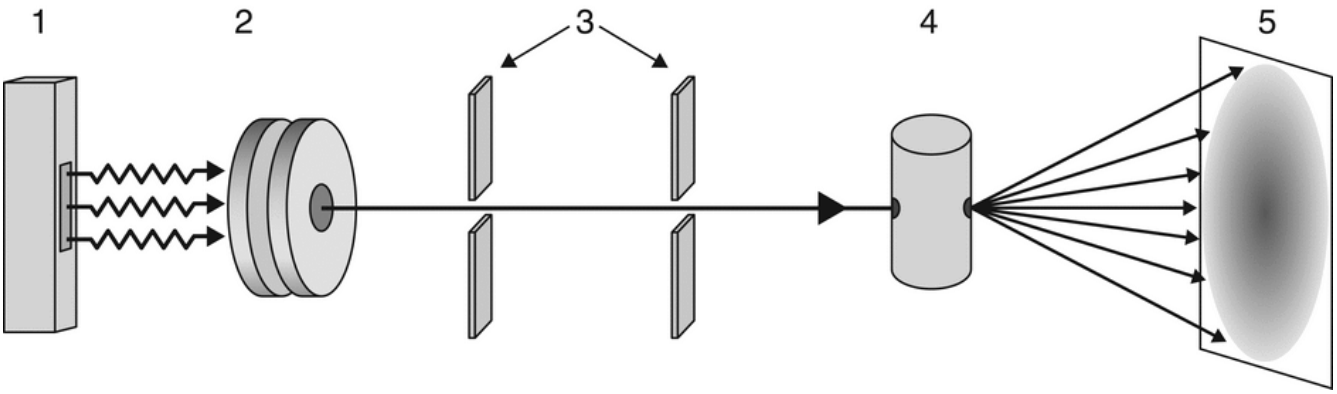

Figure 3. Schematic representation of a generic SAS instrument.

| Key | |
|---|---|
| 1. Source<br>2. Optics<br>3. Slits | 4. Sample<br>5. Detector |

SALS and SAXS are performed using monochromatic radiation, which is collimated with slits or pinholes to the desired profile regarding size (diameter or width/height) and shape (line or point). The wavelength of monochromatic radiation is determined by the choice of source (replacing one type of anode material with another), but may also be varied by changing optical filters, or adjusting the synchrotron monochromator. SANS at reactor neutron sources is also performed in this manner, with the wavelength adjustment performed by a rotating device called a velocity selector. In these fixed-wavelength measurements, altering the dynamic range in $q$ of the instrument requires changing the sample-to-detector distance (either along the incident beam direction or off-axis) in order to change the range of scattering angles subtended to the sample.

However, SANS can also be performed at pulsed neutron sources (based on particle accelerators—so-called spallation sources—or pulsed reactors). At these sources, a "polychromatic" ("white") beam of neutrons is directed at the sample, and the time of flight (TOF) of the scattered neutrons to the detector is recorded. This establishes the neutron velocity and thereby its wavelength. The dynamic range in $q$ of these TOF-SANS instruments is much broader than that of their fixed-wavelength counterparts because every wavelength that reaches a pixel on the detector corresponds to a different $q$ value, although a given pixel on the detector still represents a single scattering angle. Moreover, the intrinsic wavelength resolution, and therefore $q$-resolution, of TOF-SANS is much better than that of fixed-wavelength SANS.

The scattering from a sample actually occurs over 4πspace, but because an SAS instrument is linear, the detector only intercepts a conic section of the total scattering. Because most soft matter samples have some degree of intrinsic disorder (referred to as "polycrystallinity" by crystallographers), the detector records multiple rings of varying intensity rather than discrete spots (reflections) (see *Figure 4*).

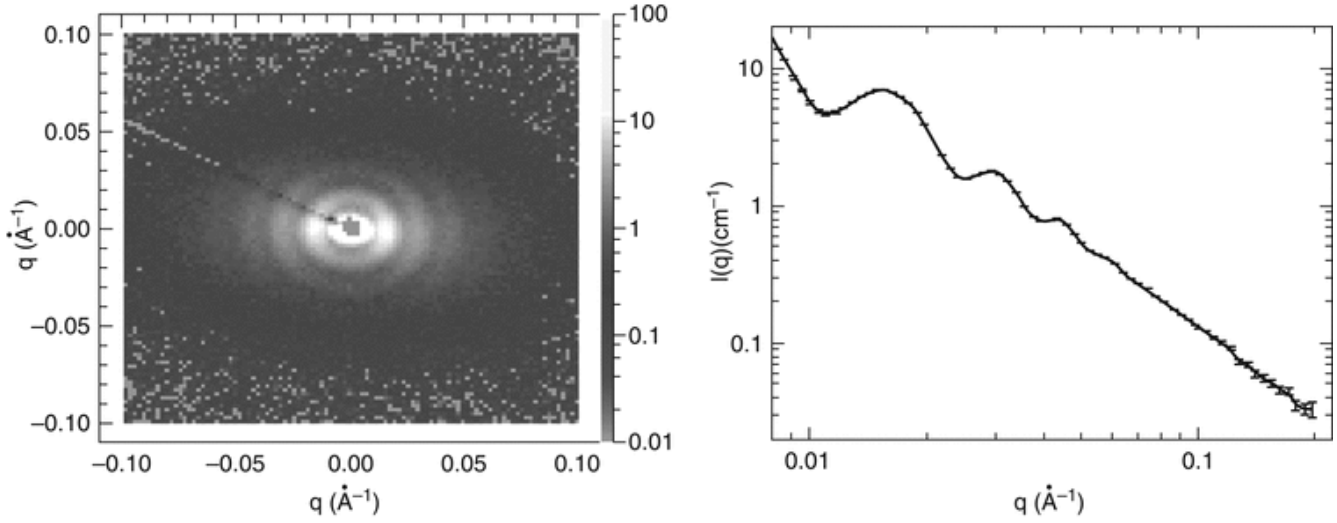

Figure 4. Two representations of the SAS (in this case, SANS) from the same aqueous dispersion of elongated surfactant micelles. The sample has gelled to form a lyotropic liquid crystalline phase exhibiting lamellar order (at least 4 orders of diffraction are visible as rings or peaks). The lamellae have then aligned vertically (giving rise to an anisotropic 2D pattern along the equatorial direction on the detector) as a result of the shear field imposed when the sample was injected into the sample cuvette.

The scattered radiation will usually be detected by solid-state charge-coupled device (CCD) cameras (SALS/SAXS), gas detectors (SAXS/SANS), or scintillator detectors (SANS). Often these will be highly pixelated two-dimensional ("area") detectors, which are extremely useful for resolving anisotropic scattering from oriented samples. A state-of-the-art SAXS detector for laboratory applications may have 1 thousand (for one-dimensional detectors) to more than 1 million pixels (for two-dimensional detectors), and more for large-facility instruments. Consequently, the data volumes generated during an experiment may be quite large (gigabytes to terabytes).

In order to allow them to access smaller angles, and because they require more substantive radiation shielding, SAXS/SANS instruments at large facilities may extend several tens of meters from the source. Even a state-of-the-art laboratory SAXS instrument is typically 3–5 m in length. While in principle one could attain ever-smaller $q$ values by building very long instruments, in practice the count rate at the detector declines as the inverse-square of the sample–detector distance; thus, measurements become impractically slow. To circumvent this limitation and permit very-small-angle scattering (VSAXS/VSANS) or ultra-small-angle scattering (USAXS/USANS) measurements, alternative strategies are employed, such as using focusing optics or slit-collimated Bonse–Hart "double–crystal" geometries. These instruments can access length scales ($d$) into the micron scale, i.e., the same realm accessible by optical microscopy. The type of source collimation, point-source (pinhole) versus slit, has implications for data processing. Very recently, a new form of SANS has emerged wherein the scattering angle is encoded in the precession of polarized neutrons. This technique, spin-echo (modulated) SANS (SESANS/SEMSANS), can also access micron-length scales but measures in $d$-space rather than in $q$-space. Its advantages over Bonse–Hart VSANS are that it retains good count rates and is much less susceptible to multiple scattering from the sample. Further discussion of these extended SAS techniques is beyond the scope of this chapter, but the reader should be aware of their existence.

***Change to read:***

# 6. EXPERIMENTAL CONSIDERATIONS

Performing a successful SAS experiment depends on many factors, including but not limited to the following factors described in subsections *6.1–6.12* (*7–9*).

## 6.1. Incident Flux

Incident flux is the number of photons/neutrons per unit area per second delivered to the sample. It is a function of the brilliance of the source (see *Table 1*) and the wavelength selection/collimation employed for the experiment. Kinetic or dynamic measurements, or measurements on very weakly scattering samples, will fare better on higher-flux instruments.

## 6.2 Resolution

There are two types of resolution of relevance to an SAS experiment:

1. Size resolution of the instrument
2. $q$-resolution of the measurement

### 6.2.1 SIZE RESOLUTION

The maximum, $d_{max}$, and minimum, $d_{min}$, length scales of the structure to be probed need to lie inside the measurement limits of the instrument, i.e.:

$$q_{min} < \frac{\pi}{d_{max}} \blacktriangle\blacktriangle \text{ (ERR 1-Dec-2019)}$$

and

$$q_{max} > \frac{\pi}{d_{min}}$$

This principle is illustrated in *Figure 5*.

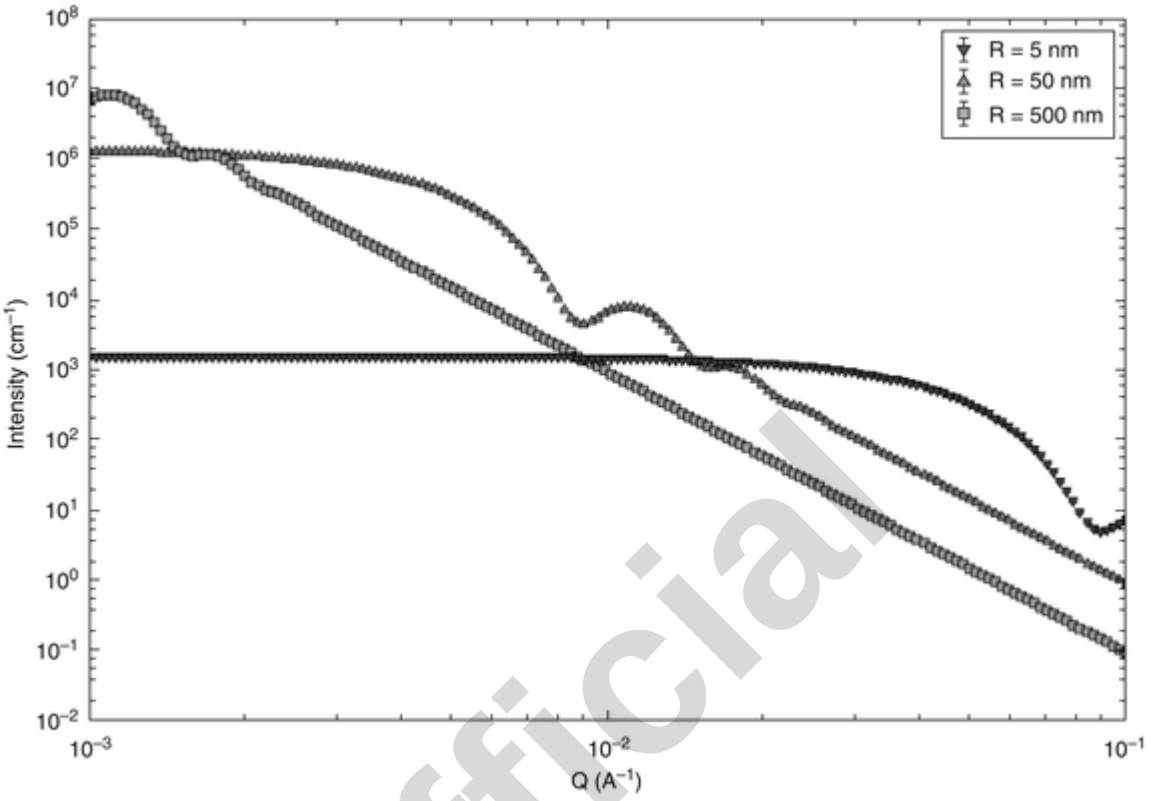

Figure 5. Calculated scattering for three dispersions of perfectly spherical homogeneous particles of the same material in the same matrix, differing only in the particle radius, *R*. A 10% log-normal particle size distribution has been applied to aid realism. The curves are displaced vertically to aid clarity. Only the scattering from the *R* = 50 nm particles is fully within the measurement window of this simulated instrument, as shown by the limiting behavior of the form factor at low Q and multiple interference fringes at intermediate Q. Also note the *q*-4 dependence of the high-*q* scattering, a manifestation of Porod's Law arising from the particle surfaces. Down triangles, *R* = 5 nm; up triangles, *R* = 50 nm; squares, *R* = 500 nm.

Official

#### 6.2.2 *q*-RESOLUTION

The *q*-resolution is the precision with which adjacent *q*-points can be distinguished, and therefore it governs the level of fine detail in the measured scattering data that can be resolved (for example, the peaks in *Figure 4*).

The *q*-resolution is primarily determined by the wavelength resolution of the instrument, then by the geometric resolution arising from the selected instrument collimation, and then by a range of other less significant factors.

Laser light sources and X-ray sources have the best wavelength resolution, with $\Delta\lambda/\lambda$ values as low as 0.01%. Conventional light sources depend on the use of a bandpass filter for which $\Delta\lambda/\lambda$ may be ~1%. Although good wavelength resolution is an intrinsic property of a laser, in the case of X-rays, it is determined by the monochromator in use. The wavelength resolution of fixed-wavelength SANS instruments depends on the specification of the neutron velocity selector employed. Typically, this resolution will be between 8% and 20%. However, in TOF-SANS the wavelength resolution is determined by the precision with which the neutron TOF (typically a few thousand microseconds) can be measured, and thus $\Delta\lambda/\lambda$ values of approximately 5% would not be uncommon. In most instances, better wavelength resolution can always be traded for reduced flux and vice versa.

The geometric resolution is essentially governed by the beam size at the sample; a smaller size is better. Laser-based SALS and SAXS instruments with submillimeter beam footprints fare much better than SANS instruments in this regard, where a relatively small beam may still be 6–8 mm in diameter. This difference is further compounded by the fact that because neutrons cannot be easily focused, reducing the beam footprint also decreases the flux on the sample.

### 6.3 Instrument Calibration

SAS instruments require two separate calibrations, but with an astute choice of calibration sample it might be possible to perform both calibrations in one measurement:

1. Calibration of the *q*-scale
2. Calibration of the intensity scale

An instrument technician or, at large facilities, the assigned experiment local contact, will normally perform these calibrations. However, if one's plan is to use several different SAS instruments it is advisable to acquire and measure one's own calibrants to ensure confidence in the local calibrations and ensure that all of one's data are on self-consistent scales.

@2024 USPC

#### 6.3.1 *q*-CALIBRATION

It is possible to omit the *q*-calibration on a fixed-geometry SAS instrument where the sample-to-detector distance is constant/known. In all other instances, it is necessary to measure a sample with a characteristic *q*–dependence related to structure that can be unambiguously verified by other means [e.g., TEM, atomic force microscopy (AFM), etc.]. Alternatively, if an SAXS instrument has an energy-responsive detector, and an accurate determination of scattering angle is possible, then an absorption edge can be used to verify *q*. Two commonly used *q*-calibrants for SAXS/SANS are silver behenate (AgBH) (see *Figure 6*) and rat tail collagen (RTC).

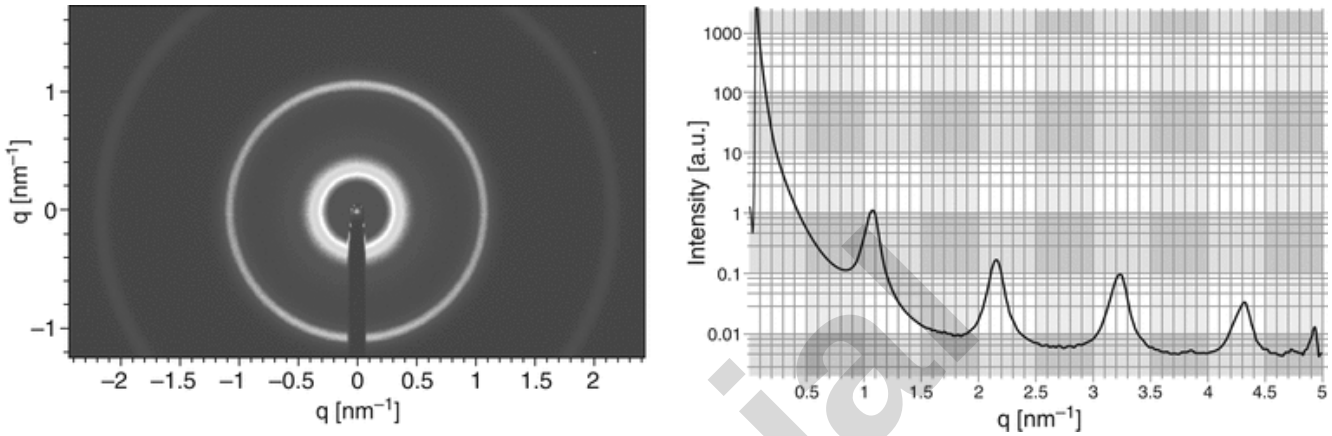

Figure 6. Two representations of the SAS (in this case, SAXS) from the same sample of polycrystalline silver behenate.

#### 6.3.2 INTENSITY CALIBRATION

Intensity calibration relies on the fact that for some types of material, $I(q = 0)$ can be related to molecular parameters that can be calculated with reliability or determined using other techniques, for example, the molecular weight of a polymer, the surface area-to-volume ratio of a porous solid, or the second virial coefficient or isothermal compressibility of a pure liquid. However, because an SAS instrument does not physically collect data at $q = 0$, an extrapolation is required. Extrapolation is only possible, with the necessary precision, if the scattering function for the chosen calibrant has a definitive form. Commonly used intensity calibrants include water (SAXS; *10*), Lupolen (SAXS), blends of hydrogenated and perdeuterated homopolymers (SANS; *11,18*), porous solids (SAXS/SANS; *18*), glassy (vitreous) carbon (SAXS/SANS; *12,18*), and vanadium (SANS).

### 6.4 Sample Quality

As in any experiment, the best results will be obtained using carefully prepared samples. In particular, because the SAS from an object scales as the sixth power of its size, the presence of even a relatively few large objects in a sample can disproportionately interfere with the quality of the data, all else being equal. SALS is particularly affected by the presence of large particles because of the aforementioned difficulties in RI matching. For this reason, all solvents used for SALS experiments should be rigorously filtered before use to exclude the presence of dust particles. SAXS and SANS (but not USAXS/USANS) are much less affected by dust because they probe shorter length scales (dust particles are micron-sized). However, the presence of unwanted, unintended, or unexpected aggregation of components of the sample can be just as troublesome. Prescreening for aggregation in biological samples destined for SAXS or SANS instruments (for example, by DLS) should be considered *de rigour*. Poor contrast in a sample can also be problematic, although in some instances (for example, in SANS contrast matching experiments), it is unavoidable.

### 6.5 Sample Concentration

Although the magnitude of $I(q)$, and the precision with which it is measured, are both generally improved by using more concentrated samples, this comes with disadvantages as well, i.e., lower transmissions (see *6.9 Sample Transmission*) and the possible introduction of atomic pair correlations manifesting themselves in an $S(q)$ contribution to the scattering function. Whether this is an issue depends on the sample being studied and the intended method of data analysis. Some relatively simple modeling of the scattering before the experiment may help to establish the viable concentration envelope.

Of course, the converse is also true, and very dilute samples will likely suffer from a poor signal-to-noise ratio and necessitate longer experimental counting times, although this longer experimental time might be mitigated by the use of a high-flux instrument. However, as an illustration, most SAXS/SANS instruments can handle protein/enzyme solutions at concentrations as low as $\Phi \sim 0.1\%$ (1 mg/mL), whereas $S(q)$ is not usually a concern in a colloidal dispersion at $\Phi < 5\%$. For investigations of $S(q)$, relevantly higher concentrations are used.

## 6.6 Sample Containers

Unless one is working with a self-supporting sample, the sample will need to be contained. The problem with sample containers is that they also scatter, so the material from which they are constructed is an important consideration. Suitable container window materials combine the mechanical strength and chemical resistance with high transmittance and scattering features, which do not interfere with those of the sample. As such, multiple window materials may be necessary to cover the entire range over which a sample is to be measured.

For SALS and SAXS, it is quite common to use glass sample containers. Glass is composed only of light atoms (an important consideration for SAXS), and its transparency is as useful for observing the sample as it is a prerequisite for SALS. However, because glass contains boron (a neutron absorber) it is not suitable for SANS.

Amorphous synthetic quartz (SiO2, also called fused silica) is a good choice of material for SALS, SAXS, and SANS. It can be cut, polished, and fabricated and is also transparent and only composed of light atoms; however, it is boron-free. It also has good thermo-mechanical stability over an experimentally useful range of temperatures and is chemically inert to all but concentrated bases and hydrofluoric acid. Material tradenames include Spectrosil and Suprasil, but in principle anything suitable for far-UV (not IR) spectrophotometry should suffice.

For SAXS, it is possible to utilize sample containers constructed from amorphous engineering polymers such as poly(carbonate) (PC), poly(etheretherketone) (PEEK), or poly(imide) (Kapton). Poly(amides) (nylons) are not suitable because they are semi-crystalline. All hydrogenous polymers are wholly unsuitable for use as SANS sample containers.

The greater penetrating ability of neutrons means that SANS sample containers can be constructed from metals. Pure metals should be used where possible (as SANS is an excellent technique for probing the nanostructure of metal alloys), or when a prior assessment of suitability has been conducted. Good choices of metals for use with neutrons are aluminum, titanium, vanadium, and copper. These metals can activate on prolonged exposure to neutron radiation but not to levels that make them impractical to use. Beryllium, being of low atomic number, is however a practical choice for SAXS.

In most experiments, the sample will simply be contained in the quiescent state in a capillary or cuvette. However, it is important to understand that quiescent conditions are not necessary. Indeed, the ability of SAS to probe a sample under changing conditions (pH, temperature, pressure) or applied fields (electric, magnetic, shear) is usually where the greatest information is ultimately derived. The use of cryostats, furnaces, pressure cells, rheometers, tensile stages, and stop-flow cells with SAXS/SANS instruments is very common. The use of flow-through cells to mitigate radiation damage (see *6.11 Radiation Damage*) is very common on high-flux SAXS instruments.

Sample containers will typically have path lengths ranging from 0.1–2 mm (SAXS) to 1–5 mm (SANS) to 10 mm or more (SALS). Multiplying this value by the incident beam size—a few micrometers (SAXS) to a few millimeters (SALS/SANS)—reveals that the required sample volume is rarely more than a couple of milliliters, and potentially less.

## 6.7 Backgrounds

In the same way that the sample container contributes to the measured scattering, so does the matrix containing the sample, for example, the dispersion medium. For this reason, it is typical to measure the scattering from the pure matrix, in the same or an identical sample container under the same experimental conditions, and then to subtract this matrix scattering from the sample scattering. This procedure should also correct for other sources of "sample-independent" background (for example, the container, vacuum windows, detector response, etc.).

Difficulties can arise if the sample component of interest occupies a substantial proportion of the overall sample volume because subtracting 100% of the matrix may no longer be appropriate, leading to over-correction of the data. In these instances, a volume fraction-weighted background correction may be appropriate.

Arguably, the most insidious form of "sample-independent" background is multiple scattering (discussed in *6.10 Multiple Scattering*).

## 6.8 Counting Times

Experimental measuring times for an SAS experiment may vary from a fraction of a second (synchrotron-SAXS) to many minutes or hours (SANS). However, because SAS measurements are Poisson counting processes, to halve the statistical uncertainty on an $I(q)$ point requires four times as much data. This calculation is further complicated by the fact that when a background is subtracted, the statistical errors on the sample and background are added in quadrature, as shown here:

$$Error_{sample-background} = \sqrt{\left\{\left(Error_{sample}\right)^2 + \left(Error_{matrix}\right)^2\right\}}$$

Thus the final data quality may not be apparent until after the experiment has finished. This means that invariably one ends up making a judgment call about the statistical quality of the data before moving on to the next sample. Therefore, counting times are often based on previous experience or simple trial-and-error, or a combination of both. A good rule of thumb is to measure each background for the same number of photons/neutrons as the sample it is intended to correct.

## 6.9 Sample Transmission

The sample transmission, $T_r$, is a dimensionless number ranging between 0 and 1 and is a measure of the balance between the scattering power of the sample and absorption as described by the Beer–Lambert Law:

$$T_r = exp(-\mu t) = 1 - A$$

@2024 USPC

where $t$ is the pathlength (in most instances, the thickness) of the sample, $\mu$ is an absorption coefficient, and $A$ is the absorbance; $\mu$ is dependent on the type of radiation in use.

Despite the simple appearance of this expression, accurately calculating $T_r$ for a sample is fraught with difficulties because $\mu$ may be unknown or difficult to determine. The best course of action is to measure $T_r$ at the time the SAS is recorded, simultaneously, if possible. Note that in TOF–SANS, $T_r$ is a function of wavelength.

A good rule of thumb is to keep $T_r > 0.37$ (i.e., $t < 1/\mu$), although this will have consequences for multiple scattering (see *6.10 Multiple Scattering*).

## 6.10 Multiple Scattering

Multiple scattering is where a photon/neutron that has been scattered once by the sample is scattered again (possibly several times). Multiple scattering should be avoided, if possible, because a routine method for correcting SAS data for multiple scattering has not been developed, except in some limited circumstances. The essence of the problem is that the history of multiply scattered photons/neutrons is unknown, and thus one cannot know whether or not to use them.

It is, however, quite straightforward to estimate the extent of multiple scattering from a sample. To a first approximation, the average number of times a photon/neutron has been scattered, $\tau$, is:

$$\tau = \mu t = -\ln T_r \propto t\lambda^2$$

Thus, even for $T_r = 0.9$ there is a 10% probability of multiple scattering. By $T_r = 0.5$ that probability has risen to almost 70%.

If multiple scattering is suspected, two strategies for mitigating its effects are to thin the sample and/or use shorter wavelengths and then re-measure and look for differences.

## 6.11 Radiation Damage

An important consideration during SAXS, particularly synchrotron-SAXS, experiments is that the X-ray beam can be extremely destructive to some samples if mitigating strategies are not deployed, such as the use of flow-through cells or cryogenic cooling. This is because the energy of the X-ray photons [for example, 8047 eV at the copper (Cu) (Kα) wavelength of 0.154 nm] is far greater than the strength of the bonds holding the sample together (for example, the C–C bond energy is just 4 eV), and hydrogen bonds are weaker still. Even visible photons from a modest blue laser can cause sample degradation if left to irradiate the sample for long enough. Conversely, the energy of neutrons of equivalent wavelengths are orders of magnitude lower (for example, a mere 0.034 eV at a wavelength of 0.154 nm), meaning neutrons are a truly non-destructive probe, especially of sensitive biological material.

## 6.12 Sample Deuteration

Although selective deuteration is a valuable experimental tool for extracting maximum information from a SANS experiment, it is unfortunately not without complications. The slightly larger atomic volume of deuterium, differences in the polarizability of C–H bonds and C–D bonds, and differences in the strength of O…H and O…D hydrogen bonds all contribute to subtle modifications of the underlying thermodynamics in the sample which can, and do, affect the phase behavior. For example, cloud points, critical micelle concentration, micelle aggregation numbers, and theta temperatures have all been known to change (sometimes in opposite directions depending on whether the solute or the solvent is deuterated). These challenges should be considered when designing a SANS experiment.

# 7. DATA PROCESSING

SAS data processing has two steps:

1. Data reduction: The transformation of the as-measured instrument-dependent data into portable instrument-independent data (ideally in absolute units on an absolute scale)
2. Data analysis: The interpretation of the instrument-independent data to extract physical information characterizing the sample

## 7.1 Data Reduction

Data reduction procedures, and the factors for which they are corrected, will vary from one SAS instrument to the next. In the case of SANS, these procedures can even vary between reactor-SANS instruments and TOF-SANS instruments. However, every SAS instrument manufacturer or large facility will provide the necessary software to correctly reduce the data collected from their instrument(s). This software is typically graphical user interface (GUI)-driven (although scripts are still used) and will offer both “novice” and “expert” modes of use, for either “manual”/“single” or “automated”/“batch” data reductions.

In general, the data reduction process will include most or all of the following steps:

1. Correct for the detector efficiency, dark current, dead time, and spatial linearity (flatness)
2. Calculate the $q$ values of each detector pixel
3. Integrate the recorded counts at a given $q$ within some region of interest (azimuthal angle, sector, etc.)
4. Normalize for the incident flux or quantum efficiency of the source
5. Correct for the sample transmission (absorbance correction)

6. Correct for the volume of sample illuminated (beam area × sample thickness)
7. Apply an intensity calibration factor
8. Convert the intensity scale into absolute units

This process is repeated for every sample measured, and for any backgrounds measured. The appropriate background is then subtracted from a sample to yield the final, fully reduced SAS data set.

## 7.2. Data Analysis

SAS data analysis for a single sample may use one or more of the following methodologies:

- Model-fitting/curve-fitting methods:
  - Involve optimized fitting of analytical functions for $P(q)$ and/or $S(q)$ to the experimental $I(q)$ data, for example, to determine generic shape information (sphere, cylinder, coil, etc.), size (radius, radius-of-gyration, cross-sectional radius, etc.), and interaction potentials (hard sphere, Percus–Yervick, etc.) (see *Figure 7*)
  - Applicable to all sample types
  - Computationally straightforward

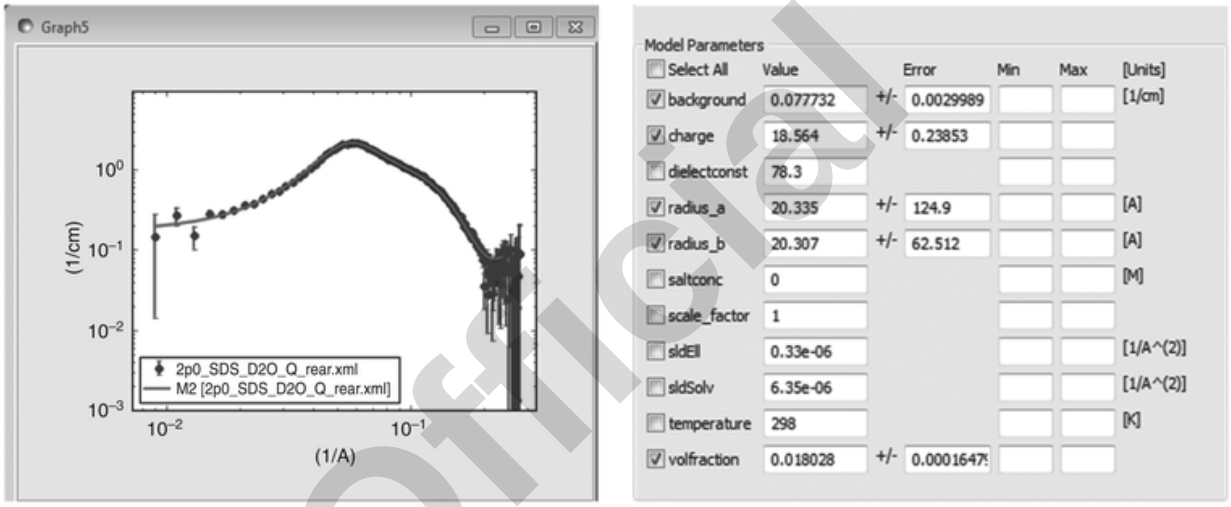

Figure 7. Left: Fit of a model calculation (line) to the SANS from a 2% (w/w) solution of surfactant sodium dodecyl sulfate (SDS) in $D_2O$ (shaded circles). At this concentration, above the critical micelle concentration (CMC), the system comprises electrostatically interacting, near-spherical, charged micelles. Right: The model parameter set, illustrating the level of sophistication that this approach can bring. Data and figures courtesy of Doucet et al., 2017 (*13*).

- Real-space methods:
  - Involve mathematical transformation of the experimental $I(q)$ data from reciprocal-space to real-space, for example, to obtain density correlation functions ($\Gamma(r)$ ), distance distribution functions [pair-distance distribution function (PDDF) or $P(r)$], or scattering length/segment density profiles [$\rho(r)$] (see *Figure 8*)
  - Applicable to all sample types
  - Computationally straightforward

@2024 USPC

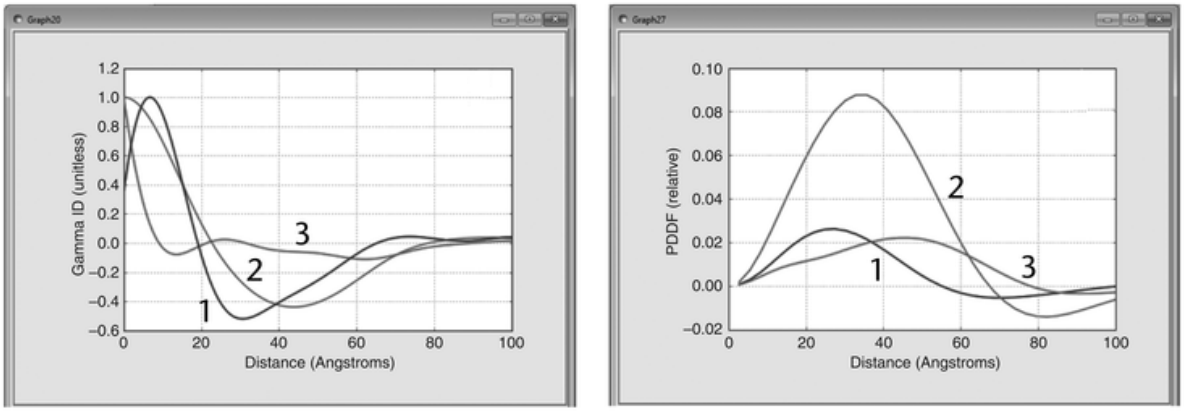

Figure 8. Two representations of the structure of a surfactant-stabilized oil-in-water emulsion system obtained from the SANS at three different scattering contrasts: "core" (line 1: where the scattering arises from the oil droplets only); "drop" (line 2: where the scattering arises from the oil cores and the surfactant layers); and "shell" (line 3: where the scattering arises from the surfactant layers only). For this system, the model-fitting approach suggests relatively monodisperse spherical objects of 25 Å radius with a 6 Å thick surfactant shell. Left: The one-dimensional density correlation functions. Right: The pair-distance distribution functions. Data and figures courtesy of Doucet et al., 2017 (*13*).

- $\Gamma(r)$ depicts the average separation of regions of similar scattering-length density in the sample. The minima and maxima in the function represent structural boundaries, for example, the edge of the object:

$$\Gamma(r) = \frac{1}{Q^*}\int_0^\infty I(q)q^2\cos(qr)dq$$

where the "scattering invariant" (also called the "total scattering") is given by:

$$Q^* = \int_0^\infty I(q)q^2dq$$

- The PDDF depicts the relative number of instances that two points in each scattering object are separated by a given distance, *r*. It is a function of distance only and is not a three-dimensional representation of the structure. The more symmetric the curve, the more rotationally symmetric the shape of the scattering object. Basic shapes like spheres, rods, and disks produce distinct distributions.

$$PDDF = \frac{1}{2\pi^2}\int_0^\infty I(q)qr\sin(qr)dq$$

- Ab-initio methods:
  - Involve the iterative creation of complex-shape envelopes, for example, from assemblies of homogeneous spheres ordered on a lattice or using spherical harmonic functions, the computed scattering of which is then compared with the experimental $I(q)$ data (*14*,*15*)
  - Are particularly useful for approximating the tertiary structure of biological molecules, but can also be applied to self-assembled soft matter systems like micelles
  - Do not take into account the chemical physics of the sample (e.g., bond lengths, bond angles, packing fractions, electrostatics)
  - Are computationally modest
- Simulation methods:
  - Involve the iterative manipulation of atomistic structures, for example, as derived from X-ray or high-resolution NMR crystal structures, by Boltzman-weighted Monte Carlo/Molecular Dynamics methods, the computed scattering of which is then compared with the experimental $I(q)$ data (*16*,*17*)
  - Are particularly useful for determining the tertiary structure of biological molecules
  - Take into account the chemical physics of the sample
  - Are computationally expensive, but can be used with coarse-graining methods

As SAS data analysis procedures become ever more sophisticated, so too does the degree of detail about the sample that they can return. However, one must never take this information in isolation; always look to cross-validate it with information derived from alternative techniques or the scientific literature. For example, model-fitting a large number of parameters without a priori information can result in "local" rather than "global" solutions. And PDDF, ab initio, and simulation methods work best when they can be constrained (e.g., to a known radius-of-gyration).

***Change to read:***

## 1. INTRODUCTION

Light-scattering particle counter instrumentation can monitor or evaluate levels of particles with an equivalent diameter below 2 μm in both liquids and gases. The monitoring and/or evaluation of these particles may be needed for certain applications in the pharmaceutical industry.

A light scattering liquid-borne particle counter (LSLPC) is used for monitoring particle contamination in liquids for sizes lower than the typical sizes measured by light extinction particle counters that are specified in *Particulate Matter in Injections* ⟨788⟩ and ▲*Methods for the Determination of Subvisible Particulate Matter* ⟨1788⟩▲ (CN 1-May-2021).

Monitoring the size, number concentration, and number size distribution of particles suspended in a gas may also be needed in the pharmaceutical industry. Depending on the application, measuring particles suspended in a gas is performed using a light scattering aerosol spectrometer (LSAS) or a light scattering airborne particle counter (LSAPC).

LSLPCs are used for the evaluation of the cleanliness of pure water and chemicals, as well as the measurement of number and size distribution of particles in various liquids. The measured particle size using the LSLPC depends on the refractive index of particles and medium; therefore, the measured particle size is defined as being equivalent to the size of calibration particles in pure water.

LSASs can be used to measure particle number concentrations and particle size distribution of particles with an equivalent diameter of approximately 0.06–45 μm in several pharmaceutical applications including but not limited to: the characterization of metered dose inhalers (MDI), dry powder inhalers (DPI), and nebulizers in pharmacy; process control of active pharmaceutical ingredient production; and the fractional separation efficiency determination of filters.

Alternatively, an LSAPC can be used in the pharmaceutical industry to measure the size distribution and number concentration of particles suspended in air. The method is used to measure particles with a typical size range of 0.05–10 μm. LSAPCs are used for the classification of air cleanliness in cleanrooms and other controlled environment rooms as well as the measurement of number and size distribution of particles in various aerosols.

## 2. THEORY

The light scattering particle counter operation is based on the principles of light scattering phenomena. Particles may be sized using a light scattering technique based on the amount and direction of light that is scattered by a particle passing through the detection area of the particle counter. The measurement principle of a particle counter or sizer considers the particles as passing individually through a light beam, i.e., there is always only one particle in the scattering volume. The resulting signal is processed before the next measurement, and the cumulative resulting scattered light is then recorded. Simultaneously, the intensity of the scattered light is correlated with the particle size by using preselected scattering models depending on the type and size of the targeted sample.

Different models cover different scattering regimes, e.g., the Rayleigh regime, Mie regime, or Fraunhofer regime (see *Analytical Methodologies Based on Scattering Phenomena—General* ⟨1430⟩ and *Analytical Methodologies Based on Scattering Phenomena—Light Diffraction Measurements of Particle Size* ⟨1430.2⟩ for general principles of scattering and scattering regime models).

Depending on the choice of model, the height of the scattered light pulses would depend, in addition to the particle size, on the particle material (usually represented by the refractive index) and the particle shape. Hence, the final measurement output is the equivalent diameter of a sphere that scatters light as defined by the calibration with spherical latex particles.

## 3. INSTRUMENTATION

Instrumentation for both LSLPC and LSAPC consists of a laser light source, an optical system, a scattered light detector(s) [photodetector(s)] to measure the scattered light from the particles, and appropriate hardware and software to conduct the necessary computations. A sample handler is used to introduce either liquid or gas at a known flow rate into the light scattering instrument. The laser light source is usually a laser diode or helium–neon laser. The optical system components include laser collimators, mirrors, and beam splitters as appropriate for a given optical arrangement. The scattered light detectors are in general photomultipliers or photodiodes. Commercial instruments use both low-angle and right-angle scattering optical configurations. A generic example of a right-angle light scattering particle counter is shown in *Figure 1*. The laser light is scattered by passing particles. The optics (collimators and/or mirrors) collect and focus the scattered light onto the photodetector, which converts it into a voltage signal pulse.

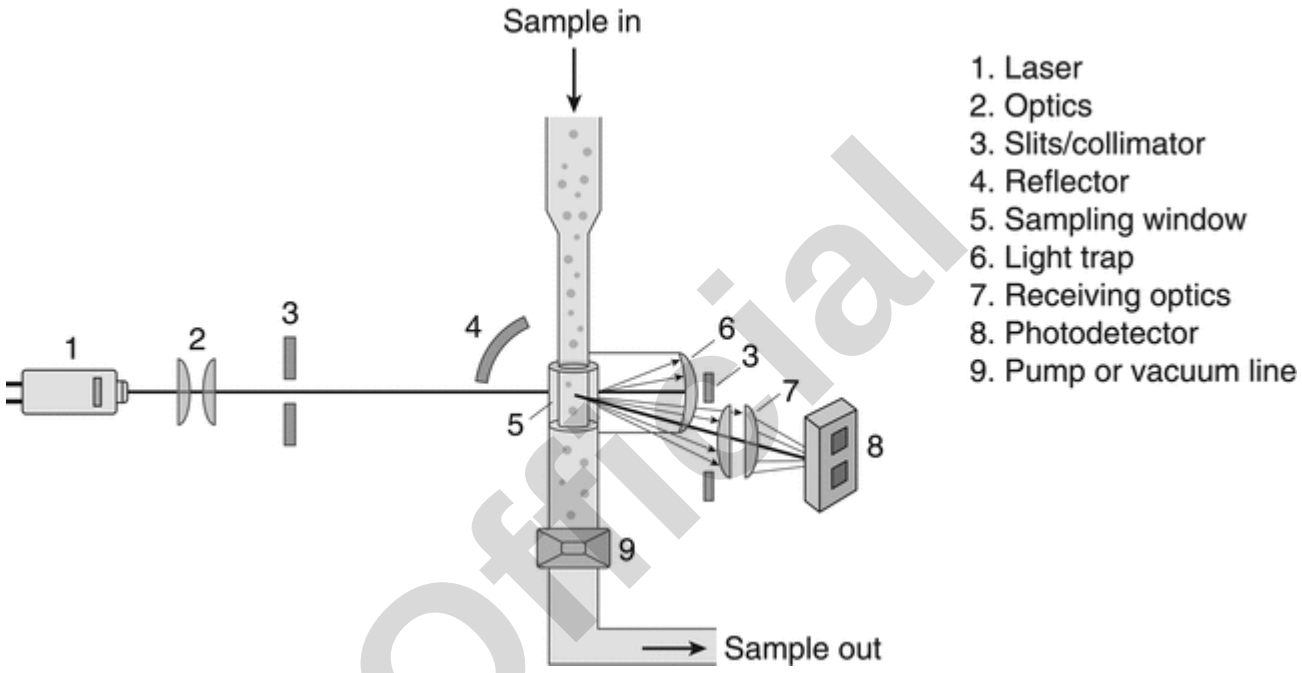

Figure 1. Schematic of a right-angle scattering particle counter.

Further descriptions of common instrumentation configurations are shown in ISO 21501. The instrumentation for light scattering particle counters is similar to but not identical to the instrumentation used for light obscuration particle counters. The primary difference between light scattering and light obscuration particle counters is the use of light scattering detectors to detect smaller-sized particles that are below the size range of particles detected by light obscuration.

### 3.1 Liquid Counters

Liquid particle counters are used to count and size the number of particles in a volume of liquid that flows at a set flow rate for a predefined time. The choice of an appropriate scattering model is very important for the liquid counters. The models assume that the refractive index of particles and the medium is the same as the calibration particles; hence, the measured particle size is the light scattering equivalent size of the calibration particles in the same medium. The actual size of the particle may be different from this reported size.

### 3.2 Airborne Counters

Aerosol particle counters are used to count and size the number of particles in a volume of air. The instrumentation and the principle of measurement are similar to the liquid counters. The preferred optic alignment for airborne counters is the right-angle scattering configuration, i.e., the airflow, laser, and collection optics are all at right angles to one another. The airborne counters differ from the liquid counters in the measuring cell and associated accessories assembly and the mode of accomplishing the fluid movement through the cell. The liquid counters have a syringe or pump at the cell's outlet that draws the sample through the cell, whereas the airborne counters have a vacuum line attached to the cell assembly outlet that draws air through the cell.

### 3.3 Light Scattering Aerosol Spectrometers

Light scattering aerosol spectrometers are a specialized type of aerosol particle counter that may be used in several pharmaceutical applications evaluating various types of aerosolized formulations and determining filter retention characteristics. The instrumentation and the principle of measurement of the light scattering aerosol spectrometers are similar to the airborne

@2024 USPC

counters, but light scattering aerosol spectrometers generally have the capability of collecting data in more size channels than the conventional airborne counter to allow for a more complete assessment of the particle size distribution.

***Change to read:***

## 4. FACTORS THAT AFFECT THE TESTING

As light scattering aerosol and liquid particle counters are typically calibrated using polystyrene latex spherical particles of known size and concentration with a preset flow rate, differences in the physical properties of the actual particles present in an unknown sample, including changes in the refractive index and/or shape of the particles, or deviations from the calibrated flow conditions when measurements are performed may affect the observed particle size and count. The presence of an immiscible fluid, such as silicone oil in aqueous solutions or gas bubbles in an unknown sample, may also affect the observed particle count and size measured from a liquid counter as these may artificially increase the observed particle count. The presence of dispersed water droplets in sampled air may also affect the observed particle count when using an airborne ▲▲ (ERR 1-May-2021) counter. In these cases, the observed particle counts and sizes from an unknown sample may require additional examination, including isolation using an appropriate filtration technique and further characterization by an orthogonal technique such as scanning electron microscopy to confirm the values reported by the light scattering particle counter.

Elevated particle concentrations in the unknown samples may also affect the observed particle size and count when the concentration of particles in the sample is above the coincidence limit of the detector. When the coincidence limit of the detector is exceeded, the concentration of particles is high enough that multiple smaller particles may be counted as fewer larger-sized particles, thus preventing accurate sizing and counting of the particulates. This can be managed by performing serial dilutions of the unknown sample with a particle-free diluent to lower the particle concentration and verifying that the particle counts match the applied dilution factors.

## 5. QUALIFICATION OF LIGHT SCATTERING PARTICLE COUNTING INSTRUMENTS

The following are the key system qualification parameters needed to ensure accuracy and precision of the measurements performed by the LSLPC, LSAS, or LSAPC:

- Size calibration
- Verification of size setting
- Counting efficiency
- Size resolution
- Sampling flow rate
- Sampling volume
- Calibration interval

The above characteristics are similar to the counterpart characteristics used in the light obscuration particle counters (see ⟨788⟩ and ⟨1788⟩). Hence, the information in these chapters may be useful to serve as references for completing performance qualification and for testing of samples when using the various light scattering particle counters and sizers.

### 5.1 Size Calibration

It is recommended to calibrate an optical instrument experimentally by means of test particles of known size and refractive index. The output of such a calibrated instrument will then be related to light scattering equivalent particle diameter.

When calibrating a light scattering particle counter with calibration particles of known size, the particles are dispersed in a fluid or gas and introduced to the counter. The particles will produce a distribution of voltages where the median voltage [or internal pulse height analyzer (PHA) channel] corresponding to the particle size (see *Figure 2*) is selected for each size. Other-sized particles are then analyzed in the same manner to generate a calibration curve.

A monotonic, steadily increasing calibration curve is important for high size resolution and classification accuracy. Due to the influence of optical properties of the particle material, particle shape, and the optical setup (light source and detection angle), experimentally measured calibration curves may differ from theoretical predictions.

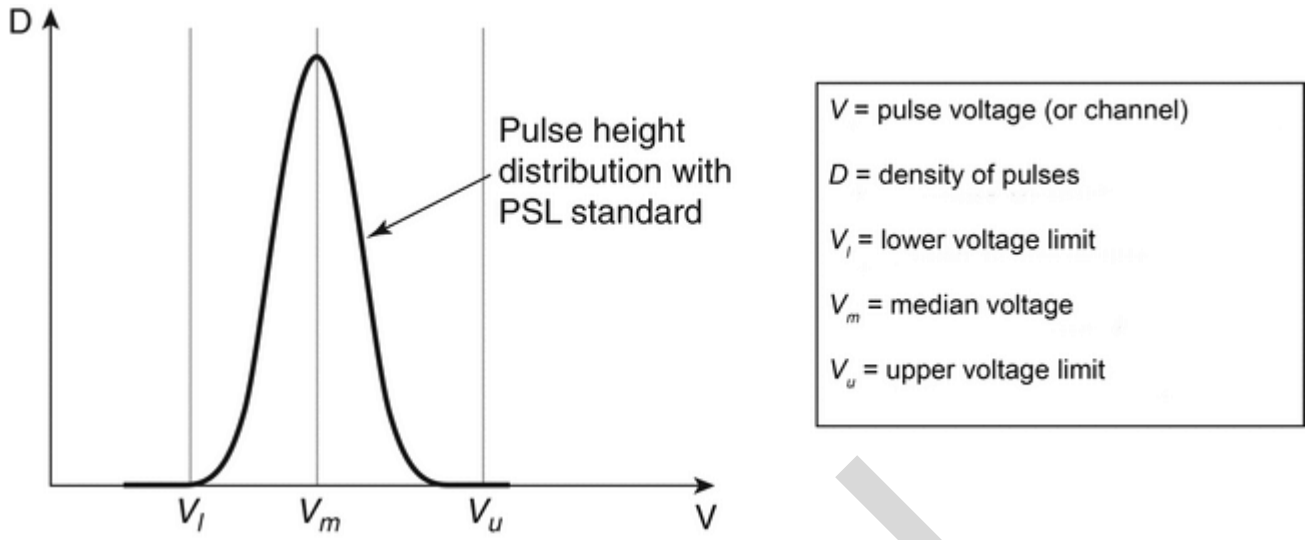

Figure 2. Pulse height distribution of polystyrene latex (PSL) particle signals.

The voltages of channels corresponding to particle size should be determined in accordance with the calibration curve provided by the manufacturer (see *Figure 3*). In general, a cubic spline fit may be necessary to generate the calibration curve.

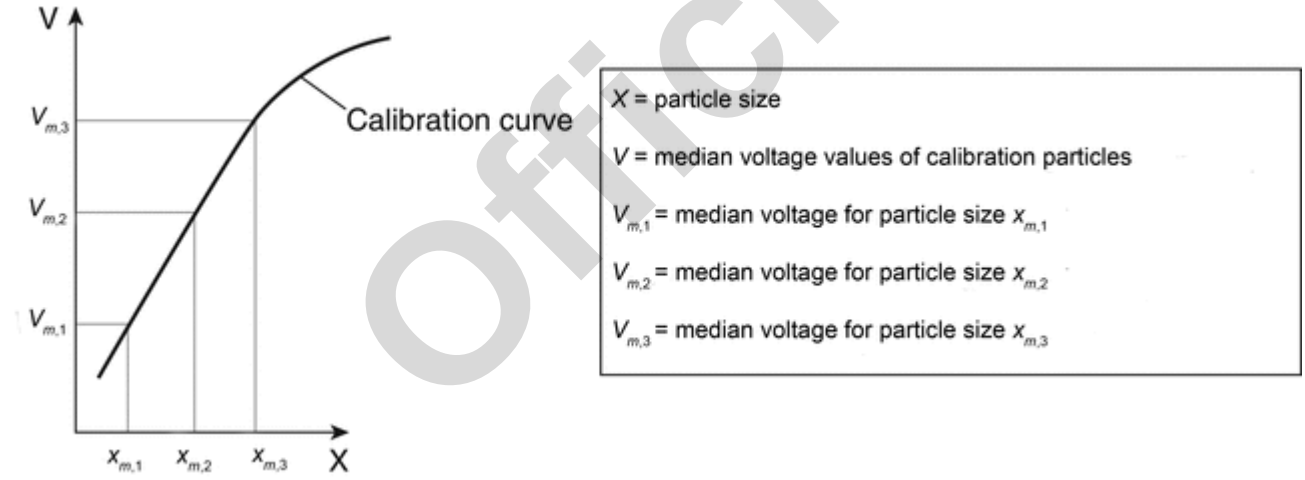

Figure 3. Calibration curve.

## 5.2 Verification of Size Setting

After calibration is completed, the calibration curve settings can be verified by obtaining response voltages (or internal PHA channel) using at least 3 sizes of calibration particles that span most of the reported size range, $x_r$, of the counter LSLPC.

Calculate the corresponding particle size, $x_s$, from the voltage setting (or internal PHA channel) of the LSLPC using the calibration curve. Obtain the percentage size-setting error, ε(%), by means of *Equation 1*. The recommended size-setting error is NMT 15%.

$$\varepsilon(\%) = \frac{x_s - x_r}{x_r} \times 100 \quad (1)$$

$x_s$ = calculated particle size (µm)
$x_r$ = reported size range (µm)

## 5.3 Counting Accuracy

To test the counting accuracy of the LSLPC, use 2 sizes of calibration particles—one that is close to the minimum detectable reported size range and another that is 1.5–2 times larger than the minimum detectable size.

@2024 USPC

Measure the particle number concentration of both particles with the LSLPC under test and either a microscopic method or a calibrated LSLPC as a reference instrument.

The counting efficiency is the ratio of the particle number concentration measured by the LSLPC under test and the particle number concentration measured by the reference instrument.

## 5.4 Sensor Resolution

The width of a measured size distribution includes contributions from both the actual range of particle sizes in the sample and the inherent variability of the system (mainly the sensor resolution). The resolution of the particle sizer can be determined by using a single-size particle standard with a known size and standard deviation and comparing the theoretical standard deviation to the experimentally measured standard deviation determined with the instrument. The procedures for determining sensor resolution are similar to those detailed in the sensor resolution section of ⟨1788⟩. The sensor resolution determination is illustrated in *Figure 4*, in which the graph represents the voltage (pulse height) density distribution of a monodispersed particle standard, where the *D*-axis represents the density and the *V*-axis represents either the raw sensor voltage (or PHA channel).

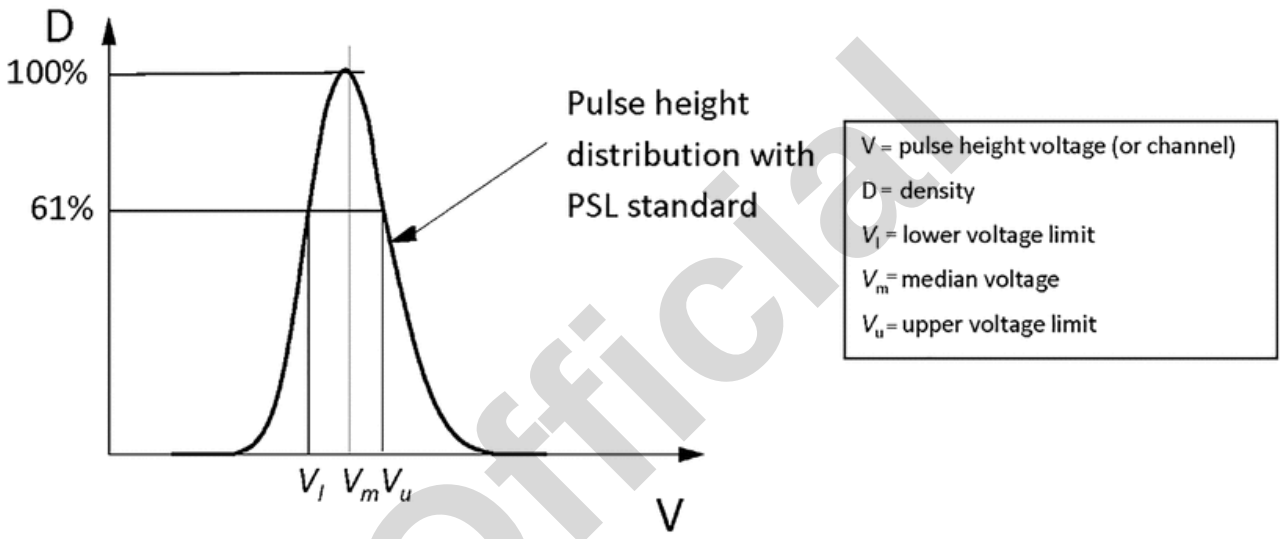

Figure 4. Sensor resolution.

The median voltage (or internal PHA channel), $V_m$, is determined. The voltages (or channels) corresponding to 61% density of the median voltage ($V_m$) are defined as the lower voltage limit ($V_l$) and the upper voltage limit ($V_u$). The particle sizes corresponding to $V_l$ and $V_u$ are determined from the calibration curve. The absolute differences in size of the nominal particle size from these sizes represent the upper and lower standard deviation. The greater of these represents the experimentally determined standard deviation, σ. The percentage size resolution, *R*(%), of the LSLPC is obtained using *Equation 2*. The recommended size resolution is NMT 15%.

$$R(\%) = \frac{\sqrt{\sigma^2 - \sigma_p^2}}{x_p} \times 100 \quad (2)$$

σ = experimentally determined standard deviation of LSLPC (µm)
$\sigma_p$ = supplier-reported standard deviation of calibration particles (µm)
$x_p$ = size of the calibration particle (µm)

## 5.5 Sampling Volume (For Liquid Counters Only)

An accurate sampling volume is critical for an accurate concentration determination. The procedure is the same as in ⟨1788⟩. The acceptable error of the sampling volume shall be NMT 5% of the preset value.

## 5.6 Sampling Flow Rate

Flow rate is important for the measurement, especially for the airborne counters, and should match the flow rate of the calibration that was performed. The acceptable error in the sampling flow rate shall be specified by the manufacturer, and the user should verify that the sampling flow rate is within the range specified by the manufacturer at the time of use.

## 1. INTRODUCTION

Nephelometry and turbidimetry are based on the direct (nephelometry) or indirect (turbidimetry) measurement of the scattered light intensity of an incident light beam from a monochromatic light source. In the rate nephelometry technique, the change of the scattered light intensity is measured as a function of time. Turbidimetry or nephelometry may be useful for the measurement of precipitates formed by the interaction of highly dilute solutions of reagents or other particulate matter such as suspensions of bacterial cells. All variables must be carefully controlled to achieve consistent results. Where such control is possible, extremely dilute suspensions may be measured.

## 2. THEORY

### 2.1 Nephelometry and Turbidimetry

For all relevant terms and definitions see *Nephelometry and Turbidimetry* ⟨855⟩. Both techniques are governed by the same equation, which describes the (time-averaged) intensity of the light beam as it interacts with matter along its path, i.e., when the incident light detected at an angle of zero decreases exponentially with the thickness, $x$, of the layer of material. See *Equation 1*. (For more information, see *Analytical Methodologies Based on Scattering Phenomena—General* ⟨1430⟩ and ⟨855⟩.)

$$I = I_0 e^{-\tau x} \quad (1)$$

### 2.2 Rate Nephelometry

As discussed above, the scattered light intensity when a sample is submitted to a constant incident monochromatic light beam depends on the number and size of the particles that scatter the light. If either or both of these factors change over time as a result of a chemical or physical process, the cumulative scattered light intensity at a given direction (usually 90° to the incident light direction) will change accordingly. Thus, rate nephelometry measures the change, or rate of change, in the intensity of light scattered during the formation of complexes (e.g., antigen-antibody) in solution. A correlation between the physicochemical changes and the scattered light intensity can be established and used to evaluate the property changes in the samples under test.

The extent of formation of light scattering complexes depends on concentrations of complex formation entities, e.g., antibodies and antigen molecules for immunonephelometry. The maximum rate response occurs when the antibody and antigen are in optimal proportions. Generally a fixed amount of antibody is used. Standard applications typically use 670-nm lasers with the detector aligned at 90° to the incident light direction, and the scattered signal is measured at 5-s intervals. System software calculates the rate of change at the end of reaction. The rate of change is converted to concentration by the system software.

https://pharmacopeia.cn/v29240/

## 2.3 Rate Turbidimetry

Rate turbidimetric methods measure the decrease in intensity of light as it passes through a solution while complexes form. The light source is a light emitting diode (LED) at 940 nm. Turbidimetric measurements are made at 0° from the incident beam. The intensity decrease is converted to an increasing scatter signal by *Equation 2*.

$$\text{Scatter signal} = -\log_{10}\left|\frac{\text{light intensity}}{\text{initial light intensity}}\right| \quad (2)$$

# 3. INSTRUMENTATION

A schematic diagram and principles of operation of a nephelometric (turbidimetric) instrument are shown in *Nephelometry and Turbidimetry* ⟨855⟩, *Figure 1*. A typical instrumental design dedicated for rate nephelometric measurement is shown below in *Figure 1*. The main components are: a light source that is usually a laser (635 nm) with a highly collimated beam to avoid stray light, a sample cell, and a light detector. The laser beam passes through the sample well into a scattered light detector assembly. Typically an integrating sphere (Ulbricht sphere), which helps improve the signal-to-noise ratio and enhance the signal for very low concentrations, is attached to a photodiode and used as the detector in rate nephelometry instruments. The unscattered light (light not deflected by particles) passes straight through the sphere and no signal is generated. Light scattered by particles is reflected around the interior of the sphere and then detected by the photodiode detector. The angle of detection of the scattered light is usually 90°, which is, in general, suitable for smaller aggregates ($d \leq \lambda/20$). A light trap is attached to the Ulbricht sphere at the opposite side of the light beam entrance window to absorb the unscattered light. The amount of scattered light is proportional to the concentration of particles. Some instruments can perform both rate nephelometry and rate turbidimetry measurements. These instruments are equipped with a laser source at 670 nm with 90° scatter detection for nephelometric measurements and an LED source at 940 nm with 0° scatter detection for turbidimetric measurements.

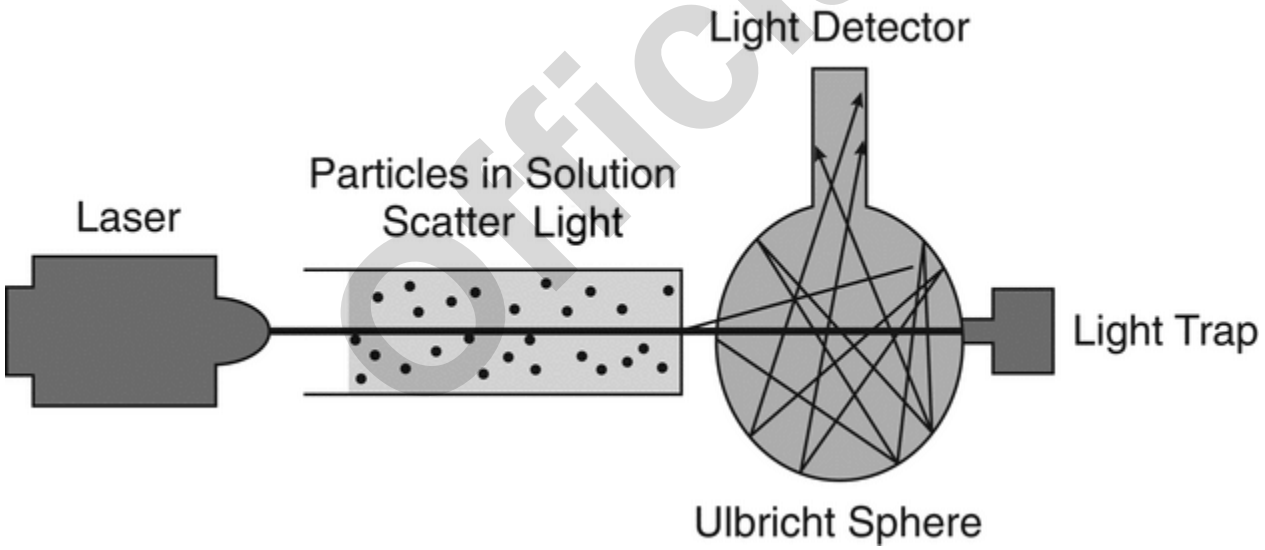

Figure 1. Schematic of a typical nephelometer.

## 3.1 Rate Nephelometry Instrumental Parameter Settings

The most important rate nephelometric system parameter settings are:

- **Acquisition time:** Reaction cuvettes, housed on a reaction wheel, are scanned in cycles of 5 s, for total reaction times ranging from 1.5 to 10 min. Acquisition time commences upon completion of a 5-min preset baseline acquisition period, also in 5-s cycles. Most reactions in nephelometric applications achieve peak rates within 2 min, whereas those used in turbidimetric applications require longer reaction times (3 min or longer).
- **Gain settings:** These settings are related to signal amplification. Generally, decreasing analyte concentration requires a concomitant increase in gain to maintain sensitivity.
- **Onboard compartment temperatures:** Reaction wheel temperature is maintained at 37° to enhance aggregate formation. The reagent compartment is cooled to extend stability of antibody reagents, whereas the sample compartment temperature is ambient.
- **Laser beam width and intensity adjustment:** If applicable, the laser beam width and intensity are adjustable in some instruments and can be optimized to obtain the best scattered signal response.

### 3.2 Calibration of Rate Nephelometric Instruments

Calibration of the rate nephelometer is typically a multitier process consisting of preprogrammed and user-defined components. The preprogrammed component is executed with each instrument run and is comprised of measurements of an onboard reference cuvette of known scatter values. The user-defined component relies on protein controls. Certified protein controls are routinely used for initial instrument calibration and may be utilized for periodic instrument performance qualification. For method calibration and performance monitoring, specially formulated product-relevant reference materials are used.

Data assessment is accomplished by comparison against the control manufacturer's published range, peer data, and/or internally established acceptance criteria. Each analytical run typically includes a calibration curve of reference material and, where applicable, a single concentration of control, each selected to represent the product of interest. The validity of an instrument run is dependent on satisfaction of acceptance criteria established through method development and statistical analysis of temporal method performance.

## 4. APPLICATIONS

⟨855⟩ gives a general overview of the applications of turbidimetric and nephelometric techniques including the rate nephelometry and rate turbidimetry (see *Nephelometry and Turbidimetry* ⟨855⟩, *3. Applications*). The following discussions represent additional and more detailed information on the applications of rate nephelometry and rate turbidimetry in biopharmaceutical industry and clinical laboratories, which are summarized in *Table 1*.

In bacterial polysaccharide-containing vaccine analysis applications, the reaction of excess of (bivalent, polyvalent) monoclonal or polyclonal antibodies with high molecular weight bacterial polysaccharides—such as those from *Haemophilus influenzae* type b (Hib vaccine), *Neisseria meningitidis* (meningococcal vaccine) or *Streptococcus pneumoniae* (pneumococcal vaccine)—causes crosslinking and the formation of high molecular weight aggregates that scatter light. Therefore, the rate at which aggregates develop allows the polysaccharides, free or conjugated, to be quantified. Endpoint nephelometry is an alternative application in which the endpoint of the reaction is determined in the analysis.

In the case of multivalent vaccines, the specificity of the antibody used allows the selective detection and quantification of a specific polysaccharide, and the use of different antibodies with different specificities allows multiple components to be quantified.

Immunonephelometry for biologics analysis is based on antibody-antigen immune complex formation (immunoprecipitation). Formation of the immunoprecipitation is dependent on the presence of the antigen and antibody molecules in optimal proportions. Quantitative methods are based on the principle that when the amount of antibody is held at a constant excess, the degree of immunoprecipitation will increase with increasing antigen content up to a maximal amount. A standard curve can be generated by maintaining a constant level of antibody and measuring the light scatter with increased concentrations of antigen. Due to the reliance upon antibody and antigenic epitope recognition, the above applications are employed for characterization purposes, monitoring of functional group content, stability, and assessment of lot-to-lot consistency, i.e., for quantification of the antigenic saccharide content in components and/or products of vaccine manufacture. Such components and/or products include: (a) bulk monovalent glycoconjugate immunogens; (b) bulk polyvalent glycoconjugate immunogen blends; (c) bulk polyvalent polysaccharide blends; (d) glycoconjugate vaccine final fills; and (e) polysaccharide vaccine final fills. Rate nephelometric analysis of the multicomponent product is generally employed in conjunction with direct saccharide quantitation of the individual components by orthogonal methods.

Turbidimetry is widely used for measurement of activity in recombinant coagulation factor and other hemophilia replacement therapies, as well as for patient monitoring in clinical hemostasis laboratories. The turbidimeter monitors the transmittance of light at 670 nm as fibrin converts into fibrinogen during clot formation. Calibrators in the form of reference plasmas, generally traceable to World Health Organization standards, serve for instrument calibration and may be used for relative activity determination for the analyzed product.

**Table 1. Examples of Analytical Applications**

| Turbidimetry | Nephelometry |
|---|---|
| Immunoagglutination assay: detection of Chagas disease | Polysaccharide quantitation: pneumococcal vaccine |
| Multiple latex immunoagglutination assays | Polysaccharide quantitation: meningococcal vaccine |
| Fibrinogen assays | Relative molecular size (nephelometry coupled with high pressure size exclusion chromatography) |

## 5. METHOD DEVELOPMENT

Thorough method development encompasses designing the method to fit the application through assessing a complex set of conditions including choice of reagents, standards, and controls; sample handling; and instrument settings. The following areas should be considered during method development in order to determine operating ranges and limits.

### 5.1 Method Design

Competitive versus noncompetitive assay modes are available. The option chosen will be dictated by the sample molecular weight/size and concentration of analyte to be analyzed; where noncompetitive immunoprecipitation mode is preferred for

https://pharmacopeia.cn/

molecular weight (MW) > $10^4$ Da. Sample concentration directs the selection of instrument gain, where lower concentrations require higher gain levels.

For each method, the optimal acquisition time, sequence of administration of components, and gain level must be determined.

Sample volumes will dictate the type and size of sample containers.

A precision study should be performed during development to determine the replication testing scheme for samples in order to obtain the desired method precision (see *Analytical Data—Interpretation and Treatment* ⟨1010⟩).

A response curve between the analyte concentration and measured light scattering unit (LSU) values (or antigenicities calculated from LSU values) is prepared from standard solutions at concentrations encompassing the anticipated concentration of the test solution. The standard curve is then evaluated using appropriate statistical methods, such as least-squares regression.

## 5.2 Sample Considerations

Care must be taken to ensure samples, as with all other components, are essentially free from particulates and air bubbles in order to minimize nonspecific contributions to light scattering and liquid level sensing errors, respectively. Analytes such as monovalent polysaccharide-protein conjugates are diluted in several steps to a single point targeting the midpoint of an established standard curve.

Samples that contain adjuvants require solubilization of the adjuvant, carefully controlled and replicated with the reference material. Select applications, such as the specific analysis of adjuvant-bound antigenicity or the separation of conjugated antigenicity from free antigenicity, may require additional manipulations such as pH adjustment, preadsorption with Excel adjuvant, or temperature treatment prior to nephelometric analysis. If adjuvant solubilization is used for the sample, then the respective reference material must be subjected to the same treatment. Solubilization should be tightly controlled to minimize variability.

Specific pretreatments may need to be developed depending on the type of antigen. For example, polysaccharide-carrier protein conjugates may be analyzed for bound, conjugated, free, or total polysaccharide content. Example pretreatments include pH adjustment, adsorption with excess adjuvant, temperature treatment, and physical separation through centrifugation.

Cross-reactivity between component analytes may also need to be addressed during reagent selection (see the antibody discussion under *5.3 Reagents*).

## 5.3 Reagents

The choice of reaction buffer is dictated by compatibility with the analyte formulation buffer. Presence of aggregation enhancers or inhibitors should be considered. Interactions with containers such as glass test tubes may need to be considered. Detergent may be required for certain analytes, and the type and concentration must be determined experimentally.

Polyclonal antibodies are preferred for rate nephelometry as they are typically optimal for appropriate lattice formation; although monoclonal antibodies are frequently required for detection of specific functional groups. All antibodies must be sufficiently specific for the analysis of individual product components and of appropriate titer and avidity.

## 5.4 Method Specific Reference Standards

Reference materials are carefully selected from process representative batches, formulated, and packaged to optimally mimic the analyte of interest. Reference samples and standards must be treated equally.

## 5.5 Controls

Both positive and negative controls are likewise selected as product representative materials that may be formulated for extended stability via freezing or lyophilization.

## 5.6 Robustness

Method robustness assessments should include the following:

- Instrument parameters, e.g., gain (signal amplification), reaction time (interval between addition of last reagent and measurement)
- Concentration optimums
  - Antigen
  - Antibody
- Mix times
- Selectivity (lack of cross-reactivity) of antibodies
- Reagent use/hold times
- Type of ions, ionic strength of solution

@2024 USPC

## 6. METHOD VALIDATION

In addition to generally applicable validation characteristics as described in *Validation of Compendial Procedures* ⟨1225⟩, the following aspects are recommended for consideration in the context of nephelometry and/or turbidimetry:

- **Accuracy:** Quantitation of polysaccharides determined by assessment of known values generated with an orthogonal validated assay.
- **Linearity:** Should be assessed in both reference standards and analyte samples.
  - Standard curve required for each type of polysaccharide being assessed.
  - Standard polysaccharide concentration determined by alternative validated method (e.g., meningococcal serogroup C polysaccharide concentration determined by the sialic acid colorimetric method of Svennerholm.)
- **Lifecycle considerations:** Appropriate performance parameters are trended over time and utilized for bridging of new reference standards and for assessment of period of use of antibodies/reference standards/controls.
- **System suitability:** Positive control is assessed at the validated limits of adjustable instrument parameters. Results for the positive control must be within its defined range.

## 7. DATA ANALYSIS

A calibration curve is generated from the duplicate readings for the reference standard versus the standard concentration (from a validated orthogonal assay, e.g., nephelometric polysaccharide quantitation standard values from suitable sugar-specific colorimetric methods, i.e., hexose, uronic acid, sialic acid, or PABA assays.)

- Percent difference between duplicate readings for standards, controls, and samples is calculated.
- Antigenicity is calculated, in μg/mL, using sample LSU values and the slope and the intercept of the standard curve as shown in *Equation 3*:
  Antigenicity = $(\bar{A}_v - y_{int})/S$ (3)

$\bar{A}_v$ = average sample values (LSU)
$y_{int}$ = *y*-intercept (LSU)
$S$ = slope$\left(\frac{\text{LSU} \cdot \text{mL}}{\mu\text{g}}\right)$

Acceptance criteria for replicate measurements of each standard solution and/or sample (in LSU) should be developed such that valid results meet the desired accuracy and precision of the method, e.g., linearity, slope, and intercept may be monitored and assessed against acceptance criteria during routine laboratory use. Acceptance criteria shall be established for slope and linearity, satisfactory precision of replicates, minimum and maximum response for matching (positive control), and baseline (negative control).

# ⟨1430⟩ ANALYTICAL METHODOLOGIES BASED ON SCATTERING PHENOMENA—GENERAL

1. OVERVIEW: GENERAL CHAPTERS BASED ON SCATTERING PHENOMENA
2. INTRODUCTION
3. THEORY (GENERAL PRINCIPLES OF SCATTERING)

***Change to read:***

## 1. OVERVIEW: GENERAL CHAPTERS BASED ON SCATTERING PHENOMENA

This chapter provides a general overview of the scientific principles and analytical procedures used in scattering techniques and their applications. *Figure 1* shows a taxonomy (tree diagram) of the techniques that are covered in this chapter. The first branch classifies the techniques according to the wavelength of the incident electromagnetic (EM) radiation: visible light (700–400 nm), X-rays (0.33–0.06 nm), as well as neutrons (2.5–0.15 nm). The next branch classifies techniques into those based on the measured intensities (i.e., scattering), where the radiation exiting the sample is measured at an angle relative to the incident beam, or transmission, where this angle is equal to zero. Scattering techniques can be further classified based on how the exiting radiation is quantified, in either a time-averaged (static) or time-dependent (dynamic) mode. Finally, because scattering techniques are often coupled with separation techniques, such as chromatography or field flow fractionation, these are included as well.

Two of the most important parameters of the EM radiation–matter interaction are the wavelength of the incident EM radiation ($\lambda = \lambda_0/m_0$, where $\lambda_0$ is the wavelength in vacuo and $m_0$ is the refractive index of the medium) and the size of the particle, often expressed as an equivalent spherical radius ($r$). A dimensionless parameter ($\alpha = 2\pi r/\lambda$) can be used to describe different scattering regimes. For $\alpha \ll 1$, the scattering is considered as being in the Rayleigh regime and the Rayleigh scattering theory applies (named after Lord Rayleigh, who developed the theory in 1871); for $\alpha \sim 1$, the scattering is considered as being in the Mie regime and the Mie scattering theory applies (named after Gustav Mie, who developed the theory in 1908); and for $\alpha \gg 1$, geometric optics apply. These theories are further addressed in the respective chapters where they are applied. *Table 1* lists all chapters whose fundamental physical principles are addressed in this overarching chapter. These chapters deal with elastic light scattering in heterogeneous systems and its applications in the pharmaceutical industry.

**Table 1. List of ⟨1430.X⟩ General Chapters Family**

| Chapter Number | Chapter Title | Measured Property | Primary Purpose |
|---|---|---|---|
| ⟨1430⟩ | *Analytical Methodologies Based on Scattering Phenomena—General* | Overarching chapter | General overview; N/A |
| ⟨1430.1⟩ | *Analytical Methodologies Based on Scattering Phenomena—Static Light Scattering* | Scattered light intensity as a function of detector's angle | Molecular weight, size, shape; molecular interactions |
| ⟨1430.2⟩ | *Analytical Methodologies Based on Scattering Phenomena—Light Diffraction Measurements of Particle Size* | Diffracted light intensity at multiple angles | Particle size distributions in the approximate range of 0.01–3000 µm |
| ⟨1430.3⟩ | *Analytical Methodologies Based on Scattering Phenomena—Dynamic Light Scattering* | Fluctuations of the scattered light intensity | Average hydrodynamic diameter and polydispersity index |
| ⟨1430.4⟩ | *Analytical Methodologies Based on Scattering Phenomena—Electrophoretic Light Scattering (Determination of Zeta Potential)* | Doppler shift of scattered light frequency | Stability of suspensions and emulsions |
| ⟨1430.5⟩ | *Analytical Methodologies Based on Scattering Phenomena—Small-Angle X-Ray Scattering and Small-Angle Neutron Scattering* | Scattered intensity of a beam of X-rays or neutrons | Direct probing of the size, shape, ordering, and interactions of individual molecules, their assemblies in the approximate length scales from 0.1–2500 nm for SAXS and 0.2–1000+ nm for SANS. Also properties of condensated phases (e.g., porosity and crystallinity) can be determined. |
| ⟨1430.6⟩▲▲ (ERR 1-Oct-2021) | *Analytical Methodologies Based on Scattering Phenomena—Particle Counting via Light Scattering* | Light scattered from individual particles passing through a light beam | Quantitation of particles in liquids and gases from 0.1–2 µm |
| ⟨1430.7⟩▲▲ (ERR 1-Oct-2021) | *Analytical Methodologies Based on Scattering Phenomena—Nephelometry and Turbidimetry* | Direct or indirect measurement of the scattered light intensities | Suspended particles in liquid or gas samples; nephelometry for lower aggregate sizes and analyte concentrations; turbidimetry for higher aggregate sizes and analyte concentrations |

Because these methods are based on the same underlying physics, the general principles are given only once in this overarching chapter. The relationships between these methods are shown in *Figure 1*.

## 2. INTRODUCTION

When an EM wave strikes/interacts with a small object (a particle or a molecule) and thereby changes its direction, the phenomenon is called scattering. If the scattered EM radiation has exactly the same energy (wavelength) as the incident one, it is called elastic scattering. When the energy (wavelength) of the scattered EM radiation is different from that of the incident

Printed by: USP NF
Do Not Distribute

EM radiation, the scattering process is termed "inelastic". Inelastic scattering is exploited, as an example, by Raman spectroscopy (refer to *Raman Spectroscopy—Theory and Practice* ⟨1858⟩). Scattered radiation may be detected and measured either directly: as a function of the angle between the incident beam direction and the detector, or indirectly: when the actual measurement is that of the transmitted light. The latter is the case for both turbidity and light obscuration methods (see the following chapters on turbidity and light obscuration: *Nephelometry, Turbidimetry, and Visual Comparison* ⟨855⟩, *Subvisible Particulate Matter in Therapeutic Protein Injections* ⟨787⟩, *Particulate Matter in Injections* ⟨788⟩, and *Methods for the Determination of Subvisible Particulate Matter* ⟨1788⟩). Both methodologies exploit time averaged signals.

In static light scattering (SLS), the inevitable short-term temporal fluctuations in scattering intensity due to Brownian motion are averaged over a range of times from tens to hundreds of milliseconds. SLS therefore measures the "time average" intensity of scattered light from particles in a (suitably prepared) sample. Depending on the specific technique, SLS provides information about molecular weight, particle size, particle shape, and molecular interactions (see *Analytical Methodologies Based on Scattering Phenomena—Static Light Scattering* ⟨1430.1⟩. Light scattered in the near-forward direction by particles is analogous to diffraction of light through an aperture. This is exploited by (laser) diffraction techniques, which are optimized to afford the derivation of a full size distribution, with moderate to high resolution, rather than a single characteristic size as in low-angle light scattering (LALS)/multi-angle light scattering (MALS).

Small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) are also static techniques in that they make use of time averaged signals. These differ from LALS (and MALS) in that they are based on scattering of X-rays (SAXS) or neutrons (SANS) rather than visible light. Like SLS, these techniques also measure size, shape, and interactions but on much shorter length scales, typically ranging from around 1 nm to several hundred nanometers. Very/ultra small-angle (VSAXS/VSANS, USAXS/USANS) and wide-angle (WAXS/WANS) analogues extend these length scales to the micrometer and sub-nanometer regimes, respectively. These applications are discussed in *Analytical Methodologies Based on Scattering Phenomena—Small-Angle X-Ray Scattering and Small-Angle Neutron Scattering* ⟨1430.5⟩.

Dynamic light scattering (DLS), which is addressed in *Particle Size Analysis by Dynamic Light Scattering* ⟨430⟩[1] and *Analytical Methodologies Based on Scattering Phenomena—Dynamic Light Scattering* ⟨1430.3⟩, differs from SLS in that DLS measures the fluctuation of the scattered light intensity over very short time intervals (e.g., approximately 200, 400 ns).

Electrophoretic light scattering (determination of zeta potential), which is addressed in more detail in *Determination of Zeta Potential by Electrophoretic Light Scattering* ⟨432⟩ ▲▲ (ERR 1-Oct-2021) and *Analytical Methodologies Based on Scattering Phenomena—Electrophoretic Light Scattering (Determination of Zeta Potential)* ⟨1430.4⟩, measures the Doppler shift of the frequency of scattered light as the result of particle movements from the cumulative effect of electrophoresis and electroosmosis.

## 3. THEORY (GENERAL PRINCIPLES OF SCATTERING)

Light/EM scattering is the result of a complex interaction between incident light/EM waves and matter. An EM wave that is redirected, i.e. changes direction, when it encounters obstacles such as a molecule or molecular aggregates, or particles, is said to have been scattered. As the EM radiation, such as light or X-rays, interacts with a discrete particle, the electron orbits within the particle's constituent atoms or molecules are perturbed periodically with the same frequency ($\nu_0$) as the electric field of the incident wave. The oscillation or perturbation of the electron cloud results in a periodic separation of charge within the molecule, which is called an induced dipole moment. The oscillating induced dipole moment manifests itself as a source of EM radiation (see *Figure 2*). Neutrons, on the other hand, are always scattered by a very short-range nuclear interaction with the nuclei in the atoms.

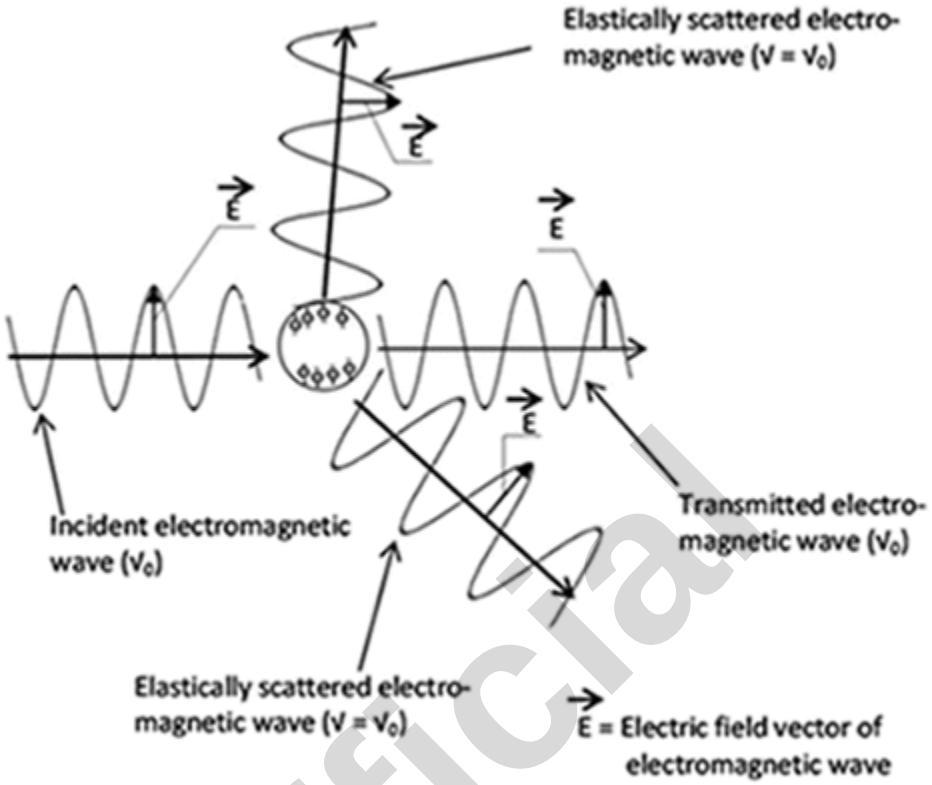

Figure 2. Scattering of an incident EM wave by an induced dipole moment.

The (time averaged) intensity ($I$) of the light beam as it interacts with matter along its path (i.e., when the incident light is detected at an angle of zero) decreases exponentially with the thickness, $x$, of the layer of material as follows in *Equation 1*:

$$I = I_0 e^{-\tau x} \qquad (1)$$

where $\tau$ is the turbidity and $x$ is the distance that the incident light travels through the sample.

This equation is the basis for turbidimetry and nephelometry (see ⟨855⟩).

In SLS, the theoretical description of the relationship between the (time averaged) intensities of incident and scattered light, although quite complex, originates from the following simple relationship (*Equation 2*).[2]

$$I = I_0 \frac{1}{r^2} \sigma_{scat} \qquad (2)$$

The scattering coefficient, $\sigma_{scat}$, and with it the intensity of the scattered light depend on factors determined by the interaction of the incident light with the material/particles itself as well as those stemming from the equipment used for generating and detecting the signal (e.g., $r$, the distance of the detector from the sample; $I_0$, the intensity of the incident light; and, $\Theta$, the angle of observation).

On the other hand, when studying the fluctuations in scattered intensity (DLS), the way to extract useful, quantitative information is by calculating the so-called "autocorrelation function", denoted $g_2(\tau)$ based on the measured intensities (*Equation 3*):

$$g_{2,\text{theory}}(\tau) = (\Sigma A_i e^{B_i \tau})^2 + 1 \qquad (3)$$

where in this case, $\tau$ denotes a correlation time (not to be confused with the $\tau$ in *Equation 1* above), and the use of the index, $i$, accounts for different particle types (e.g., different sizes) present. A computer program is used to find the parameters $A_i$, $B_i$ (= $A_1$, $B_1$, $A_2$, $B_2$,…) that produce the best agreement between the measured and theoretical autocorrelation function.

Depending on the methodology, the equations above are transformed to obtain a measure that relates the measured intensities, $I$ and $I_0$, respectively, and the autocorrelation function $g_2(\tau)$ to the material itself, independent of equipment characteristics. These are further discussed in the specific chapters in the *USP–NF* dedicated to the corresponding techniques (see *Table 1*).

# ⟨1467⟩ RESIDUAL SOLVENTS—VERIFICATION OF COMPENDIAL PROCEDURES AND VALIDATION OF ALTERNATIVE PROCEDURES

The procedures defined in *Residual Solvents* ⟨467⟩ have been validated for Class 1 and 2 solvents over the range of 50%–150% of the concentrations described in the standard preparation for procedures A and B in *Residual Solvents* ⟨467⟩*, 8. Analytical Procedures for Class 1 and Class 2 Residual Solvents*.

The suitability of these residual solvent procedures must be verified under actual conditions of use. When using the procedures for testing residual solvents described in ⟨467⟩, verification can be accomplished using the recommendations below. There are separate recommendations for limit and quantitative procedures in *Residual Solvents* ⟨467⟩*, 8. Analytical Procedures for Class 1 and Class 2 Residual Solvents*.

Alternative procedures include different analytical procedures from those described in ⟨467⟩, as well as modifications to the procedures described therein that go beyond the stated validation of the method (e.g., different concentrations or other analytes or variations to chromatographic conditions beyond those permitted by *Chromatography* ⟨621⟩). Alternative procedures are permitted (see *General Notices, 6.30 Alternative and Harmonized Methods and Procedures*), provided that they are properly validated. A risk-based approach may be appropriate to determine the degree and extent of the verification or validation process to assure the fitness for purpose of the procedure. Recommendations for validation of alternative procedures (limit and quantitative tests) are described in *Validation of Alternative Procedures*. A summary of the requirements is shown in *Table 1*.

**Table 1. Summary of Verification and Validation Requirements**

| | Verification of Compendial Procedures | | Validation of Alternative Procedures | |
|---|---|---|---|---|
| **Validation/Verification Characteristics** | **Limit Test Methods** | **Quantitative Methods** | **Limit Test Methods** | **Quantitative Methods** |
| Specificity | Yes | Yes | Yes | Yes |
| Detection limit | Yes[a] | No | Yes | No |
| Quantitation limit[b] | No | Yes[a] | No | Yes |
| Accuracy | No | Yes | No | Yes |
| Precision/repeatability | No | Yes | No | Yes |
| Linearity | No | No | No | Yes |
| Range | No | Demonstrated by accuracy and precision | No | Demonstrated by accuracy and precision |
| Intermediate precision | No | No | No | Yes |
| Solution stability[c] | Yes | Yes | Yes | Yes |
| Robustness[d] | No | No | Yes[e] | Yes[e] |

[a] System suitability may be used instead to demonstrate sensitivity.
[b] In quantitative tests, quantitation limit may be demonstrated by accuracy and precision determination.
[c] Solution stability should be determined for the timeline of the test.
[d] Evaluation of robustness should be considered during the development phase and depends on the type of procedure under study.
[e] The "Yes" quotation here is intended to emphasize the importance of assessing the robustness of the procedure before the implementation.

## VERIFICATION OF COMPENDIAL PROCEDURES

### Limit Procedures: Procedure A and Procedure B

The analytical characteristics to be verified include specificity, detectability, and solution stability.

VERIFICATION WHEN SOLVENTS LIKELY TO BE PRESENT (LTBP) ARE NOT KNOWN

**Samples**

Prepare a reagent blank.

Prepare *Standard solutions* as described in *Residual Solvents* ⟨467⟩*, 8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*.

Prepare the *Spiked sample solution* as described in *Class 1 System suitability solution* in *Residual Solvents* ⟨467⟩*, 8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*.

**Specificity**

*Recommended acceptance criteria:* An appropriate blank should be injected to assure the lack of a significant interference. A significant interference is one producing a deviation in the fitness for purpose of the procedure that affects precision and/or

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M11016_05_01

@2024 USPC

accuracy. The procedure must be able to separate acetonitrile and methylene chloride (*Procedure A* in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*), or ▲methylisobutylketone▲ (ERR 1-Dec-2020) and *cis*-dichloroethene (*Procedure B* in *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*) with a resolution of NLT 1.0.

**Detection Limit (see** *Table 1, Footnote a***)**

*Recommended acceptance criteria:* The mean signal-to-noise ratio for each solvent in the *Standard solution* and *Spiked sample solution* [after correction for native (original) solvent content] from at least three determinations from a single preparation is NLT 3.

**Solution Stability**

*Recommended acceptance criteria:* Detection limit should meet the requirements throughout the testing period.

VERIFICATION WHEN SOLVENTS LTBP ARE KNOWN

**Samples**

Prepare a reagent blank.

Prepare *Standard solution(s)* and *Sample solution(s)* as described in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles* depending on the specific sample solubility using only those solvents likely to be present (LTBP).

Prepare *Spiked sample solution(s)* as described in *Quantitative Procedures: Procedure C* for solvents LTBP [corrected for native (original) solvent content].

**Specificity**

*Recommended acceptance criteria:* The reagent blank does not produce any significant interference with any of the peaks from solvents LTBP.

The procedure must be able to separate each of the solvents in the *Standard solution(s)* from each other and from other peaks in the *Spiked sample solution* with a resolution of NLT 1.0. If the resolution between any pair of peaks is less than 1.5, then verification must demonstrate that the method is suitable for its intended use.

If the solvents present in the *Standard solution(s)* are not separated with a resolution of NLT 1.0 when using the *Chromatographic System* of *Procedure A*, then *Procedure B* in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles* should be used as confirmatory.

**Detection Limit**

*Recommended acceptance criteria:* The mean signal-to-noise ratio for each solvent in the *Standard solution* and the *Spiked sample solution* [after correction for native (original) solvent content] from at least three determinations from a single preparation is NLT 3.

**Solution Stability**

*Recommended acceptance criteria (not required if only running fresh solutions):* Detection limit for limit tests and quantitation limit for quantitative tests should be met throughout the testing period.

## Quantitative Procedures: Procedure C

[NOTE—When performing *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.5 Quantitative Tests—Procedure C*, solvents LTBP are typically known, either based on results from *Procedure A* or *Procedure B* in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*, or based on available knowledge. The analytical characteristics to be verified include specificity, accuracy (which addresses quantitation limit), range, repeatability, and solution stability.]

**Samples** Prepare a reagent blank.

**Standard stock solution:** Prepare a solution containing each solvent LTBP or each peak identified and verified by *Procedure A* and *Procedure B* in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*, with a concentration as described in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.5 Quantitative Tests—Procedure C* for water-soluble articles or water-insoluble articles, as appropriate.

**Sample stock solution:** Prepare as described in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*.

**Spiked sample solution:** Prepare as described in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.5 Quantitative Tests—Procedure C*, using the *Standard stock solution*.

**Spiked sample solutions A, B, C, etc.:** Prepare *Spiked sample solutions* with the sample matrix and spiked with each solvent LTBP or identified and verified by *Procedure A* and *Procedure B* in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*, in triplicate, at NLT 3 levels covering the range of interest or at least 50%–150% of the corresponding concentration of the *Standard solution* as described in *Procedure A* in *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles*.

[NOTE—The *Spiked sample solution* may be used as one of the solutions.]

**Specificity**

**Recommended acceptance criteria:** The procedure must be able to separate each of the solvents in the *Standard solution(s)* from each other and from other peaks in the *Spiked sample solution* with a resolution of NLT 1.0. If the resolution between any pair of peaks is less than 1.5, then verification must demonstrate that the method is suitable for its intended use.

Official

https://pharmacopeia.cn/v-29240/

If the solvents present in the *Standard solution(s)* are not separated with a resolution of NLT 1.0, then chromatography described in *Procedure B* in *Residual Solvents* ⟨467⟩, *8. Analytical Procedures for Class 1 and Class 2 Residual Solvents, 8.2 Screening of Water-Soluble Articles* or *8.3 Screening of Water-Insoluble Articles* should be used as confirmatory.

**Quantitation Limit**

**Recommended acceptance criteria:** The mean signal-to-noise ratio for each solvent in the *Standard solution* and the *Spiked sample solution* [after correction for native (original) solvent content] from at least three determinations is NLT 10, or the *Quantitation Limit* may be demonstrated by *Accuracy* and *Precision*.

**Accuracy**

**Recommended acceptance criteria:** The mean recovery for *Spiked sample solutions A, B,* and *C, etc.*, when calculated relative to the *Spiked sample solution*, is 80%–120% of the expected theoretical amount.
[NOTE—Recoveries should be corrected for native (original) content of any solvent under test.]

**Precision/Repeatability** Use at least six independent *Spiked sample solution* preparations from the same lot, prepared as described in the *Spiked sample solution* in the *Accuracy* test above, or use nine independent preparations as described in *Spiked sample solutions A, B, C, etc.*

**Recommended acceptance criteria:** Relative standard deviation is NMT 20% for each solvent present.

**Solution Stability:** Demonstrate acceptable solution stability for the period of time to run the test.

**Recommended acceptance criteria:** NMT 20% change in solvent(s) content compared to the initial time point

## VALIDATION OF ALTERNATIVE PROCEDURES

Chromatographic alternative procedures should meet the acceptance criteria for the analytical performance characteristics shown below. When non-chromatographic alternative procedures are validated, the analytical performance characteristics listed should be addressed, although, it may be appropriate to apply other analytical performance characteristics. For more information, refer to *Validation of Compendial Procedures* ⟨1225⟩.

### Limit Procedures

Analytical characteristics to be validated are specificity, detection limit, and solution stability. The same criteria used for *Verification when solvents LTBP are known*, as described above, may be used.

### Quantitative Procedures

Analytical characteristics to be validated are specificity, linearity and range, quantitation limit, accuracy, repeatability, intermediate precision, and solution stability.

**Samples** Prepare a reagent blank.

**Spiked sample solutions P, Q, R, etc.:** Prepare *Spiked sample solutions* with the sample matrix and spiked with each solvent LTBP at NLT 5 levels covering the range of interest. [NOTE—Results should be corrected for native (original) content of any solvent under test.]

**Specificity**

**Recommended acceptance criteria:** The analytical procedure must have the ability to assess unequivocally the analytes of interest in the presence of the components expected to be present.

**Linearity and Range**

**Recommended acceptance criteria:** Perform linear regression analysis on the results for *Spiked sample solutions P, Q, R, etc.* The coefficient of determination, $r^2$, is NLT 0.90.

**Quantitation Limit**

**Recommended acceptance criteria:** The mean signal-to-noise ratio for each solvent in the standard solution and the *Spiked sample solution* [after correction for native (original) solvent content] from at least three determinations is NLT 10. The *Quantitation Limit* may also be demonstrated by *Accuracy* and *Precision*.

**Accuracy**

**Recommended acceptance criteria:** The mean recovery for each *Spiked sample solution* should be 80%–120%.
[NOTE—Recoveries should be corrected for native (original) content of any solvent under test.]

**Precision/Repeatability:** Prepare at least six independent *Spiked sample solution* preparations from the same lot.

**Recommended acceptance criteria:** Relative standard deviation is NMT 20% for each solvent present.

**Precision/Intermediate Precision:** Perform the *Repeatability* test over at least two independent events, e.g., on different days, and/or using different instruments and/or analysts.

**Recommended acceptance criteria:** Testing for intermediate precision should demonstrate that the method is suitable for its intended use.

**Solution Stability:** Standard solutions and *Spiked sample solutions* should be stable throughout the testing period.

**Recommended acceptance criteria:** NMT 20% variation

## 1. INTRODUCTION

The presence of nitrosamine impurities has been detected recently in several drug substances and drug products. In 2018, *N*-nitrosodimethylamine (NDMA) and *N*-nitrosodiethylamine (NDEA) were detected in some valsartan drug substances and the drug products manufactured from drug substances using specific synthetic routes. This observation triggered extensive synthetic route assessments and development of analytical procedures to quantify these two nitrosamine impurities. As additional pharmaceuticals were evaluated and, in some cases tested, other nitrosamines beyond NDMA and NDEA were added as impurities of concern. Given the potentially broad implications of the presence of carcinogenic members of this class of chemicals, this chapter has been developed to provide a science- and risk-based approach for the control of nitrosamine impurities to ensure that the potential presence of nitrosamines in drug substances and drug products is identified, assessed, and controlled.

Recommendations are provided regarding: a) the establishment of controls of nitrosamine levels in order to ensure their elimination or reduction; and b) analytical procedure performance characteristics for procedures used to monitor nitrosamine levels.

## 2. NITROSAMINE IMPURITIES

Nitrosamines addressed in this general chapter are listed in *Table 1* by their common names and chemical names. This list is a compilation of the information shared by multiple global health authorities. As additional nitrosamines are identified as potential concerns, the principles described herein should be applied for the assessment of these nitrosamines. If a manufacturer finds a nitrosamine not listed in *Table 1*, the appropriate regulatory authority should be contacted for determining appropriate AI limits. The potential presence of any one or more of these impurities is dependent on the reaction chemistries and processes. The list of nitrosamines is not intended to be exhaustive but represents those that have been observed and communicated by regulators and manufacturers as being potentially present or observed.

*N*-nitroso compounds are among the structural groups of high potency mutagenic carcinogens in several animal species, and some are classified as probable or possible human carcinogens referred to as the “cohort of concern" in ICH M7: *Assessment and Control of DNA Reactive (Mutagenic) Impurities in Pharmaceuticals to Limit Potential Carcinogenic Risk* (*1*), a designation that carries with it a recommendation to control the impurities at or below the acceptable cancer risk. As a result of the potential toxicity associated with these impurities, it is recommended to take steps to control and limit their presence in pharmaceutical materials.

## 3. SOURCES OF NITROSAMINES

There are a number of pathways by which nitrosamines can be introduced into or generated as impurities in pharmaceutical drug products. Specifically, nitrosamines are formed by chemical reaction of secondary or tertiary amines with nitrites (the latter via intermediate degradation) under acidic conditions (see *3.1. Nitrosamine Formation Reaction*). Some examples of the reported sources or pathways leading to the generation of nitrosamines identified empirically or reported in the literature (*2–3*) include (but are not limited to) the following:

- Drug substance processing under specific conditions and in the presence of certain reagents, solvents, raw materials, and processing aids. There is evidence that despite processing and purification steps, reactive species, whether intentionally added to or formed during the process/reaction sequence (e.g., nitrites and secondary amines in the presence of acidic conditions), can carry over to subsequent steps (see *3.1 Nitrosamine Formation Reaction*). Special attention should be given to the formation of nitrogen-containing heterocycles by employing azide followed by quenching with nitrous acid to remove excess azide.
- The drug substance itself, which may degrade under some conditions resulting in the formation of nitrosamines (e.g., ranitidine).
- Degradation of solvents (e.g., dimethylformamide [DMF]) leading to the formation of dialkyl amines.
- Impurities in raw materials, solvents (including recycled solvents), reagents, or catalysts.
- Impurities in materials and intermediates, reagents, and solvents used to prepare the starting materials or intermediates.
- Impurities in water, excipients, or processing aids used in the production of the finished drug product.
- During drug product manufacture under certain reaction conditions and in the presence of requisite precursors necessary for the formation of nitrosamines.

- Impurities in the container–closure system for the finished drug product, which may include impurities capable of forming nitrosamines, especially if associated with materials containing amines and potential sources of a nitrosating agent (e.g., nitrite, nitrocellulose).

A risk assessment should be conducted to determine the materials that contribute to the potential for inclusion of nitrosamines in the drug product. All potential sources for the introduction of nitrosamines should be considered in the risk assessment including, for example, the drug substance, excipients, water, solvents, the manufacturing process, packaging components, and formation on stability. See *Figure 1* for a diagram of some potential sources to be considered.

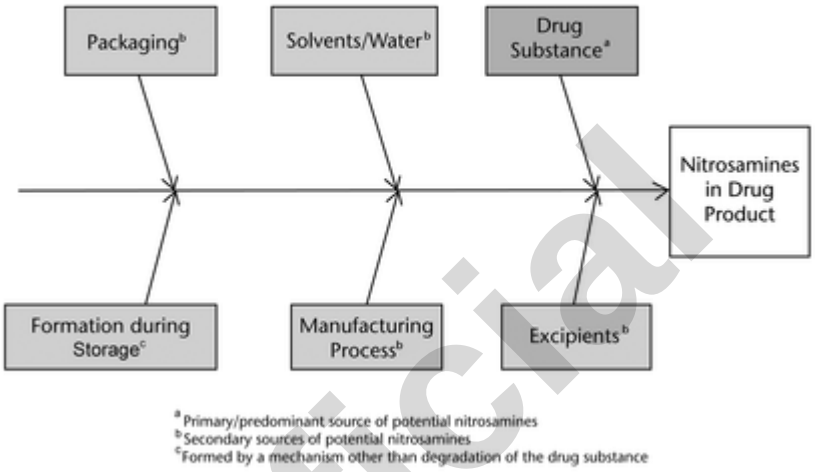

Figure 1. Potential sources of nitrosamine impurities in drug product.

Ongoing assessments and evaluations have identified risks associated with several of the potential sources of nitrosamines. Some of the examples identified are summarized in *Table 2*.

**Table 2**

| Potential Source of Nitrosamines | Observed Risk[a] |
|---|---|
| Solvents | • Presence of residual dialkyl amines or tri-substituted amines that can degrade to form intermediates that can further react with nitrosating agents<br>• Presence of nitrites or other nitrosating agents<br>• Presence of acid<br>• Limited controls/specification limits for recycled solvents<br>• Poor quality solvents |
| Water | • Presence of residual dialkyl amines or impurities that can degrade to form dialkyl amines<br>• Presence of acid and nitrosating agents |
| Excipients | • Presence of nitrites or other nitrosating agents and/or nitrosamine impurities (if applicable) |
| Drug substance | • Use of sodium azide in the synthesis followed by use of nitrites in acidic medium (nitrous acid) for quenching excess azides<br>• Use of di- or tri-alkylamines and amides (e.g., dimethylformamide [DMF], dimethylamine [DMA], triethylamine [TEA], *N*-methylpyrrolidone [NMP]) in the presence of nitrites and acid media<br>• Use of recycled solvents that may contain nitrosamines or their precursors<br>• Use of sanitized water (e.g., chloramines)<br>• Insufficient purification<br>• Degradation of drug substances containing functional groups that can then participate in nitrosation reactions |
| Manufacturing process | • Contamination<br>• Use of poor quality or recycled solvents that may contain nitrosamines or their precursors<br>• Presence of nitrous oxides in air used to dry the drug substance or drug product<br>• Carryover of relevant reactive species into subsequent steps |

[a] General chemical reactions leading to formation of nitrosamines can be found in *3.1 Nitrosamine Formation Reaction*.

### 3.1 Nitrosamine Formation Reaction

The general schematic representation of the chemical reaction responsible for the formation of nitrosamines from secondary amines is described in *Figure 2*. Examples of representative reactions are described in the scientific literature (*2*–*3*).

Official

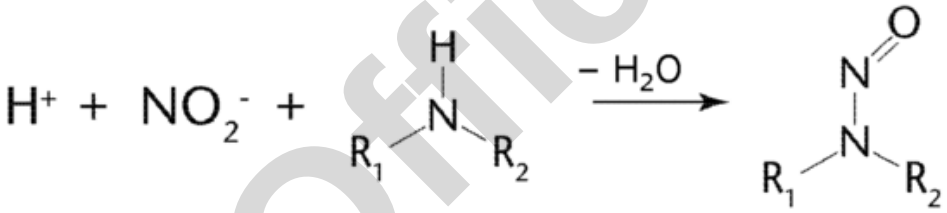

Figure 2. General example of formation of nitrosamines, where $R_1$ and $R_2$ are alkyl or functionalized alkyl groups (and only one of them could be an aryl or functionalized aryl group).

If the potential for the presence of nitrosamines is identified, where appropriate, a control strategy should be developed. If nitrosamines are identified as impurities in ingredients, they may be controlled as appropriate in the ingredients (e.g., manufacture of the drug substance or controls placed on the drug substance). If nitrosamines are identified as degradation products (i.e., being formed during manufacturing of the drug product or formed during product storage), they should be controlled as appropriate in the drug product. In some cases, changes to the manufacturing process(es) or ingredients may be required to achieve acceptable levels or the elimination of nitrosamine impurities in the drug product.

## 4. NITROSAMINE RISK ASSESSMENTS—DEVELOPMENT OF A CONTROL STRATEGY

In order to determine the level of control, if any, which may be required for ensuring that levels of nitrosamines are at or below the acceptable intake (AI) if their presence cannot be avoided, the components of drug products should be assessed by the drug product manufacturer for the potential to form nitrosamines or to be contaminated with nitrosamines. Although one of the sources with the highest potential for nitrosamines is the drug substance synthetic route, the drug substance manufacturing process, drug product manufacturing process, and excipients and raw materials should also be included in a risk assessment to establish if controls or additional controls are needed. An example of high-level process flow for evaluating materials is shown in *Figure 3*.

1, 2, 3; D1, D2 = Decision 1, 2)

In all cases, if nitrosamines are predicted by the risk assessment or confirmed to be present through testing of the drug substance, drug product, or other materials, a control strategy should define an approach to ensure that the nitrosamine levels comply with the established AIs. The control strategy should be aligned with the current regulatory requirements in place.

## 5. LIMITS OF NITROSAMINES

Nitrosamine impurities identified in this chapter have potential and established toxicity with no therapeutic value. Because nitrosamines are among the structural groups of high potency mutagenic carcinogens of the "cohort of concern" in ICH M7 (*1*), the threshold of toxicological concern (TTC) does not apply. Instead, the available safety data should be used to establish a material-specific AI on a case-by-case basis. The AI is defined as an intake level that poses a negligible health risk.

### 5.1 Derivation of AI Limits

There are a number of methodologies that toxicologists have applied in establishing AIs. In this case, the median tumorigenic dose ($TD_{50}$) of NDMA, NDEA, and other nitrosamines was used as representative data in a linear extrapolation to establish an acceptable risk level. The limits have been published in the FDA Guidance for Industry: *Control of Nitrosamine Impurities in Human Drugs* (*4*).

### 5.2 Example Calculations of Nitrosamine Limits

The AIs in nanograms per day and the maximum daily dose (MDD) of the drug substance (DS) from the drug label in milligrams per day can be used to calculate the maximum nitrosamine concentration limits, in ppm, for individual drug products using the following equation:

$$\text{Concentration} = \text{AI}/\text{DS}_{\text{dose}}$$

Since the exposure to nitrosamines is related to the MDD of the DS, different concentrations of nitrosamines (ng/g) may be acceptable for each material evaluated. The acceptable concentration in the material can be calculated using the following equation:

$$\text{Acceptable nitrosamine content} = \text{AI}/\text{MDD}$$

AI = acceptable intake of the nitrosamine (µg/day)
MDD = maximum daily dose of the drug substance (g/day)

**Table 3. Example Using an AI of 96 ng/day for the Target Nitrosamine**

| Name | Acceptable Concentration (µg/g) | | | |
|---|---|---|---|---|
| | 0.050 (50-mg dose) | 0.100 (100-mg dose) | 0.250 (250-mg dose) | 1.00 (1000-mg dose) |
| Nitrosamine 1 | 1.920 | 0.960 | 0.384 | 0.096 |

[NOTE—If multiple nitrosamines are identified in the material and the total exceeds 26.5 ng/day, the appropriate regulatory authority should be consulted to determine an acceptable approach.]

## 6. TESTING FOR THE PRESENCE OF NITROSAMINES

Upon completion of the risk assessment, exploratory testing may need to be performed to confirm the conclusions of the risk assessment and proposed control strategy. On the basis of the controls identified (e.g., incoming material testing or specification limit; drug substance or drug product specification limit), it may be necessary to implement routine testing for nitrosamines. If testing is applied to ensure that the nitrosamine(s) concentration(s) do not exceed the AI, methods should be established following the recommendations detailed in this chapter. Example analytical procedures can be found in *8. Analytical Procedures*.

### 6.1 Presence of Two or More Nitrosamines

The current published AIs reflect limits for the presence of a single nitrosamine. If multiple nitrosamines are possible and are determined analytically to be present at levels exceeding the maximum amount permitted by the regulatory authority, the relevant health authority should be consulted to determine a specific path forward. Manufacturers should contact FDA for determining the AI limits if multiple nitrosamine impurities are detected in a drug substance or drug product in which the total nitrosamine level exceeds 26.5 ng/day based on MDD.

## 7. TEST METHOD PERFORMANCE CHARACTERISTICS OF NITROSAMINE METHODS

The AIs associated with nitrosamines require the application of sensitive analytical procedures. In many cases, the most reliable procedures take advantage of the sensitivity and selectivity of chromatographic separation techniques coupled with quantitation by mass spectrometry (e.g., HPLC–MS/MS, GC–MS/MS). For additional guidance on validation of alternative methods for nitrosamines, see *Validation of Compendial Procedures* ⟨1225⟩.

### 7.1 Considerations for Sample Preparation

Appropriate sample preparation is a critical step in trace impurity analyses such as those required to evaluate the levels of nitrosamines in drug substances and drug products. This is particularly critical to prevent the loss or generation of nitrosamines as artifacts of the analytical procedure itself, as in the following circumstances.

- The presence of dialkyl amine (dimethylamine) as a process impurity or counter ion of the salt form of the active ingredient in the presence of nitrite and acid can lead to in situ formation of nitrosamines as an artifact, especially in GC analyses.
- Total solubilization versus selective extraction: If the active ingredient contains a dimethylamino group, total dissolution of the drug substance should be avoided when applying GC techniques. High concentration of the active ingredient, when injected in the GC instrument can generate nitrosamines in the injection port if a

@2024 USPC

nitrosating agent is present. In these situations, sample extractions should be modified to prevent the solubilization of the active ingredient while maintaining the extraction efficiency for nitrosamines present in the material.

The recommended method performance characteristics that need to be evaluated for quantitative analysis of nitrosamines include range, accuracy, repeatability, intermediate precision, and limit of quantitation. If a limit test is intended for use, the recommended method performance characteristics to be assessed include specificity, recovery, detectability, and solution stability. The performance criteria for these parameters should be properly set and confirmed through validation to ensure that the method is suitable for its intended use based on the specific analytes, matrices, and required precision and accuracy of the analytical procedures. Precision and recovery depend highly on concentration and matrix complexity, and the final proposed acceptance criteria need to be justified in the procedure validation documentation. Higher variability may be tolerated or acceptable at concentrations approaching the limit of quantitation of the procedure while lower variability (higher precision) would be expected at higher concentrations. Examples of quantitative analytical procedures are included in *8. Analytical Procedures*. Additional example methods may be provided as they become available for these additional nitrosamines.

## 8. ANALYTICAL PROCEDURES

The following procedures have been established as suitable for their intended (specified) purpose. Users should validate these methods while considering the effect of sample solubility and extraction efficiency on the test results for other materials for which they are intended to be applied (see ⟨1225⟩ and *Verification of Compendial Procedures* ⟨1226⟩).

### 8.1 Quantitative Procedures

**Procedure 1: Quantitation of NDMA, NDEA, NDIPA, NEIPA, NMBA, NMPA, and NDBA in selected sartans (valsartan, irbesartan, and losartan potassium) by HPLC–HRMS**

**Diluent:** Methanol

**Solution A:** 0.1% formic acid in water

**Solution B:** 0.1% formic acid in methanol

**Mobile phase:** See *Table 4*.

**Table 4**

| Time (min) | Solution A (%) | Solution B (%) |
|---|---|---|
| 0 | 90 | 10 |
| 1.5 | 90 | 10 |
| 7.0 | 45 | 55 |
| 17.0 | 45 | 55 |
| 17.1 | 10 | 90 |
| 21.0 | 10 | 90 |
| 21.1 | 90 | 10 |
| 25.0 | 90 | 10 |

**Sensitivity solution:** 1.0 ng/mL each of USP *N*-Nitrosodimethylamine RS, USP *N*-Nitrosodiethylamine RS, USP *N*-Nitrosoethylisopropylamine RS, USP *N*-Nitrosodiisopropylamine RS, USP *N*-Nitrosodibutylamine RS, USP *N*-Nitrosomethylphenylamine RS, and USP *N*-Nitrosomethylaminobutyric Acid RS in *Diluent*

**Standard solution:** 6.0 ng/mL each of USP *N*-Nitrosodimethylamine RS, USP *N*-Nitrosodiethylamine RS, USP *N*-Nitrosoethylisopropylamine RS, USP *N*-Nitrosodiisopropylamine RS, USP *N*-Nitrosodibutylamine RS, USP *N*-Nitrosomethylphenylamine RS, and USP *N*-Nitrosomethylaminobutyric Acid RS in *Diluent*

**Sample solution:** 20 mg/mL of drug substance prepared as follows. Transfer 100 mg of drug substance into a suitable container. Add 5.0 mL of *Diluent* and vortex until fully dispersed or dissolved. Pass the solution through a suitable filter of 0.2-µm pore size. Use the filtrate for analysis.

**Procedure 2: Quantitation of NDMA, NDEA, NDIPA, and NEIPA in selected sartans (valsartan, irbesartan, losartan potassium, olmesartan medoxomil, candesartan cilexetil, and telmisartan) by headspace GC–MS**

**Diluent:** Methanol

**Internal standard stock solution:** 0.4 µg/mL of NDMA-d6 in *Diluent*

**Internal standard solution:** 0.016 µg/mL of NDMA-d6 prepared as follows. Transfer 2.0 mL of *Internal standard stock solution* into a 50-mL volumetric flask, and dilute with *Diluent* to volume.

**Nitrosamine RS stock solution:** 0.4 µg/mL each of USP *N*-Nitrosodimethylamine RS, USP *N*-Nitrosodiethylamine RS, USP *N*-Nitrosoethylisopropylamine RS, and USP *N*-Nitrosodiisopropylamine RS prepared as follows. Transfer an appropriate amount of USP *N*-Nitrosodimethylamine RS, USP *N*-Nitrosodiethylamine RS, USP *N*-Nitrosoethylisopropylamine RS, and USP *N*-Nitrosodiisopropylamine RS into a suitable volumetric flask, and dilute with *Diluent* to the volume.

**Standard stock solution:** 0.016 µg/mL each of USP *N*-Nitrosodimethylamine RS, USP *N*-Nitrosodiethylamine RS, USP *N*-Nitrosoethylisopropylamine RS, and USP *N*-Nitrosodiisopropylamine RS prepared as follows. Transfer 2.0 mL of *Nitrosamine RS stock solution* and 2.0 mL of *Internal standard stock solution* into a 50-mL volumetric flask, and dilute with *Diluent* to volume.

**Standard solution:** Transfer 1 mL of *Standard stock solution* to an appropriate headspace vial containing about 100 mg of imidazole and 1.0 mL of acetonitrile. Apply the stopper, cap, and crimp tightly.

**Sensitivity stock solution:** 0.004 µg/mL each of USP *N*-Nitrosodimethylamine RS, USP *N*-Nitrosodiethylamine RS, USP *N*-Nitrosoethylisopropylamine RS, and USP *N*-Nitrosodiisopropylamine RS in *Diluent* prepared as follows. Transfer 0.5 mL of the *Nitrosamine RS stock solution* and 2.0 mL of *Internal standard stock solution* into a 50-mL volumetric flask and dilute with *Diluent* to volume.

**Sensitivity solution:** Transfer 1 mL of *Sensitivity stock solution* to an appropriate headspace vial containing about 100 mg of imidazole and 1.0 mL of acetonitrile. Apply the stopper, cap, and crimp tightly.

**Sample solution:** Transfer 200 ± 10 mg of drug substance and about 100 mg of imidazole into a headspace vial, and then add 1.0 mL of *Internal standard solution* and 1.0 mL of acetonitrile. Apply the stopper, cap, and crimp tightly.

**Blank:** Transfer about 100 mg of imidazole into a headspace vial, and then add 1.0 mL of *Internal standard solution* and 1.0 mL of acetonitrile. Apply the stopper, cap, and crimp tightly.

**Table 9** *(continued)*

| | |
|---|---|
| **Ch 2 m/z** | 130.00 > 43.10 |
| **CH 2 collision energy** | 18.00 V |

[NOTE—Ch 1 m/z in multiple reaction mode (MRM) is used for quantitation.]

**System suitability**

**Samples:** *Standard solution*, *Sensitivity solution*, and *Blank*

[NOTE—The relative retention times for NDMA, NDMA-d6, NDEA, NEIPA, and NDIPA are 0.80, 0.80, 0.90, 0.96, and 1.00, respectively.]

**Suitability requirements**

**Relative standard deviation:** NMT 20.0% for the ratio of the impurity standard peak response to the internal standard peak response from 6 replicate injections, *Standard solution*

**Signal-to-noise ratio:** NLT 10 for the impurity peak, *Sensitivity solution*

**Interference:** There should be no interfering peak in the *Blank*.

**Analysis**

**Samples:** *Standard solution* and *Sample solution*

Calculate the concentration, in ppm, of each specified nitrosamine impurity in the portion of drug substance taken:

$$\text{Result} = 1/W \times (R_U/R_S) \times C_S$$

$W$ = weight of the drug substance in the *Sample solution* (g)
$R_U$ = peak response ratio of the specified nitrosamine impurity to that of the internal standard from the *Sample solution*
$R_S$ = peak response ratio of the specified nitrosamine impurity to that of the internal standard from the *Standard solution*
$C_S$ = concentration of USP *N*-Nitrosodimethylamine RS, USP *N*-Nitrosodiethylamine RS, USP *N*-Nitrosoethylisopropylamine RS, and USP *N*-Nitrosodiisopropylamine RS in the *Standard stock solution* (µg/mL)

Report the nitrosamine impurity concentration in the drug substance in ppm (µg/g).

**Procedure 3: Quantitation of NDMA, NDEA, NDIPA, NEIPA, NMBA, and NDBA in selected sartans (valsartan, losartan potassium, olmesartan medoxomil, candesartan cilexetil, and telmisartan) by HPLC–MS/MS**

**Diluent:** 1% formic acid in water

**Solution A:** 0.1% formic acid in water

**Solution B:** 0.1% formic acid in methanol

**Mobile phase:** See *Table 10*.

**Table 10**

| Time (min) | Solution A (%) | Solution B (%) |
|---|---|---|
| 0 | 97 | 3 |
| 1.5 | 97 | 3 |
| 4.0 | 50 | 50 |
| 7.0 | 25 | 75 |
| 8.1 | 15 | 85 |
| 9.2 | 5 | 95 |
| 12.0 | 5 | 95 |
| 12.1 | 97 | 3 |

**Internal standard solution:** 10 µg/mL each of NDMA-d6 and NMBA-d3, 1 µg/mL each of NDEA-d10 and NDBA-d18 in water

**Nitrosamine standards stock solution mixture:** Prepare a mixture of 200 ng/mL each of *N*-nitrosodimethylamine, *N*-nitrosoethylisopropylamine, *N*-nitrosodiisopropylamine, *N*-nitrosodibutylamine, and *N*-nitrosomethylaminobutyric acid by mixing appropriate volumes of the respective USP Reference Standards and dilute with water.

[**CAUTION**—Prepare *Nitrosamine standards stock solution mixture* in amber vials and store at –18° to –20°).]

**NDEA standard stock solution:** Prepare a solution of 132 ng/mL of *N*-nitrosodiethylamine by diluting USP *N*-Nitrosodiethylamine RS with water.

**Standard solutions:** Depending on the targeted nitrosamine concentration in the sample, prepare a set of 5 consecutive linearity solutions from *Table 11* from the *Nitrosamine standards stock solution mixture* and *NDEA standard stock solution* by mixing specified volumes of each solution as indicated. [NOTE—*Table 11* represents an example for preparing solutions for constructing the calibration curve. Other dilution schemes may be used for preparing the set of 5 linearity solutions covering the range of interest. L1 is used only for NDEA when applicable. For others, linearity starts with L2.]

| 9 | L9 | 90/59.4 | 1350/891 | 540 | 540 | 108 | 12 | 1200 |

**Sample solution:** Transfer about 80 mg of the drug substance into a 2-mL lidded centrifuge tube. Add 1188 µL of *Diluent* and 12 µL of the *Internal standard solution*. Vortex at 2500 rpm for 20 min (except for losartan potassium, which should be vortexed NMT 5 min). Centrifuge at about 10,000 rpm for 10 min, and filter into a vial using a hydrophilic polytetrafluoroethylene (PTFE) filter of 0.45-µm pore size.

**Chromatographic system**

(See *Chromatography* ⟨621⟩, *System Suitability*.)

**Mode:** LC

**Detector:** MS/MS (triple quadrupole mass spectrometer)

**MS conditions**

**Ionization:** Atmospheric pressure chemical ionization (APCI)

**Scan settings:** See *Table 12*.

**Table 12**

| Nitrosamine Impurity | Acquisition Mode | Polarity | MRM Transitions (m/z) | |
|---|---|---|---|---|
| | | | MRM-1[a] | MRM-2 |
| NDMA | MRM | Positive | +75.0 → +43.0 | +75.0 → +44.1 |
| NDMA-d6 | MRM | Positive | +81.2 → +46.0 | +81.2 → +64.1 |
| NDEA | MRM | Positive | +103.1 → +75.1 | +103.1 → +47.1 |
| NDEA-d10 | MRM | Positive | +113.2 → +34.2 | +113.2 → +49.1 |
| NMBA | MRM | Positive | +147.1 → +44.1 | +147.1 → +117.1 |
| NMBA-d3 | MRM | Positive | +150.1 → +47.1 | +150.1 → +120.2 |
| NDBA | MRM | Positive | +159.2 → +41.1 | +159.2 → +29.1 |
| NDBA-d18 | MRM | Positive | +177.3 → +66.2 | +177.3 → +46.2 |
| NEIPA[b] | MRM | Positive | +117.1 → +75.1 | +117.1 → +47.2 |
| NDIPA[b] | MRM | Positive | +131.2 → +89.1 | +131.1 → +47.1 |

[a] MRM-1 is used for quantitation.
[b] NDEA-d10 is used as internal standard for NEIPA and NDIPA.

**Column:** 3.0-mm × 15-cm; 2.7-µm packing L1

**Temperatures**

**Autosampler:** 18°

**Column:** 60°

**Flow rate:** 0.5 mL/min

Official

https://nhathuocngocanh.com/

**Flow rate to ion source:** 0.5 mL/min
**Injection volume:** 20 µL

**System suitability**
**Samples:** *Standard solutions*
Generate the peak response ratio of the specified impurity to that of the internal standard versus the concentration standard curve for each nitrosamine impurity under test using the corresponding selected *Standard solutions* and perform the linear regression analysis.
[NOTE—The relative retention times for NDMA, NMBA, NDEA, NEIPA, NDIPA, and NDBA are 0.20, 0.31, 0.46, 0.57, 0.66, and 1.00, respectively.]

**Suitability requirements**
**Correlation coefficient:** NLT 0.99
***y*-Intercept:** NMT 25% of the response of the medium concentration solution used in standard curve generation

**Analysis**
**Samples:** *Standard solutions* and *Sample solution*
Calculate the concentration, in ppm, of each specified nitrosamine impurity in the *Sample solution* using the corresponding calibration curve:

$$\text{Result} = [(R_U - y_{int})/a] \times (1/C_U) \times 10^3$$

$R_U$ = peak response ratio of the specified nitrosamine impurity to that of the internal standard from the *Sample solution*
$y_{int}$ = *y*-intercept of the calibration curve for the specified nitrosamine impurity from the *Standard solutions*
$a$ = slope of the calibration curve for the specified nitrosamine impurity from the *Standard solutions* [(µg/mL)$^{-1}$]
$C_U$ = concentration of the drug substance in the *Sample solution* (mg/mL)

Report the nitrosamine impurity concentration in the drug substance in ppm (µg/g).

**Procedure 4: Quantitation of NDMA, NDEA, NDIPA, NEIPA, NMPA, and NDBA in selected sartans (valsartan, losartan potassium, and candesartan cilexetil) by GC–MS/MS (triple-quad)**
**Internal standard solution:** 50 ng/mL of NDMA:C13-d6 in methylene chloride
**Standard solution:** Prepare a mixture of 0.1 µg/mL each of *N*-nitrosodimethylamine, *N*-nitrosodiethylamine, *N*-nitrosoethylisopropylamine, *N*-nitrosodiisopropylamine, *N*-nitrosomethylphenylamine and *N*-nitrosodibutylamine by mixing appropriate volumes of respective USP Reference Standards and diluting with *Internal standard solution*.
**Calibration solutions:** Depending on the targeted nitrosamine concentration in the sample, prepare a set of 5 consecutive solutions from *Table 13* that are used for generating the calibration curve by following the preparation scheme shown in the table. Volumes may be adjusted to prepare larger quantities of the calibration solutions as needed, maintaining final concentrations of the nitrosamines. For each calibration solution, transfer the designated aliquot of *Standard solution* to the designated volumetric flask, and adjust the volume with the *Internal standard solution*.

**Table 13**

| Calibration Solution ID | Standard Solution Aliquot (µL) | Final Volume (mL) | Final Nitrosamine Concentration (µg/mL) | Equivalent Nitrosamine Concentration (µg/g) |
|---|---|---|---|---|
| Cal 1 | 50 | 10 | 0.0005 | 0.005 |
| Cal 2 | 100 | 10 | 0.001 | 0.010 |

$a$ = slope from the calibration curve for the specified nitrosamine impurity from the corresponding *Calibration solutions* [$(\mu g/mL)^{-1}$]

Report the nitrosamine impurity concentration in the drug substance in ppm (µg/g).

**8.2. Limit Test Procedures**

While a limit test analytical procedure for nitrosamines content is not currently available, recommended sample preparation procedures are shown in *Table 16*.

**Table 16**

| Solutions | Solution Preparation |
|---|---|
| Internal standard solution | Prepare a suitable *Internal standard solution* that, when added to the *Sample solution*, will have the resultant peak response at the highest appropriate target limit of the nitrosamines of interest in the sample. |
| Sample solution | Prepare a solution of the article to be examined, spiked with the internal standard, and prepared as described in the sample preparation. The amount of substance to be examined is chosen in such a way that the amount, in ppm, of a target *N*-nitrosamine, if present at its limit concentration for that substance, would be equal to the contribution of the respective spiking solution. |
| Spiking solution | A solution of target *N*-nitrosamine(s) of a concentration that, if added to the amount of article used for the preparation of the *Sample solution*, would result in the acceptance limit. |
| Spiked sample solution | Prepare a solution of the article to be examined spiked with a) appropriate *Spiking solution*(s) and b) *Internal standard solution* prepared as described in the *Sample solution*. |

**Analysis**

**Samples:** *Spiked sample solutions* and *Sample solution*

Determine the peak response ratio of the respective target *N*-nitrosamine to the internal standard from the *Sample solution*: $R_{U(i)}$

Determine the peak response ratio of the respective target *N*-nitrosamine to the internal standard from the *Spiked sample solution*: $R_{ST(i)}$

**Acceptance criteria:** $R_{U(i)}/R_{ST(i)}$ is NMT 0.5

## 9. ADDITIONAL SOURCES OF INFORMATION

Several test procedures have been developed for the specific testing of nitrosamines in sartans and/or other official articles based on different scientific principles and are publicly available from many regulatory agencies. The hyperlinks in this section direct the user to the respective regulatory agencies' procedures. These can be used as alternative procedures and must be validated under actual use for the respective performance characteristics recommended in *7. Test Method Performance Characteristics of Nitrosamine Methods*.

## INTRODUCTION

The pharmaceutical industry's interest in peptides as drug candidates—based on their potency, enormous functional diversity, high degree of specificity, and general lack of toxicity—has existed since their general structure was first elucidated more than 100 years ago. The early development of synthetic peptides for therapeutic use was, however, challenged by the high costs of production, their inherently short in-vivo half-lives, the lack of sensitive and discriminating analytical methods for intermediates, and the relatively complex manufacturing methods, which are now referred to as "solution peptide synthesis" or "liquid-phase peptide synthesis" (LPPS).

The introduction of solid-phase peptide synthesis (SPPS) was a key factor in facilitating the expansion of peptide research and made the production of peptides with sequences longer than 20 amino acids feasible. Also, in recent years, new formulations and conjugation strategies have resulted in alternative routes of administration and longer half-lives for peptide therapeutics, which have facilitated patient compliance. As a result, more peptide drugs have been approved and are in clinical development. In spite of these successes—or perhaps because of them—some challenges in peptide manufacturing remain, especially with the increasingly complex molecules entering development.

Because synthetic peptides are not easily classified as small molecules or biological products, they are specifically excluded from many guidance documents. Hence, this chapter provides an overview of the current status and the quality attributes of synthetic therapeutic peptides, with particular emphasis on drug substance impurities and related contributing factors, including 1) manufacturing methods, 2) raw materials, 3) peptide general characteristics and specifications, 4) assay and peptide content, 5) impurities, 6) microbiological contamination, 7) bacterial endotoxins, and 8) specific tests.

Drug product quality attributes and recombinant DNA technologies, which can also be employed for manufacturing peptides for pharmaceutical use, are not included in this chapter.

## PEPTIDE DEFINITION

Peptides are short chains of two or more amino acids covalently linked by amide bonds. They can be derived from rDNA or from a biological source or made by chemical synthesis. In the absence of clear scientific consensus on the criteria that distinguish proteins from peptides, including the exact size at which a chain or chains of amino acids become a protein, the FDA, in its final rule on the *Definition of the Term "Biological Product"* (*Federal Register* 85: 10057; February 21, 2020), distinguishes proteins from peptides based on size (i.e., number of amino acids).

FDA regulations state that a "protein is any alpha amino acid polymer with a specific defined sequence that is greater than 40 amino acids in size. When two or more amino acid chains in an amino acid polymer are associated with each other in a manner that occurs in nature, the size of the amino acid polymer for purposes of this interpretation will be based on the total number of amino acids in those chains, and will not be limited to the number of amino acids in a contiguous sequence" (21 CFR §600.3(h)(6)). FDA considers any polymer composed of 40 or fewer amino acids to be a peptide. Unless a peptide meets the statutory definition of a "biological product" (e.g., a peptide vaccine), it would not be considered a "biological product", and it would be regulated as a drug product under the Federal Food, Drug, and Cosmetic Act (FD&C Act). The concepts and approaches described in this chapter generally are applicable to chemically synthesized peptides.

## MANUFACTURING METHODS

A number of chemistries and methods have been developed for building peptide chains. The strategies selected are largely determined by the size and characteristics of the peptide needed. The classical approach to peptide synthesis, LPPS, is often

@2024 USPC

chosen for manufacturing small peptides; however, SPPS has become the preferred option for manufacturing peptides of larger sizes. A hybrid SPPS/LPPS technique can also be used for manufacturing large peptides and peptide conjugates.

Differences in the LPPS and SPPS processes are particularly important, as they lead to differences in the impurity profiles of the final drug substance. In LPPS, potential impurities may be predicted based on the reaction scheme and usually can be identified and controlled individually for each reaction step. Typically, peptide-related impurities are easier to control in LPPS because they are less similar to the target peptide and their accumulation can be minimized by intermediate purification.

In SPPS processes, the peptide chain is assembled on a solid support, enabling excess reagents and amino acid derivatives to be washed off the resin-bound peptide on a filter screen at each step. Hence, non-peptide process-related impurities usually are not a major concern. However, all peptide-related impurities that are incorporated into the resin-bound peptide accumulate throughout the coupling and deprotection steps, leading to a complex profile of impurities very similar to that of the target peptide.

Regardless of the synthetic strategy, manufacturing highly purified peptides under good manufacturing practices (GMP) is a complex process and requires robust control strategies. Quality should be built into every step of the process, and a quality-by-design (QbD) strategy is often beneficial for a successful outcome.

## RAW MATERIALS

Starting material (SM) selection, impurity characterization, control strategies, supplier qualifications, and regulatory acceptance are integral to the strategy for the development of any synthetic peptide manufacturing process. The term "raw materials" is used to describe the SMs, solvents, and reagents that are used in the production of the peptide drug substance.

A "starting material" is a raw material, intermediate, or an active pharmaceutical ingredient that is used in the production of—and incorporated as a significant structural fragment into—the drug substance, as described in the following International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use guidelines: ICH Q7—*Good Manufacturing Practice Guide for Active Pharmaceutical Ingredients*; ICH Q11—*Development and Manufacture of Drug Substances (Chemical Entities and Biotechnological/Biological Entities)*; and the ICH Implementation Working Group's Q11 *Questions and Answers* document.

Typically, the most relevant quality attributes to be controlled for SMs are identity and purity, including related impurities and stereoisomeric impurities content, due to their impact on the quality of the drug substance. The determination of adequate acceptance criteria for the SM quality attributes is based on development data, validation of the manufacturing process, and the corresponding risk assessment. Historical batch data may also be used to set SM specifications. Guidance is provided for the management of SMs and their suppliers in ICH Q7 Sections 7 and 13; ICH Q10—*Pharmaceutical Quality System*, Section 2.7; ICH Q11; and ICH Q11—*Questions and Answers*. It is recommended that SMs be manufactured under a quality system that assures the consistency of batches and the ability to trace the operations carried out to reach the desired material. SMs coming from different qualified suppliers should comply with the overall control strategy for the drug substance. Thus, the selection of SMs should be based on knowledge of the intended commercial process and should take into account the relationship of the SM to the impurity profile of the drug substance.

The ICH Q11 guideline emphasizes that appropriate controls should be in place for the impurities present in the SMs, and that the impact of the impurities on the drug substance quality should be assessed. ICH Q11 also makes an important distinction between commercially available chemicals and custom synthesized chemicals. ICH Q11 states that while the use of a commercially available chemical as an SM generally does not need to be justified, chemicals produced by custom synthesis are not considered to be commercially available. Thus, their proposed use as an SM should be justified.

In some cases, amino acids, protected amino acid derivatives, or any other compound such as dipeptide derivatives may not have a pre-existing, non-pharmaceutical use to meet the ICH Q11 definition of commercially available chemicals; but provided they are simple enough in structure, they may be acceptable as SMs with the appropriate justification. Per ICH Q11—*Questions and Answers*, Section 5.6, a rationale should be provided explaining why the SM is considered appropriate and why the proposed strategy is suitable for controlling impurities in the drug substance. This usually includes, but is not limited to, justification of the proposed SM specifications, including the acceptance criteria for amino acid impurities and their enantiomers [and diastereomers for isoleucine (Ile) and threonine (Thr)], as well as data to support that the proposed control strategy is adequate for manufacturing a peptide drug substance of acceptable purity. Likewise, fragments proposed as SMs in the synthesis of peptides are considered custom synthesized chemicals. Therefore, manufacturers should consider all of ICH Q11 Section 5.1, *General Principles*, and ICH Q11—*Questions and Answers*, clarifications for the selection and justification of such fragments as SMs.

The origin of the SMs should be known in order to evaluate their potential risk of contamination with adventitious agents, including agents that cause transmissible spongiform encephalopathies (TSE). When possible, use of materials from "non-TSE-relevant animal species" or non-animal origin is preferred. If animal sources are necessary, efforts should be made to minimize the risk of transmission of TSE, including not obtaining materials from specific geographic regions.

The most common impurities found in the SMs used for the synthesis of peptides are listed in *Table 1*.

**Table 1. Potential Impurities in Starting Materials**

| Impurities | Origin |
|---|---|
| Incorrect enantiomers (e.g., D-amino acid instead of L-amino acid or L-amino acid present in D-amino acid) | Poor chiral purity of the SM |
| Dipeptides in fluorenylmethyloxycarbonyl protecting group (Fmoc) amino acid derivative (e.g., Fmoc-Leu-Leu-OH [Leu=leucine] instead of Fmoc-Leu-OH) | Synthetic impurities |
| β-Alanine-containing impurities (e.g., Fmoc-β-Ala-OH [Ala=alanine] and Fmoc-β-Ala-AA-OH [AA=amino acid or amino acid derivative]) | Generated during Fmoc-protection of the amino acid when using 9-fluorenylmethyl *N*-succinimidyl carbonate |
| Free amino acids (not amine protected); partially protected amino acids | Loss of N-terminal α-amino-protecting group or incomplete protection |

**Table 1. Potential Impurities in Starting Materials** *(continued)*

| Impurities | Origin |
|---|---|
| Isomeric contaminants (e.g., residual isoleucine [Ile] in Leu derivatives) | Poor SM purity |
| Residual acetic acid (e.g., ethyl acetate) | From residual solvent used during synthesis of amino acid derivatives |

Solvents, reagents, and resins (with the exception of resins preloaded with the first amino acid or amino acid derivative) are not considered SMs, but the impact of their quality on the final drug substance quality should be evaluated through a formal risk assessment. For solvents and reagents, it is recommended to use the highest quality material available. The use of lower grade raw materials is appropriate if their use has been justified. High quality grade water (i.e., at least purified water) should also be used for the purification of peptides.

## PEPTIDE GENERAL CHARACTERISTICS AND SPECIFICATIONS

The specification for a drug substance needs to reflect the critical quality attributes proposed and justified by the manufacturer. The drug substance specification also needs to be approved by the regulatory authorities, as recommended by ICH Q6A—*Specifications: Test Procedures and Acceptance Criteria for New Drug Substances and New Drug Products: Chemical Substances* and by the International Cooperation on Harmonisation of Technical Requirements for Registration of Veterinary Medicinal Products (VICH) guideline GL-39—*Specifications: Test Procedures and Acceptance Criteria for New Veterinary Drug Substances and New Medicinal Products: Chemical Substances*.

The process of setting a specification ensures that the quality of a drug substance is controlled through general characteristics, identity, assay, impurities determination, and specific tests. For reference, the *USP* general chapters that describe the test methods most frequently used for characterization and quality control of peptide drug substances are listed in *Table 2*.

**Table 2. Summary of Tests for Characterization and Quality Control of the Drug Substance**

| Test | Method | Comments |
|---|---|---|
| **Characteristic** | | |
| Appearance[a] | Visual inspection | — |
| **Identification** | | |
| High-performance liquid chromatography (HPLC) coelution with reference standard[a] | ⟨621⟩[b] | The method used for the identification of the active pharmaceutical ingredient (API) may be the same as the one used for the detection of related substances or for determination of the assay based on comparison with a reference standard |
| Mass spectrometry (MS)[a] | ⟨736⟩[c] | Monoisotopic mass |
| Amino acid analysis (AAA) | ⟨1052⟩[d] and ⟨507⟩[e] | Hydrolysis and derivatization protocols should be specified |
| Tandem mass spectrometry (MS–MS) sequencing | ⟨736⟩[c] | May be complicated for longer sequences |
| Nuclear magnetic resonance (NMR) spectroscopy (i.e., $^{1}H$, $^{13}C$ and $^{15}N$) | ⟨761⟩[f] | Complex interpretation for longer sequences |
| Peptide mapping by chemical or enzymatic cleavage methods | ⟨1055⟩[g] | Used for longer sequences (e.g., >20 amino acids); equivalent to MS–MS |
| Enantiomeric purity | ⟨621⟩[b] and ⟨736⟩[c] | AAA in combination with chiral chromatography and MS detection |
| N-Terminal sequence analysis | Edman degradation | Complicated analysis, especially for sequences that are N-terminally blocked; largely superseded by LC with MS–MS (LC–MS/MS) |
| Infrared spectroscopy | ⟨197⟩[h] and ⟨854⟩[i] | Limited use for peptides |
| Higher order structures | Circular dichroism, NMR, and Fourier-transform infrared spectroscopy (FTIR) | Used for investigation of secondary and tertiary structures in aqueous solutions |
| Bioidentity | ⟨1032⟩[j], ⟨1033⟩,[k] and ⟨1034⟩[l] | No longer a routine test for most peptides; may be required for large peptides or those with complex sequences |
| **Assay** | | |
| Assay by HPLC[a] | ⟨621⟩[b] | Method is based on a comparison with a reference standard and may be the same method used to measure related substances and for identification |
| **Peptide Content** | | |
| Peptide content by AAA | ⟨1052⟩[d] and ⟨507⟩[e] | Hydrolysis protocols must be validated; only well-recovered amino acids should be included in the calculation of mean peptide content |

**Table 2. Summary of Tests for Characterization and Quality Control of the Drug Substance** *(continued)*

| Test | Method | Comments |
|---|---|---|
| Peptide content by nitrogen analysis | ⟨461⟩[m] | Direct analysis by elemental analysis, or Kjeldahl, or using HPLC with chemiluminescence nitrogen detector (CLND) |
| UV Spectroscopy | ⟨197⟩,[h] ⟨857⟩,[n] and ⟨507⟩[e] | Only useful for drug substances containing amino acids with suitable chromophores |
| Quantitative NMR (qNMR) | ⟨761⟩[f] and ⟨1761⟩[o] | A suitable internal standard is required |
| **Impurities** | | |
| Peptide-related substances[a] | ⟨621⟩[b], LC–MS | Method specific for drug substances; must be validated for both process-related impurities and degradation products; limits for total and individual impurities should be specified, LC–MS is a commonly used method for characterization |
| Residual solvents[a] | ⟨467⟩[p] | If justified, may be limited to solvent used in the final steps of the manufacturing process |
| Elemental impurities[a] | ⟨232⟩,[q] ⟨233⟩,[r] and ⟨1065⟩[s] | Required if metal catalysts are used in the manufacturing process; elemental impurities may be required based on the risk assessment |
| Residual trifluoroacetic acid[a] | ⟨503.1⟩[t] | Required if TFA is used during the manufacturing process |
| Residual fluoride[a] | ⟨1065⟩[s] or ion-selective electrodes | Required if hydrofluoric acid (HF) is used during the manufacturing process (e.g., due to *tert*-butyloxycarbonyl protecting group or *tert*-butoxycarbonyl protecting group [Boc]-chemistry) |
| Other small-molecule impurities | Impurity dependent | Non-peptide impurity limits are recommended to follow ICH Q3A(R2), *Impurities in New Drug Substances*; potentially mutagenic impurities require additional evaluation |
| **Specific Tests** | | |
| Counter-ion content[a] | For acetate, ⟨503⟩[u], for others, ⟨1065⟩[s] | Titration with silver nitrate may be used to determine chloride |
| Water content[a] | ⟨921⟩[v] | ⟨921⟩, *Method I, Method Ic (Coulometric Titration)*[v] preferred |
| Optical rotation | ⟨781⟩[w] | For characterization only |
| Thiol groups | Ellman's test | Only required if the reduced form(s) of a peptide containing disulfide bonds cannot be determined using the HPLC methods for related substances |
| Bioburden[a] | ⟨61⟩[x] and ⟨62⟩[y] | Often required for the drug substances used in the manufacture of parenteral drug products |
| Bacterial endotoxins[a] | ⟨85⟩[z] | Required for the drug substances used in the manufacture of parenteral drug products |

## Color and Appearance

The color and appearance test by visual inspection is included in the specification of a drug substance because it gives a qualitative description of the color and physical state. The test also ensures a consistent appearance from batch to batch. However, because the processes adopted by different manufacturers can result in subtle variations in the color and appearance, tests by visual inspection are not included in *USP* monographs. In some cases, the description is available in *Reagents and Reference Tables, Reference Tables, Description and Relative Solubility*.

## Identification

Identification tests are specific for a peptide drug substance and, as stated by ICH Q6A, "should optimally be able to discriminate between compounds of closely related structure which are likely to be present". Identity is normally verified by multiple orthogonal techniques, generally including at least one specific test. The most commonly used identification tests for synthetic peptides are reverse-phase high-performance liquid chromatography (RP-HPLC) (see *Chromatography* ⟨621⟩) and mass spectrometry (MS) (see *Mass Spectrometry* ⟨736⟩). Other identification tests such as amino acid analysis (AAA), peptide mapping, or nuclear magnetic resonance (NMR) spectroscopy may be used.

HPLC identification tests rely on the comparison of the retention times of the peptide drug substance's main peak from a reference standard and the test sample, when injected separately, or by coelution of a reference standard and the test sample when co-injected as an equal mixture. Co-injection of an equal mixture of a reference standard and the sample is the recommended best practice. If the HPLC method is capable of distinguishing between the peptide and its closely related impurities, the same method can be used for the identification and impurity measurements.

The monoisotopic mass can be determined by MS, an orthogonal identification test. For peptides larger than 2 kDa, the use of high-resolution instruments may be necessary. In addition, tandem mass spectrometry (MS–MS) can be used for peptide mapping and sequencing to further characterize the synthetic peptide drug substance and to confirm the primary sequence of the peptide. However, peptide mapping and sequencing by MS–MS are normally not part of routine release testing of peptides.

Although AAA was previously a commonly used technique for identification, it has been gradually replaced by techniques such as HPLC and MS. Despite providing the amino acid composition of a peptide, AAA is unable to differentiate aspartic acid (Asp) from asparagine (Asn) and glutamic acid (Glu) from glutamine (Gln) or pyroglutamic acid (Pyr). However, AAA is still a useful tool when discrimination between leucine (Leu) and isoleucine (Ile) is required.

Infrared spectroscopy (IR) is of limited use for identification of a peptide drug substance due to the complexity of peptide molecules, but it is sometimes still used as an orthogonal identification test.

## Bioassays

Bioassays are laboratory tests that mimic the drug substance's mechanism of action towards a therapeutic target. In the past, many of these methods used animal models. Today, depending on the complexity of the biologic response, cell-based, or ligand- or receptor-based binding methods are used instead. During drug discovery and development, bioassays are commonly used to discover new chemical or biologic entities that may be agonists or antagonists of a specific therapeutic target. In later stages, for small molecules and many simple, small peptides, bioassay methods are not used for release once the more precise physicochemical methods are validated and justified. ICH Q6A does not mention bioassay use.

For more complex or long peptides, regulatory authorities may require that a bioassay remain as a release test to measure potency or to confirm that the functional activity of the peptide drug is maintained throughout the manufacturing process. Bioassays may be needed because a very small chemical change may cause a loss of functional activity. A "bioidentity" test, sometimes found in *USP* monographs, is a subset of the bioassay class and is used as an orthogonal identity test and to confirm the functionality of a drug substance or drug product. In the case of peptide monographs that include an HPLC-based assay and a bioidentity test, the number of replicates may be reduced because the acceptance criterion is often a limit (e.g., "activity not less than").

ICH Q6B—*Specifications: Test Procedures and Acceptance Criteria for Biotechnological/Biological Products*, which applies to proteins, allows bioassays to be replaced by physicochemical tests when a well-established manufacturing history exists and when "sufficient physicochemical information about the drug, including higher-order structure, can be thoroughly established by such physicochemical methods, and relevant correlation to biologic activity demonstrated".

Manufacturers are encouraged to contact regulators early in development for control strategy related to bioassays, e.g., the need for a bioassay, its purpose, etc. Additional guidance for development, validation, and analysis of bioassays can be found in *Biological Assay Chapters—Overview and Glossary* ⟨1030⟩, *Design and Development of Biological Assays* ⟨1032⟩, *Biological Assay Validation* ⟨1033⟩, and *Analysis of Biological Assays* ⟨1034⟩.

## Assay and Peptide Content

The peptide drug substance assay is normally defined on an anhydrous, counter-ion free basis. Routine assay testing is normally performed by a specific chromatographic method. Assay by HPLC, based on the use of an established, quantitative standard, e.g., a pharmacopeial reference standard or an in-house developed peptide standard, is a relative method that is often the method of choice for peptides. If the HPLC method separates all peptide-related impurities, no correction for impurities is generally required. However, a correction for levels of additional impurities determined from a separate method may be applied. The specific method(s) used and the basis for the calculation should be defined and justified for each peptide drug substance. It is important to note that significant variability of assay results must be considered when establishing acceptable

https://nhathuocngocanh.com/

ranges. The main causes for assay variability are difficulty of sample preparation due to the hygroscopicity of peptides and batch-to-batch variability of reference standards. Peptide content (sometimes referred to as net peptide content) is the percentage of total peptides (i.e., drug substance plus peptide-related impurities) relative to everything else present in the sample, such as water, counter ions, residual solvents, and salts. Peptide content is usually determined by an absolute method such as quantitative AAA or nitrogen content determination. Peptide content may be helpful in the following cases:

- Drug substance testing, if no quantitative reference standard is available
- Qualification of a quantitative reference standard
- Investigations of an assay out-of-specification result, especially of the reference standard used

Peptides normally contain residual water, a counter ion, peptide-related impurities, and residual solvents. While all of these components can be determined individually, there are tests that will determine combinations of them. While primary or absolute methods do not require a reference standard, relative methods are based on a comparison to a reference standard. The quantitative qualification of a primary reference standard requires absolute methods. There are several absolute methods available to determine the peptide content.

It is important to consider that most absolute methods are non-specific and will only determine the peptide content, not discriminating between the drug substance and peptide-related impurities. If a specific result for the peptide drug substance assay is needed to substitute for an HPLC assay result, the peptide content may be corrected for the total related impurities, which are usually determined by HPLC. Where relevant, other impurities, such as oligomers measured by size-exclusion chromatography (SEC) or peptide impurities measured by ion-exchange chromatography, should also be included in the correction.

The easiest approach to determine the net peptide content is a simple mass balance calculation that consists of deducting the percentage of water, of counter ion, and, if relevant, of total other non-peptide impurities from 100%.

Peptide content can also be determined by elemental nitrogen analysis, Kjeldahl analysis, or chromatographic methods with nitrogen chemiluminescence detection (NCD) (see *Biotechnology-Derived Articles—Total Protein Assay* ⟨1057⟩ and *Nitrogen Determination* ⟨461⟩).

Quantitative AAA (see *Biotechnology-Derived Articles—Amino Acid Analysis* ⟨1052⟩ or *Protein Determination Procedures* ⟨507⟩, *Procedure, Method V. Amino Acid Analysis*) has traditionally been used for the determination of peptide content; however, because the method involves a relatively complex sequence of operations, results may vary. Peptide content by quantitative AAA compares the peak areas of the amino acids in a hydrolyzed sample with the peak areas of the same amino acids in an external standard. The peptide hydrolysis procedure should be validated to ensure good recovery, and only well-recovered amino acids should be used in the calculation of mean peptide content. Some peptide sequences containing multiple, adjacent hydrophobic residues, such as isoleucine (Ile), phenylalanine (Phe), leucine (Leu), and valine (Val), or sterically hindered amino acids, such as valine (Val) and isoleucine (Ile), may give a lower recovery than expected.

Quantitative NMR (qNMR) is also a useful tool for peptide content determination, although it requires a suitable internal standard with signals that fully resolve from the signals associated with the peptide. The versatility of qNMR for quantitative analysis of peptides that do not contain an appropriate UV chromophore makes it well-suited for the determination of peptide concentration in aggregation studies.

UV at 280 nm is used during characterization to determine the content of peptides containing tryptophan (Trp) or tyrosine (Tyr). The molar absorption coefficient required for the measurements at UV 280 nm can be calculated theoretically based on knowledge of the sequence; however, the method should be independently validated using orthogonal techniques. Peptide content by UV absorption may be applied as a fast and simple method for frequent or on-line, in-process determination of peptide concentrations.

## Impurities

A peptide impurity profile may differ significantly depending on the technology used for manufacturing. Hence, it is difficult to generalize the impurities and their control strategies. In addition, because the manufacturing technologies for the production of peptides are diverse and complex compared to small molecules, the impurity guidelines applicable to small molecules usually cannot be applied to peptides.

### CLASSIFICATION

*Impurities in Drug Substances and Drug Products* ⟨1086⟩ classifies impurities into three categories: organic impurities, inorganic impurities, and residual solvents. However, from a practical perspective, impurities can be classified as either peptide related or non-peptide.

**Peptide-related impurities:** Peptide-related impurities, also referred to as "related substances" in this chapter, comprise all impurities that are related to the structure of the target molecule. These are by-products derived from SM impurities, side-reactions during synthesis, or degradations during storage. Thus, peptide-related impurities are either process related or drug related. Stereoisomers are also considered process-related impurities or degradation products. *Table 3* summarizes the categories and types of peptide-related impurities, their origin and/or relevance, and the recommended analytical techniques for their identification. The information provided focuses on the most-common examples and should not be considered exhaustive.

**Non-peptide impurities:** Non-peptide impurities are impurities that are introduced by the manufacturing process and are not related to the structure of the target molecule. These comprise residues of raw materials, reagents, and auxiliary materials such as catalysts and solvents. Such residues also include reaction by-products and contaminants carried over by these materials, as shown in *Table 4*. Peptide drug substances are often defined with counter ions such as acetate or chloride. These counter ions are not considered impurities but concomitant components according to *Ordinary Impurities* ⟨466⟩. Nevertheless, excess bases or acids should be limited.

## IMPURITIES IN SYNTHETIC PEPTIDES

The purity of a peptide is usually determined by HPLC. The method should be capable of separating SM, process-related, and degradation impurities. When using multiple methods, orthogonal separation techniques are recommended. One or more analytical procedures may be required for comprehensive quantitation of all relevant peptide-related impurities. For peptides containing hydrophobic residues, RP-HPLC methods may be appropriate, although alternatives, such as ion-exchange or mixed-mode methods could be considered. For hydrophilic peptides, hydrophilic interaction chromatography stationary phases may achieve the necessary resolution. Anion- and cation-exchange chromatography may be also useful. Liquid chromatography–mass spectroscopy (LC–MS) compatible methods are also advantageous for the identification of impurities. At least one of the methods should be a stability-indicating method.

In order to set acceptance criteria for peptide-related impurities, it is helpful to further classify impurities as specified or unspecified. Specified impurities can be identified or nonidentified. Impurities are classified as identified when their structure has been elucidated. Impurities are classified as qualified when their limits have been justified by toxicological studies, clinical trials, or by a structure-based scientific rationale. If present in the drug substance, qualified identified and unidentified impurities are usually included in the final release specification as specified impurities. Non-qualified impurities should be limited by a general acceptance criterion for “any unspecified impurity”. While ICH Q3A(R2), *Impurities in New Drug Substances*, limits each unspecified impurity to 0.10% or 0.05%, peptides are excluded from this guideline. The higher threshold (0.5% for identification) adopted by the *European Pharmacopoeia* (*Ph. Eur.*) is recognized by authorities of *Ph. Eur.* member states. Other authorities, e.g., the FDA may consider the limits for unspecified impurities for new peptides on a case-by-case basis.

In order to define appropriate targets for process and analytical development, regulators encourage case-specific meetings [e.g., pre-investigational new drug (pre-IND)]. As appropriate, the specification parameters should include each specified identified impurity, each specified unidentified impurity, any unspecified impurity, and the total impurities as the sum of all impurities.

**Peptide-related impurities:** A control strategy for peptide-related impurities, built on process characterization, should be implemented. The control strategy should account for the impurities introduced with the SMs and the impurities generated during the peptide synthesis and purification processes. Appropriately validated in-process control analytical procedures may be used to ensure the quality of the final drug substance, especially when an impurity cannot sufficiently be controlled by the release method.

The purity of a very complex peptide (i.e., very large or conjugated peptides) may be difficult to monitor due to broad signals and poor resolution in HPLC. The control strategy should then comprise the control of related substances for appropriate key intermediates, e.g., the peptide prior to conjugation. To determine possible peptide polymerization, a test for the presence of multimers is needed. A specific methodology such as SEC can be used to quantitate multimers.

HPLC with UV detection is often chosen for the determination of impurities. Because of the frequent similarities between the peptide-related impurities and the drug substance, and because of their potential coelution, smaller particle sizes allow for superior resolution of related compounds on C18, C8, and biphenyl columns. Incomplete separation may be observed with conjugated peptides or as the peptide chain length increases. UV detection is not specific for peptide-related impurities and cannot unequivocally identify these impurities by retention time and UV absorbance, or quantify impurities that coelute. Understanding the impurity profile is important to ensure drug quality and safety, such as any adverse events associated with immunogenicity. Hence, more sensitive and specific LC-HRMS method is recommended for characterizing peptide-related impurities.

**Table 3. Peptide-Related Impurities: Origin and Commonly Used Analytical Techniques**

| Type | Description | Origin | Analytical Techniques |
|---|---|---|---|
| Deletion (clipped forms, fragments, truncations) | Loss of one or more amino acids | Synthesis (incomplete coupling or deprotection) or storage (hydrolysis of N- or C-terminal amino acids or fragments) | LC–MS or LC–MS/MS |
| Insertion | Presence of one or more additional amino acids | Raw materials (SMs containing the respective protected dipeptide) or synthesis (loss of the N-protecting group during coupling, presence of unprotected amino acids in the starting material) | LC–MS or LC–MS/MS |
| Substitution | Presence of one or more different amino acids | SM contaminants or insufficient washes during peptide-resin synthesis | HPLC/UHPLC spiking with synthesized analogs or isolation/AAA/LC–MS or LC–MS/MS |
| Truncation | Sequences containing N-terminal deletions | Raw materials (materials containing residual acetic acid), synthesis (steric hindrance, deliberate acetylation of incomplete coupling reactions), or storage | LC–MS or LC–MS/MS |
| Stereoisomers (diastereomers) | Sequences containing epimerized amino acids | SMs, synthesis, or degradation | HPLC/UHPLC spiking with synthesized diastereomeric analogs or chiral analysis |

**Table 3. Peptide-Related Impurities: Origin and Commonly Used Analytical Techniques** *(continued)*

| Type | Description | Origin | Analytical Techniques |
|---|---|---|---|
| Asp/Asn-related impurities | Aspartimide/succinimide-containing sequences | Cyclization to the backbone via loss of water or ammonia, respectively, from the sidechain of Asp or Asn | HPLC, LC–MS, LC–MS/MS |
| | β-Asp-containing sequences | Hydrolytic ring-opening of the aspartimide/succinimide intermediate during processing or storage | HPLC/UHPLC spiking with synthesized analogs or isolation |
| | Asp stereoisomers (diastereomers) | Epimerization of the aspartimide/succinimide intermediate followed by ring-opening during processing or storage | HPLC/UHPLC spiking with synthesized analogs or isolation |
| | Chain cleavage products | Total hydrolysis of the aspartimide/succinimide intermediate during processing or storage | HPLC/UHPLC spiking with synthesized analogs or isolation |
| β-Alanine insertion | Sequences containing β-alanine | SM contaminants | LC–MS or LC–MS/MS |
| Pyroglutamic acid | Sequence containing N-terminal glutamine or glutamic acid | Synthesis | HPLC or LC–MS |
| Oligomers | Polymers or aggregates | Conformational changes or peptide polymerization | SEC or SEC–multi-angle light scattering (SEC–MALS), sedimentation velocity analytical ultracentrifugation (SV–AUC), dynamic light scattering (DLS), field-flow fractionation (FFF), or ion mobility spectrometry (IMS) |
| Disulfide reduction | Sequences containing disulfides | Synthesis or storage | LC–MS or LC–MS/MS |
| Others | Deamidation of glutamine, asparagine, or C-terminus | Synthesis or storage | LC–MS or LC–MS/MS |
| | Acetylation of amino functional group | Synthesis or storage | LC–MS or LC–MS/MS |
| | Oxidation of certain residues, e.g., aromatic or sulfur-containing side-chains | Synthesis, storage, or analytical sample preparation | LC–MS or LC–MS/MS |
| | Alkylation, acylation of amino acids | Deprotection (cleavage) | LC–MS or LC–MS/MS |

*Stereoisomers:* Non-routine determination of stereoisomeric purity is possible using chiral AAA. The method is based on acid hydrolysis of the peptide, suitable derivatization of the resulting amino acids, and determination of the optical isomers of the constituent amino acids, e.g., by chiral gas chromatography with mass spectrometry (GC–MS) detection. HPLC-based methods of chiral AAA involve pre- or post-column derivatization of amino acid hydrolysates, e.g., using Marfey's reagent or *o*-phthalaldehyde (OPA), respectively. The method should be validated to account for potential epimerization during hydrolysis or subsequent derivatization. The use of deuterated reagents, e.g., deuterium chloride (DCl) and deuterium oxide ($D_2O$), results in substitution of the α-carbon hydrogen with deuterium during the epimerization process, permitting correction for the epimerization during hydrolysis and derivatization when using MS-based detection methods. It is recommended that stereoisomeric purity data are established for at least three representative batches to demonstrate that the manufacturing process does not lead to unacceptable levels of diastereomers. If there are indications of significant epimerization, the respective diastereomers should be identified and routinely controlled.

**Non-peptide impurities:** Reagents used in the manufacturing process should be included in the drug substance specification if there is a risk of residues of such reagents in the drug substance. One example is trifluoroacetic acid (TFA) used in the cleavage and deprotection steps when fluorenylmethyloxycarbonyl protecting group (Fmoc) chemistry is utilized. The drug substance specification should include tests for the determination of residual solvents "likely to be present" in accordance with ICH Q3C(R7)—*Impurities: Guideline for Residual Solvents*; acceptance criteria are to be set in accordance with the same guideline.

Other examples of potential process residues include elemental impurities. As described in ICH Q3D(R1)—*Guideline for Elemental Impurities*, *Elemental Impurities—Limits* ⟨232⟩, and *Elemental Impurities—Procedures* ⟨233⟩, elemental impurities may arise from several sources: they may be residual catalysts that were added intentionally during synthesis, they may be present as impurities (e.g., through interactions with processing equipment or container–closure systems), or they may be derived from the raw materials.

The acceptance criteria for residual elemental impurities are established based on permitted daily exposure (PDE) for each element of toxicological concern. Guidance for elemental impurity limits is provided in ICH Q3D(R1). If the risk assessment fails to demonstrate that an elemental impurity level is consistently below the control threshold, additional control should be implemented to ensure that the elemental impurity level in the drug product does not exceed the PDE. In some cases, lower levels of elemental impurities may be warranted when levels below toxicity thresholds have been shown to have an impact on other quality attributes of the drug product (e.g., element-catalyzed degradation of drug substances).

For many process-related impurities, it is possible to rely on the manufacturing process to remove them. HPLC purification methods may also be able to remove residual process materials. For analysis of residual solvents, elemental impurities, and residual anions and cations, methods such as GC, inductively coupled plasma mass spectrometry (ICP–MS), and ion chromatography (IC) should be used, respectively. NMR is particularly useful during process characterization because diffusion experiments allow for rapid differentiation between small-molecule organic impurities and peptide-bound modifications.

[i] *Microbiological Examination of Nonsterile Products: Acceptance Criteria for Pharmaceutical Preparations and Substances for Pharmaceutical Use* ⟨1111⟩.
[j] *Bacterial Endotoxins Test* ⟨85⟩.

## Microbiological Contamination

In contrast to biotechnological processes, the manufacturing of peptides by chemical synthesis normally involves organic solvents and conditions that do not support microbiological growth. Unless pure aqueous solutions or buffers at neutral pH are involved, microbiological growth can easily be prevented. Bioburden should be controlled according to *Microbial Enumeration Tests* ⟨61⟩ and *Tests for Specified Microorganisms* ⟨62⟩. Appropriate acceptance criteria are recommended in *Microbiological Examination of Nonsterile Products: Acceptance Criteria for Pharmaceutical Preparations and Substances for Pharmaceutical Use* ⟨1111⟩.

## Bacterial Endotoxins

In most cases, when used in injection products, peptides should be controlled for bacterial endotoxins according to *Bacterial Endotoxins Test* ⟨85⟩. The final endotoxin content of a synthetic peptide is mainly dependent on the endotoxin content of materials introduced in late manufacturing stages, as synthesis conditions will normally not favor microbiological growth. Consequently, the endotoxin contribution of these materials needs to be controlled.

## Specific Tests

### WATER

Water is often a constituent of the peptide drug substance when it is isolated from aqueous solutions by, for example, lyophilization. As peptides are typically hygroscopic, the water content can significantly affect the peptide content and stability of the drug substance and should therefore be controlled. The acceptance criterion for water content is specific to each drug substance and is usually set based on batch history. This specification parameter may contribute to the peptide stability. It is usually included in the stability study of the peptide drug substance because it is required for the calculation of the assay by HPLC. As per ICH Q6A, the acceptance criterion may be justified with data on the effects of hydration or moisture absorption.

Typically, *Water Determination* ⟨921⟩ is used to monitor the water content. The more specific Karl Fischer titration in ⟨921⟩, *Method I, Method Ic* is preferred. If volatile components in addition to water are also expected, then *Loss on Drying* ⟨731⟩ is a suitable alternative. In addition, if residual solvents are expected, they should be quantitated independently (see *Residual Solvents* ⟨467⟩).

### COUNTER ION

Most peptide drug substances contain a counter ion, commonly acetate or chloride. The counter ion acceptance criterion is specific to each drug substance and is usually set based on batch data history. Counter-ion determination usually is not included in stability studies of peptide drug substances. A common method for acetate determination is described in *Acetic Acid in Peptides* ⟨503⟩. Alternatively, *Ion Chromatography* ⟨1065⟩ provides additional information on common techniques used for this purpose.▲ (USP 1-Aug-2021)

# ▲⟨1504⟩ QUALITY ATTRIBUTES OF STARTING MATERIALS FOR THE CHEMICAL SYNTHESIS OF THERAPEUTIC PEPTIDES

## SCOPE

This general chapter is intended to provide recommendations on the minimum quality attributes for starting materials used in the manufacture of synthetic therapeutic peptides. Because it is not possible to cover the wide variety of available starting materials that may be used, including amino acids, protected amino acid derivatives, and peptide fragments, the discussion in this chapter will be limited to the most commonly used protected amino acid derivatives (AAD), i.e., 9-fluorenylmethyloxycarbonyl (Fmoc) amino acid derivatives (including resin-bound AAD). However, it is intended that the general concepts and guidance provided for this class of starting materials should be applied to all peptide starting materials, where applicable. This chapter is to be used in conjunction with *Quality Attributes of Synthetic Peptide Drug Substances* ⟨1503⟩.

## INTRODUCTION

The increased interest in peptides as drug candidates during the past few decades can be attributed to a number of factors, including advances in proteomics and high-throughput screening techniques, which have accelerated the development of new potential therapeutic candidates. Furthermore, the development of efficient synthetic chemical strategies, combined with robust purification processes and more powerful and discriminating analytical methodologies, have facilitated the manufacture of peptides with high-quality standards. The evolution of these synthetic strategies started with the manufacture of relatively short peptides but today, the manufacture of longer peptides, which traditionally have been manufactured by biological processes, is feasible using synthetic chemical techniques.

Because synthetic peptides are not classified as small molecules or biological products [final rule on the *Definition of the Term "Biological Product"* (85 FR 10057, February 21, 2020)], they are excluded from many guidance documents. ⟨1503⟩ provides an overview of the current status regarding the quality attributes of synthetic peptides used as drug substances.

In the manufacture of any active pharmaceutical ingredient (API; this term is used interchangeably with "drug substance"), the term "raw material" is used independently for describing starting materials (SMs), solvents, and reagents. From a quality point of view, the "most critical" raw materials are those that are incorporated as significant structural fragments into the structure of the API. From a regulatory perspective, these critical raw materials are known as SMs because their introduction into the manufacturing process establishes the point at which the production of the API begins.

Special attention must be paid to the quality attributes of these SMs because they have the potential to directly impact the quality of the drug substance. For the manufacture of peptides by chemical synthesis, the starting materials are amino acids, protected amino acid derivatives, and fragments. Hence, this chapter will focus on the quality criteria for the starting materials used in the manufacturing process with a particular emphasis on impurities.

## SUPPLIER QUALIFICATION AND EVALUATION OF SYNTHETIC ROUTE

The scope of good manufacturing practices for APIs as described in the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) guidelines ICH Q7—*Good Manufacturing Practice Guide for Active Pharmaceutical Ingredients* and ICH Q11—*Development and Manufacture of Drug Substances (Chemical Entities and Biotechnological/Biological Entities) Questions and Answers (Regarding the Selection and Justification of Starting Materials) Section 5.13* excludes the steps prior to the introduction of the "API starting material" into the manufacturing process. This lack of specific guidance for the manufacture of starting materials does not exclude the responsibility of peptide manufacturers to establish a qualification program for their suppliers and the starting materials they manufacture that is aligned with their process design and their process risk assessment.

It is recommended that the suppliers of starting materials manufacture their products under a quality system that ensures the consistency of batches manufactured and the traceability of the operations carried out to reach the product. The level of the requirements of this quality system should be higher in the case of fragments used as starting materials than for amino acids or protected amino acid derivatives. For more discussion of this topic, refer to ⟨1503⟩.

The implementation of technical agreements or quality agreements for the suppliers of starting materials is strongly recommended. These agreements must consider the obligation for the supplier to inform the customer about changes in the synthetic route used for the protected amino acid derivatives. Peptide manufacturers must assess the impact of these changes on the quality of their final drug substances. Starting material manufacturers are required to provide sufficient information to support regulatory submissions. Publicly available, published synthetic routes for the manufacture of starting materials can be used as supportive information. Implementation of confidentiality agreements between peptide manufacturers and their suppliers of critical raw materials will be helpful in performing such impact assessments.

Manufacturers of drug substances must assess any changes of starting material supplier or significant changes in the starting material manufacturing process for their impact on the quality attributes of the drug substance. The level of requirements for this assessment must take into consideration whether the starting material is an amino acid, a protected AAD, or a fragment. The existence of a supplier qualification program and a common control strategy at the reception of the starting material (common quality requirements aligned with the assessment of their impact on the quality of the final product) should be adequate. For fragments, as they may be customized, a change of manufacturer should be appropriately justified.

@2024 USPC

The synthetic route for the amino acid derivative used for the manufacture of synthetic peptides potentially could result in different impurities. Impurities can be classified into three main categories:

1. AAD-related impurities originating from the amino acids
2. AAD-related impurities originating from the AAD manufacturing process
3. Non-AAD-related impurities

The first two categories are considered to be critical because they can increase the level of related impurities in the drug substance. The third category refers to process impurities (for example, solvents, elemental impurities, and nitrosamines) that do not generally interfere with the manufacture of peptides especially for solid-phase synthesis; however, their levels must be assessed to determine whether their presence poses a risk to the safety of the product and the health of the patients.

## AAD-RELATED IMPURITIES ORIGINATING FROM AMINO ACIDS

One potential cause for critical impurities in the protected amino acid derivatives is related to contaminants of the unprotected amino acids used to manufacture those AADs. Amino acid-related impurities, such as stereoisomers and foreign amino acids, especially, may become critical AAD-related impurities after the introduction of the protecting groups. This will be discussed in this section.

For the sake of simplicity within this chapter, the term “amino acid” shall be limited in its meaning to the 20 proteinogenic (“natural”) α-amino acids and their stereoisomers.

### Amino Acid Enantiomers

Of the 20 proteinogenic α-amino acids, 19 have an asymmetrical center at their α-carbon. The only achiral exception is glycine. The chiral proteinogenic amino acids have the L-configuration in the Fisher projection that is equivalent to the *S*-configuration in International Union of Pure and Applied Chemistry (IUPAC) nomenclature according to Cahn–Ingold–Prelog sequence rules.

Most chiral amino acid isomers exist in two forms that are enantiomers to each other, namely the *S*- and *R*-enantiomers (or L- and D-, respectively). Exceptions are isoleucine and threonine as discussed below.

Due to their abundance in nature, the *S*-amino acids are the ones that are most frequently required for peptide synthesis. They are commercially available in excellent optical purity (<0.1%–0.5% D-content) as *R*-amino acids as their most likely isomeric contaminants are rare in natural sources. For the same reason, *R*-amino acids are much more difficult to obtain in high optical purity when needed for peptide synthesis.

### Amino Acid Diastereomers

Isoleucine and threonine have two asymmetrical centers: one at the α-carbon and one at the β-carbon. Hence, four isomeric configurations exist and lead to the two enantiomeric pairs *SS*/*RR* and *SR*/*RS*, respectively. These two pairs of enantiomers are diastereomers of each other. Proteinogenic isoleucine and threonine have the *SS*-configuration; whereas their enantiomers have the *RR*-configuration. The *SR*/*RS*-diastereomers of isoleucine and threonine are called *allo*-isoleucine and *allo*-threonine, respectively. The diastereomers are also the most likely isomeric impurities of isoleucine and threonine due to inversion at the α-carbon.

### Foreign Amino Acids

Amino acids are normally manufactured from natural protein sources and must be separated from all other amino acids present. Hence, amino acids may be contaminated with residual foreign amino acids that could carry over into the AAD and finally be incorporated into the target peptide. Therefore, foreign amino acids are critical impurities of amino acids and must be controlled and limited if relevant. In particular, contamination with isomeric impurities such as isoleucine in leucine is especially challenging.

### Control of the Critical Impurities

The critical amino acid-related impurities may be controlled either directly in the amino acids or in the subsequently manufactured AAD. In most cases, separating foreign or isomeric amino acids is easier at the unprotected stage than at the protected stage as AAD properties are mainly determined by the bulky protecting groups, i.e., the Fmoc group in Fmoc chemistry. Therefore, it is recommended that AAD manufacturers should control these critical impurities directly in the amino acids used for manufacturing the AADs. Peptide manufacturers who purchase the AADs should ensure appropriate quality by:

1. Verifying that their AAD manufacturers appropriately control the critical impurities in their starting amino acids
2. Including the resulting critical impurity derivatives into their AAD specification and incoming material testing

The stereoisomers of both amino acids and their protected derivatives can be quantitated by chiral chromatographic methods. Chiral gas chromatography (GC) analysis with pre-column derivatization and flame ionization detector (FID) detection is recommended for unprotected amino acids, whereas HPLC on chiral reverse-phase (RP)-columns is the recommended technique for Fmoc amino acid derivatives.

Chiral GC analysis is also frequently used for AADs. In this case, the protecting groups must first be removed by hydrolysis. Because the hydrolysis may lead to epimerization, it must be performed in deuterated solvents (deuterium chloride/deuterium oxide), in which case molecules that epimerize during hydrolysis will have the α-hydrogen replaced by deuterium. By using the chiral GC method with mass detection, the isomers that epimerized during hydrolysis will be disregarded. However, the accuracy

of this method is generally limited to a standard deviation (SD) of 0.1%. For the determination of very low isomer levels, chiral RP-HPLC is the more accurate technique.

Foreign amino acids may also be determined together with the stereoisomers by the methods described above. Of course, the usual methods for amino acid analysis may also be applied to screen for foreign amino acids.

## AAD-RELATED IMPURITIES ORIGINATING FROM THE AAD MANUFACTURING PROCESS

Several types of impurities related to the AAD production process may be found in protected amino acids used for peptide synthesis. They can be divided into several groups based on their origin and potential impact on the quality of the peptide drug substance.

### Partially Protected and Unprotected Amino Acids

The first group is the unprotected and partially protected amino acids. These impurities can be formed during the AAD production process or by degradation on storage or transportation. In general, the incomplete protection of functional groups causes a significant change in polarity compared to the fully protected AAD. Therefore, partially protected AADs can normally be removed easily from the target AAD but, nevertheless, these impurities should be controlled through the specification. Partially protected AADs can be divided into three subgroups.

#### PARTIAL LOSS OF THE SIDE CHAIN PROTECTING GROUP

In peptide synthesis, fully protected amino acids are used to avoid formation of impurities due to various possible side reactions of the unprotected functional groups. However, the presence of a small amount of side chain unprotected amino acid derivatives will not usually result in significant impact on the purity of the peptide (depending on the amino acid, the target peptide, and the synthesis conditions). Therefore, the acceptance criteria for such impurities should be set based on careful evaluation of the particular production process during development. Because amino acid derivatives are frequently protected by an Fmoc group at the N-terminus, these impurities can be easily controlled by regular HPLC methods and identified by liquid chromatography-mass spectrometry (LC-MS).

#### PARTIAL LOSS OF THE FMOC GROUP

These impurities can have a critical impact on the quality of the drug substance since their presence will lead to formation of double insertion impurities due to double coupling of the amino acid. Moreover, depending on the coupling conditions, the free amino groups may cause further Fmoc cleavages in the coupling mixture thus increasing the impurity concentration autocatalytically. If the amino acid also contains suitable side chain protection, they can be controlled by RP-HPLC method and identified by LC-MS.

#### UNPROTECTED AMINO ACIDS

Similar to the previous type of impurities without the Fmoc group, these impurities are also critical for the quality of the drug substance, since they can lead to double insertion due to double coupling and also side chain derivatization. Most of the amino acids are very polar and don't have a chromophore to enable sensitive detection by UV; consequently, they elute at the beginning of the run on an RP-HPLC column and are difficult to detect. Therefore, in most cases regular HPLC methods are not adequate for their determination and the development of specific methods is required, usually based on pre-column derivatization. Thin-layer chromatographic (TLC) methods may also be appropriate for this purpose if a limit test is sufficient. In general, free amino acids should not be present in AADs since they can be removed readily from the respective Fmoc derivative.

### β-Alanine (Ala) Impurities

The second group of impurities originating from the manufacturing process are derived from the side reaction that takes place during the introduction of the Fmoc-protecting group. If this is accomplished using Fmoc-succinimide (Fmoc-OSu) as the reagent, Fmoc-β-alanine (Ala) and Fmoc-β-Ala-amino acid (AA) impurities may be formed. Because these impurities can be formed in all Fmoc-protected amino acid derivatives, without strict control of the starting material, many potential impurities derived from the addition of β-alanine can be formed at different positions during the synthesis of the peptide sequence. Some of these impurities are very difficult to separate from the target peptide. Control of the presence of these impurities in the AAD and limiting them to acceptable levels is critical for the reduction of β-alanine contamination to acceptable levels during the production of peptide drug substances using Fmoc chemistry. Levels of Fmoc-β-Ala and Fmoc-β-Ala-AA can be controlled by RP-HPLC techniques through use of the appropriate Reference Standard with parallel identification by LC-MS methods, if required.

### Other Process-Related Impurities

Additional impurities may be found in the AAD, which are related to the manufacturing process. Such impurities can be dipeptides (for example, Fmoc-glycine-glycine) or derivatives of the AAD formed due to side reaction during the process, especially if Fmoc-chloride is used to introduce the Fmoc protection group. In most cases, such impurities can be controlled by

HPLC methods and identified by LC-MS. The acceptable limit of each impurity should be defined based on its ability to form potential impurities in the drug substance and the relative ease of removal of the impurities during purification.

## NON-AAD IMPURITIES

Control of non-AAD impurities in starting materials is very important to assure the safety, quality, and efficacy of the resulting peptide drug substances. The major potential non-AAD related impurities in the starting materials are:

- Residual solvents and reagents used in the preparation of starting materials
- Elemental impurities
- Residual allergens and melamine
- Bovine spongiform encephalopathy-transmissible spongiform encephalopathy (BSE-TSE) prions
- Nitrosamines and other genotoxic impurities

### Residual Solvents and Reagents Used in the Preparation of Starting Materials

The most commonly used solvents in amino acid and Fmoc amino acid manufacturing processes are Class 2 and Class 3 solvents such as acetonitrile, acetic acid, triethylamine, dioxane, dichloromethane, chloroform, tetrahydrofuran, methanol, etc. The quality of these solvents must be controlled to eliminate the presence of any Class 1 solvent contaminants. For this reason, the manufacturers of all solvents should limit the content of benzene unless they can certify that solvents are benzene-free.

Fmoc amino acids may contain traces of acetic acid, ethylacetate (a potential source of acetic acid), or other potentially reactive solvents such as aldehydes, which can cause chain termination during synthesis. For this reason, it is recommended that very low limits for acetic acid content, as well as the content of other potentially reactive solvents, should be established for all Fmoc amino acids.

### Elemental Impurities in Starting Materials

Elemental impurities are important quality attributes for the safety of peptide drug substances. Whereas the processes used for solid-phase synthesis of peptides are likely to eliminate elemental impurities in starting materials, it is important to consider these impurities as part of the risk assessment during development in order to ensure that the drug substance complies with the limits specified in ICH Q3D, *Elemental Impurities* and *USP* chapters *Elemental Impurities—Limits* ⟨232⟩ and *Elemental Impurities—Procedures* ⟨233⟩.

### Residual Allergens and Melamine

Sources of amino acids in starting materials are either synthetic or of plant origin and may be derived from potential allergens such as soybeans, wheat, rye, oat, barley, corn, maize, spelt, kamut, sugar, and alcohol. Because amino acids that are produced from proteins undergo harsh hydrolysis conditions and are further purified, it is extremely unlikely that allergens would pass through the hydrolysis and purification steps. Allergen- and melamine-free statements should be obtained from the starting material vendor and may also be ensured by the quality supply agreement.

### BSE/TSE-Free Starting Materials

Only synthetic or plant-derived starting materials should be used in peptide synthesis. Amino acids that originate from or come into contact with animal materials (waste from slaughterhouses, bones, cartilage, gelatin, etc.) should be avoided. The origin of the amino acids should be known and manufacturers of starting materials should provide adequate certification of TSE compliance. Preferably, human- and animal-derived amino acids should be avoided. If use of amino acids of animal origin cannot be avoided, the respective material should meet the requirements of the *European Pharmacopoeia* general chapter *5.2.8. Minimising the Risk of Transmitting Animal Spongiform Encephalopathy Agents Via Human and Veterinary Medicinal Products*. The requirement for BSE/TSE-free statements should be part of the quality supply agreement.

### Nitrosamines and Other Genotoxic Impurities

Chemically synthesized peptide manufacturers are required to assess the risk for the presence of *N*-nitrosamines impurities in their products. Nitrosamines are chemical compounds with potential carcinogenic risk. It is commonly accepted that the formation of *N*-nitrosamine impurities can occur due to the presence of a nitrosating agent together with a secondary or tertiary amine (named as the nitrosatable substance) usually under acidic reaction conditions. Although the most common source of nitrosating agents from a synthetic point of view are nitrite salts, all potential nitrosating agents should be considered (nitrate salts, nitrous acid, nitrous acidum ion, nitryl chloride, nitrosothiol, nitrosyl halides, and alkyl nitrites, among others). Amino acid derivatives used for the manufacturing of chemically synthesized peptides are considered a potential source of *N*-nitrosamines that could be transferred to the drug substance. It is recommended to avoid those manufacturing processes that could lead to the formation of *N*-nitrosamines. The presence of other genotoxic impurities should be carefully considered and evaluated during development, taking into consideration the requirement of ICH M7—*Assessment and Control of DNA Reactive (Mutagenic) Impurities in Pharmaceuticals to Limit Potential Carcinogenic Risk*.

## CONCLUSION AND RECOMMENDATIONS FOR AAD SPECIFICATIONS

Based on the considerations outlined above, the most common quality attributes to be used for protected amino acid derivative starting materials are:

- Appearance
- Identification
- Related impurities
  - Total
  - Specified
  - Foreign amino acids
  - Optical isomers (diastereomers and enantiomers)
  - Unspecified
- Other impurities (not related)
  - E.g., residual reagents, solvents, elements
- Assay (e.g., by titration)
- Other components as necessary

Limits for specified impurities (e.g., unprotected amino acids, other amino acid derivatives, foreign amino acids, and chiral isomers) are set and justified based on prior batch history and an understanding and risk assessment of the API manufacturing process. The correlation between the content of a specified impurity in the starting material and the content of the related impurity in the API must be considered. For example, will the manufacturing process produce a related impurity in the API and to what extent is the process able to reduce a related impurity that has been formed? For unspecified impurities, batch history and the API specification for unspecified impurities are used as a starting point for the specification in the starting material. Assay by base titration is recommended for verification that the amino acid derivative is supplied as the carboxylic acid form suitable for activation and coupling and that no salts of the amino acid derivative are present. Other impurities (not related) and potential components are included in the specification based on their potential effect on the API manufacturing process and the quality of the final API.▲ (USP 1-Dec-2023)

# ▲⟨1567⟩ PYRROLIZIDINE ALKALOIDS AS CONTAMINANTS

## 1. INTRODUCTION

This informational general chapter is intended to provide an overview of pyrrolizidine alkaloids (PAs), heterocyclic organic compounds that are synthesized by many plant species (*1–2*) and can contaminate or be present in many plant-related products. The most potent PAs exhibit hepatotoxic, genotoxic, carcinogenic, or mutagenic activities. PAs can be found as contaminants in botanical drugs, herbal medicines, botanical dietary ingredients, and botanical dietary supplements, thereby posing a potentially serious threat to human health. PAs are derived from ornithine and are characterized by bicyclic pyrrolizidine moieties that are referred to as "necines" (*3–4*). PAs occur in two forms: pyrrolizidine alkaloids *N*-oxide (PANO) and tertiary bases (*4–5*). More than 660 PAs have been identified in approximately 6000 plant species (*2*) or in 3% of the world's flowering plants (*6–7*). PAs are reported to be present mainly in the Boraginaceae (all genera), Asteraceae or Compositae (specifically in the tribes Senecioneae and Eupatorieae), and Leguminosae or Fabaceae (genus *Crotalaria*) families (*5,8–9*). PAs are mainly concentrated in the seeds and flowering parts of plants and, in lesser amounts, the leaves, stems, and roots (*5*). PAs of concern have been detected in dietary supplements (*6*); teas and herbal infusions (*2*); honey and pollen (*4,10*), predominantly due to the presence of PA-containing plants growing near plants of interest and being accidentally coharvested with plants used in these products. Because of the wide distribution of PAs in many plant species, dietary exposures to potent PAs are a safety concern (*6*). Published literature reports suggest that tea and herbal infusions were the main contributors to total unsaturated PA exposure. Therefore, efforts should be made to obtain information specifically on the sources of PA contamination in tea, such as the adventitious PA-containing plants responsible for the contamination, and to use measures to control infestation and coharvest (*11*).

## 2. PA CHEMISTRY

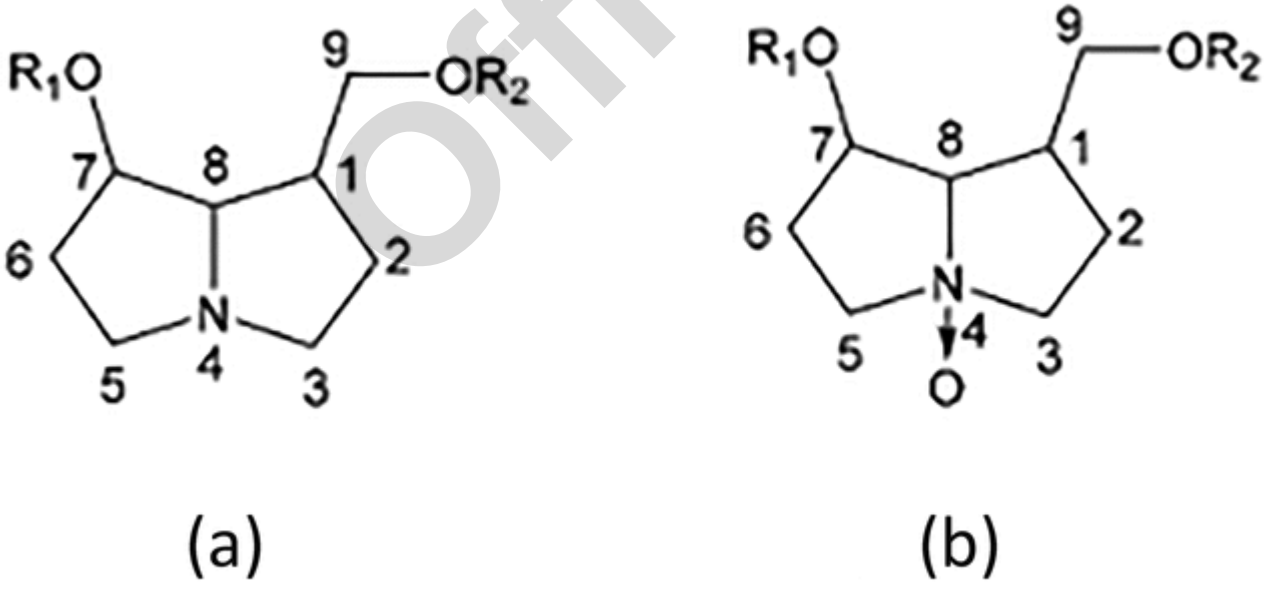

Figure 1. General structure of a) PA molecule and b) PANO molecule. $R_1$ and $R_2$ are hydrogens or necic acids.

PAs are typically found as esters composed of a necine base and one or more necic acids (*Figure 1*).The necine base typically includes pyrrolizidine, a bicyclic aliphatic hydrocarbon comprised of two fused 5-membered rings with a nitrogen atom at position 4. The necine base usually has a hydroxymethyl group at C-1 and a hydroxyl group at C-7 (*12*) (when $R_1$ and $R_2$ are hydrogens in *Figure 1*[a]). Esterification with necic acids occurs at these hydroxyl groups forming monoester (*Figure 2*), open-chain diester (*Figure 3*), or macrocyclic diester alkaloids (*Figure 4*) (*13*). Necic acids are either mono- or dicarboxylic acids with branched carbon chains bearing hydroxy, epoxy, carboxy, acetoxy, methoxy, or other alkoxy groups as substituents (*14*). The high diversity in the structures of PAs is due in part to combinations of various necine bases and necic acids and the formation of monoesters at different positions (*5*). The diversity is further enhanced with their presence in plants as both tertiary bases and as *N*-oxides (PANO) *Figure 1*(b).

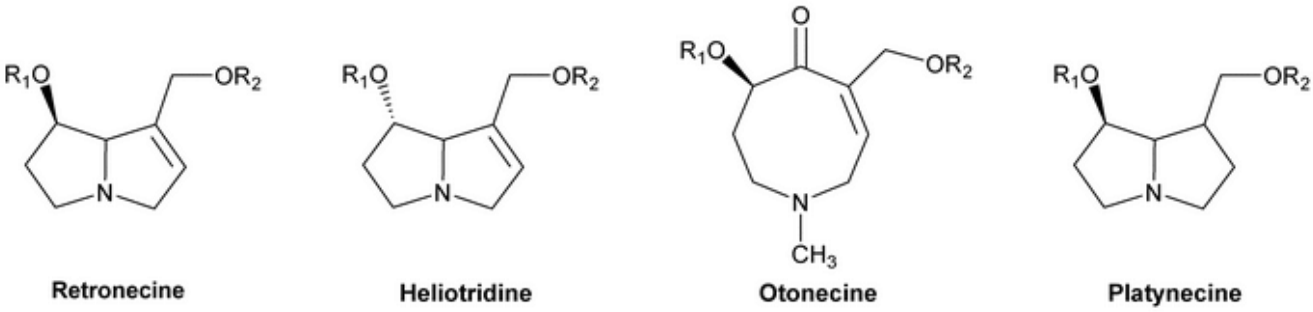

Figure 5. Classification of PAs based on the structure of the necine base.

Official

https://pharmacopeia.cn/v-cn/

Based on the structure of necine base, PAs are further categorized into four groups: retronecine, heliotridine, otonecine, and platynecine types (*Figure 5*) (*15*). Retronecine, heliotridine and otonecine are unsaturated bases, i.e., they contain a double bond in the 1,2-position, whereas platynecine is a saturated base (*16–17*). Structurally, otonecine stands as the most distinct among all types because it is oxidized at C-8 and contains a monocyclic ring, thus deviating from other types that contain a bicyclic ring (*18–19*). Some esters of 1,2-unsaturated necine bases are toxic while esters with platynecine type are considered nontoxic PAs (*14,20*).

### 2.1 Structural Requirements for Toxicity

Not all PAs are toxic to humans at the levels found in herbal products. The toxic potential of a PA varies considerably with chemical structure (*21*). The structural requirements for PAs to exhibit toxicity are outlined below:

- The presence of a 1,2-double bond in the necine base (*22*). Cytochrome P-450 mediated metabolism of 1,2-unsaturated PAs forms reactive pyrroles, which can then form protein and DNA adducts (*17,23*). In contrast, the saturated structure of the platynecine-type PAs forms nonreactive polar compounds that are water soluble and readily excreted.
- The presence of one or two hydroxyl groups in the necine base.
- The esterification of one or two hydroxyl groups in the necine base and branching in at least one of the carboxylic acids (*24*). Due to this, cyclic diesters exert the highest toxicity, followed by open-chain diesters (intermediary), with monoesters having the lowest toxicity (*25*).

For the remainder of this paper, the term "PAs" will refer to more-potent and most-potent pyrrolizidine alkaloid molecules with the chemical characteristics described above, not all PAs.

### 2.2 Stability of PAs

It has been suggested that PAs, particularly their *N*-oxides, are heat sensitive, and thus, heat treatment could be utilized to control PA levels (*26*). Although high concentrations of some 1,2-unsaturated PAs and their *N*-oxides may occur in certain plants, much lower and variable concentrations of these substances are present in finished products due to processing (*26*). Drying plant materials is reported to cause significant decomposition of 1,2-unsaturated PAs, especially their *N*-oxides (*27*).

## 3. DIETARY EXPOSURE TO PAS

Seeds of PA-containing plants can contaminate grains, and prolonged consumption of such grains or grain products have resulted in rare but serious large-scale outbreaks of PA poisoning (pyrrolizidine alkaloidosis). One such example is a serious outbreak in 1974 that occurred in Afghanistan due to the consumption of bread made from wheat contaminated with seeds of *Heliotropium* sp. plants (*28*).

Lately there has been a growing interest in the use of botanical ingredients, leading to concern about the potential for PA poisoning primarily due to contamination from PA-containing plants in widely distributed botanical and herbal products. Recent literature reports have revealed the presence of PAs in herbal teas, predominantly senecionine-type, followed by lycopsamine- and heliotrine-types (*29*). Cross-contamination with plants containing PAs during the harvesting of herbal ingredients is responsible for the occurrence of PAs in ingredients of botanical drugs and botanical dietary supplements such as *Matricaria chamomilla* and *Mentha* × *piperita* L, which are not known to contain PAs (*30–31*).

Apart from exposure to PAs through herbal products, secondary contamination in foods of animal origin such as milk, eggs, honey, and pollen products was also observed.

Honey and supplement products containing bee pollen frequently contain PAs (*5,11*) such as senecionine, echimidine, lycopsamine and their *N*-oxides (*32–33*).

### 3.1 Measures to Avoid PA Contamination

Total eradication of PA-containing plants is not possible. It is necessary to identify potential risks associated with every step involved in the process chain, such as cultivation, harvesting, inspection of incoming goods, and drug processing, until the release of the botanical drug, botanical dietary ingredient, or botanical dietary supplement. For example, the risk of coharvesting PA-containing weeds during the harvest of the cultivated plant material can be controlled by optimization of timing, technology, cutting height, and other such factors associated with harvesting technology. Apart from coharvesting of PA-containing weeds, an alternate path of contamination that involves horizontal transfer and exchange of PA and/or PANO between living plants via the soil was recently discovered (*34*). To avoid PA contamination through this process, alkaloidal weeds have to be extracted completely from the soil and entirely removed from the fields rather than just leaving them to rot (*34*).

## 4. TOXICOLOGY

PAs are absorbed in the gastrointestinal tract and approximately 80% of PAs are excreted in the urine, feces, and breast milk (*4*). Because PAs are highly lipophilic, some are able to cross the placenta (*4*). The toxicity of potent PAs is mainly associated with their metabolic byproducts (*2,4*). PAs require metabolic activation to form highly reactive electrophiles (*4,35*). The liver is the main target organ of toxicity because the metabolic activation of PAs primarily occurs in the liver (*4*). Metabolic activation occurs through the oxidation of PAs, mostly catalyzed by the cytochrome P450 enzymes CYP3A and CYP2B, to form reactive pyrrolic esters. The hydrolysis of pyrrolic esters produces dihydropyrrolizines (DHP) (*4,5*). Liver toxicity results from the electrophilic pyrrolic esters and DHP, which further binds or forms adducts with vital cellular macromolecules such as proteins and DNA (*5,36*). The lungs are also a target organ of PA exposure as a result of reactive metabolites reaching the lungs through

Official

https://pharmacopeia.cn/v-cn/

the systemic circulation (*4–5,37*). Experimental animal studies on potent PAs have reported hepatotoxicity, developmental toxicity, genotoxicity, and carcinogenicity (*37*). Both acute and chronic toxicity of PAs have been described and are characterized by different symptoms (*2,4*) as outlined below.

### 4.1 Acute and Subchronic Toxicity

Acute liver toxicity in humans and animals due to PA exposure is characterized by hepatic veno-occlusive disease (HVOD), which is considered a marker of PA toxicity (*2,5,37–38*). It is estimated that in 20% of acute PA poisoning cases humans die, 50% recover clinically, and 20% may develop chronic HVOD and cirrhosis years later (*39*). Acute PA poisoning symptoms include hemorrhagic necrosis, hepatomegaly, and ascites, while subacute liver effects present as hepatic sinusoidal obstruction syndrome (HSOS) due to blockage of the hepatic veins, (*4*) which is characterized by portal hypertension and liver dysfunction (*40*). Acute PA toxicity may also target the lungs (*5,37,39*) causing damage similar to HVOD, resulting in pulmonary hypertension and congestive heart failure (*4,38–39*). The lowest exposures of PAs associated with acute or short-term toxicity range from 0.8–3 mg/kg per day (*5*). However, based on available human and experimental data, even one-time exposure to unsaturated PAs may lead to liver cirrhosis; the level of exposure was not provided (*41*). Importantly, long-term exposure to much lower levels of PAs (15 µg/kg per day for 6 months) may cause chronic liver diseases including HVOD (*5,35*).

### 4.2 Chronic Toxicity

Animal studies have shown that long-term exposure to some PAs is associated with carcinogenicity, primarily in the liver (*5*), although other organs have also been rarely implicated. The occurrence of PA-associated tumors has also been reported in the lungs, bladder, skin, brain, spinal cord, pancreas, and gastrointestinal tract (*4*). Tumorigenic PAs belong to heliotridine-, retronecine- and otonecine-type structural classes. The DHPs formed by metabolism of these PAs form DNA adducts, which are thought to be the main mechanism responsible for tumorigenesis (*4–5*). Lasiocarpine, monocrotaline, and riddelliine are classified as possibly carcinogenic to humans (Category 2B) based on carcinogenic effects observed in rodent studies. Riddelliine has been shown to form DNA adducts in human liver microsomes similar to the DNA adducts observed in rodents, suggesting that PAs could be genotoxic and carcinogenic in humans (*4*).

## 5. PAS RECOMMENDED FOR MONITORING

Twenty-eight PAs, shown in *Table 1*, are selected for monitoring in botanical drugs, botanical dietary ingredients, and botanical supplements.

**Table 1. List of PAs Selected for Monitoring**

| PA | CAS number | PA | CAS number |
|---|---|---|---|
| Echimidine | 520-68-3 | Lycopsamine | 10285-07-1 |
| Echimidine-*N*-oxide | 41093-89-4 | Lycopsamine-*N*-oxide | 95462-15-0 |
| Erucifoline | 40158-95-0 | Monocrotaline | 315-22-0 |
| Erucifoline-*N*-oxide | 123864-94-8 | Monocrotaline-*N*-oxide | 35337-98-5 |
| Europine | 570-19-4 | Retrorsine | 480-54-6 |
| Europine-*N*-oxide | 65582-53-8 | Retrorsine-*N*-oxide | 15503-86-3 |

| Heliotrine-*N*-oxide | 6209-65-0 | Seneciphylline-*N*-oxide | 38710-26-8 |
| Intermedine | 10285-06-0 | Senecionine | 130-01-8 |
| Intermedine-*N*-oxide | 95462-14-9 | Senecionine-*N*-oxide | 13268-67-2 |
| Jacobine | 6870-67-3 | Senecivernine | 72755-25-0 |
| Jacobine-*N*-oxide | 38710-25-7 | Senecivernine-*N*-oxide | 101687-28-9 |
| Lasiocarpine | 303-34-3 | Senkirkine | 2318-18-5 |
| Lasiocarpine-*N*-oxide | 127-30-0 | Trichodesmine | 548-90-3 |

## 6. REGULATORY AND PROPOSED TOLERABLE DAILY INTAKE LEVELS

The US current good manufacturing practice (cGMP) regulations for dietary supplements (21 CFR §111) require manufacturers to take certain measures to prevent contamination in the manufacturing process. The cGMP regulations do not specifically require testing for PAs, but manufacturers are required to set limits on the types of contamination that may adulterate or may lead to adulteration of the product within the meaning of the Federal Food, Drug and Cosmetic Act (FFDCA). Manufacturers also generally have a responsibility to ensure that their dietary supplement products do not present a significant or unreasonable risk of illness or injury that would cause the FDA to deem the product adulterated under §402(f)(1)(A) of the FFDCA. Additionally, under §402(a)(1) of the FFDCA, certain foods, including dietary supplements, are deemed adulterated if they contain poisonous or deleterious substances. Currently, there are no required FDA limits for PAs. In the absence of required

@2024 USPC

FDA limits, the Division of Risk and Decision Analysis evaluates the safety of contaminants in food on a case-by-case basis using a safety assessment (SA) approach. The SA considers exposure and toxicity of the contaminant in the food product. Exposure is estimated using the contaminant level reported in the food and consumption or recommended intake amounts for specific subpopulations.

Regulations governing levels of PAs in food and food supplements have been established in several countries based on the potential exposure to contaminants from the increased use of herbal medicines leading to PA intoxication as a public health concern (*4,42*). The range of tolerable daily intake levels for PAs provided in *Table 2* may provide some guidance to manufacturers on the highly potent PAs (e.g., cyclic diesters).

**Table 2. Proposed Tolerable Daily Intake Levels for PAs**

| Regulatory Authority | Tolerable Daily Intake | Reference |
|---|---|---|
| German Federal Department of Health *Bundesanzeiger* (1992) | ≤1 µg/day (maximum 6 weeks use per year) ≤0.1 µg/day (for prolonged use) | (*4,42,43*) |
| US FDA (2001) | Ban on PA-containing comfrey supplements; no tolerable intake level established | (*42,45*) |
| Netherlands (2001) | ≤1 µg/kg or ≤1 µg/L PA concentration in final product (herbal preparation or plant extract) | (*4,42,46*) |
| Food Standards Australia New Zealand (FSANZ) (2001) | ≤1 µg/kg/day (provisional) based on veno-occlusive disease (cancer risk considered not proven in humans) | (*41,47*) |
| EFSA (2011) | MOE of 10,000 or higher than BMDL10 of 70 µg/kg/day considered a "low concern from a public health point of view" (based on NTP carcinogenicity data) | (*5*) |
| BfR (2011) | 0.007 µg/kg/day | (*48*) |
| JECFA (2015) | MOE of 10,000 or higher than BMDL10 of 182 µg/kg/day (based on NTP carcinogenicity data) | (*49*) |
| EFSA (2017) | MOE of 10,000 or higher than BMDL10 of 237 µg/kg/day considered a "low concern from a public health point of view" (based on updated BMD modeling approach and NTP carcinogenicity data) | (*37*) |
| European Commission | 400 µg/kg in food supplements and 500 µg/kg in pollen-based food supplements | (*50*) |
| EMA (2020) | Accepted limit of 1.0 µg/day with no temporary restrictions | (*44*) |

## 7. RELATIVE POTENCIES OF PAS

The risk-based decisions for tolerable daily intake levels presented above are based on approaches that assume all PAs are equally potent, i.e., as potent as the highly toxic PAs such as lasiocarpine (*5*) or riddelliine (*49*). There is another risk-based approach based on relative risk factors (RRF) that may be appropriate. The RRF approach may be applicable because large structure-dependent differences have been documented between subgroups of unsaturated PA congeners with respect to their genotoxicity and cytotoxicity (*51*). The concept of relative potency (REP) was developed to address cases where a group of compounds share the same major mode of action, but individual members exhibit extraordinarily different potencies sometimes spanning several orders of magnitude. REP factors represent the potency of the congener relative to the most-toxic congener(s). The latter is assigned an REP factor of 1.0, and then all other congeners have REP factors of ≤1.0. For a given sample (e.g., a mixture of PAs) the sum potency can be derived by multiplying the amount of the specific congeners and their respective REP factors, which are then summed up for all congeners present in the sample. This REP concept has been successfully applied in evaluating the toxicology of polychlorinated dioxins, furans, and PCBs (*52*), and has also been suggested for phototoxic furanocoumarins (*53*). In an attempt to factor in the varied PA potencies in risk assessment, efforts have been made to derive PA potency factors relative to riddelliine. REP factors for PAs can be derived based on an approach that correlated fundamental structural differences between PAs and acute toxicity data from rodents, cytotoxicity data in mammalian cell culture, and genotoxicity data in *Drosophila*. Cyclic PA diesters are markedly more toxic than open-chain diesters followed by monoesters, consistent with experimental data. Generally, PA monoesters and open diesters showed lower toxicity than cyclic diesters. However, some PAs such as lasiocarpine and lasiocarpine *N*-oxide (PA monoesters) had the same REP factors as monocrotaline, riddelliine, and retrorsine (cyclic diesters, most potent) (*54*).

Manufacturers of dietary supplements containing PAs should aim at minimizing the presence of PAs in their products.

## 8. ANALYTICAL METHODS AND CHALLENGES

A wide range of analytical techniques to quantitate PAs and PANOs—such as chromatography, nuclear magnetic resonance (NMR), enzyme-linked immunosorbent assay (ELISA), capillary electrophoresis (CE), droplet countercurrent chromatography (DCCC), and miscellaneous electrokinetic chromatography (MEKC) methods—have been reported in the literature (*55–57*). However, selective and sensitive analytical methods are needed to meet the limits set by different regulatory bodies as the methods cited above should be validated for the different matrices at the analytical range required to establish the level of PA

Official

https://pharmacopeia.cn/v-gb/

Status: Currently Official on 05-Jan-2024
Official Date: Official as of 01-Dec-2023
DOI Ref: gj1gt
DocId: GUID-BC0FFC47-A6DA-4AC3-9B59-59D8A9877017_2_en-US

DOI: https://doi.org/10.31003/USPNF_M16216_02_01
@2024 USPC

contaminants. Chromatographic separation methods, particularly high- or ultra-high performance liquid chromatography (HPLC, UHPLC) and gas chromatography (GC), are preferred to quantitate PAs. Detection methods including ultraviolet (UV), flame ionization (FI), evaporative light scattering (ELS), and refractive index (RI) could not achieve the required limit of detection (LoD) and limit of quantitation (LoQ). Mass spectrometric techniques offer improved detection limits and provide the advantage of mass selectivity via detectors such as quadrupole, triple quadrupole, time of flight (ToF), and orbital ion-trap along with various ionization techniques. It is not feasible to quantitate PANOs using GC without prior derivatization or reduction due to their instability at high temperatures. Further, the extraction and clean-up procedures associated with GC methods are time consuming and require very large volumes of solvent. As a result, high-performance liquid chromatography–tandem mass spectrometry (HPLC–MS/MS) has become the method of choice because of the extraction methods, which are more appropriate for the matrix, and the capability to simultaneously analyze PANOs along with PAs.

The most preferred analytical technique is LC–MS/MS, but this also has limitations. A baseline chromatographic separation is not always achieved for a few PA isomers such as intermedine/lycopsamine or senecionine/senecivernine, as well as their respective *N*-oxides (*37*). Also, because these isomers have the same molecular weight, it is not possible to distinguish them by mass spectrometry. An accurate quantification of individual PAs is not always possible for the above reasons. This necessitates the use of multiple methods for the accurate quantification of isomeric PAs. Furthermore, coelution of indicine could happen with the intermedine/lycopsamine pair (*58*). Similarly, coelution of indicine *N*-oxide has been observed with *N*-oxides of the intermedine/lycopsamine pair.

There is a need for highly sensitive and selective analytical methods to provide the level of quantification required to control contaminant PAs in botanical drugs, botanical dietary ingredients, and botanical dietary supplements. Apart from the above-mentioned challenges associated with analytical methods for the quantitation of PAs, there are challenges related to the reference standards: most of them are not commercially available, are very expensive to procure, are difficult to synthesize or isolate, and are not stable.

## CONCLUSIONS

PAs are naturally occurring heterocyclic phytotoxins that have been reported to be hepatotoxic, mutagenic, and carcinogenic. PAs have been detected in various dietary sources such as grains, herbal teas, honey, milk, and eggs. We included a list of PAs to be monitored in *Table 1*. Manufacturers should evaluate the levels of PAs in their product considering their potential presence arising from the plant itself, from contamination with external PAs (e.g., due to coharvesting, absorbed from soil), and/or from supply chain vulnerabilities that may increase the risk of contamination of ingredients. Manufacturers should use a risk-based approach for determining appropriate limits and testing requirements, which should take into consideration that select PAs are more toxic and their levels should be minimized. The range of tolerable daily intake levels for PAs provided in *Table 2* may provide some guidance to manufacturers for the highly potent PAs (e.g., cyclic diesters). Extraction and analytical quantitation of PAs is associated with several challenges and would benefit from evolving strategies for both efficient extraction and advanced selective analytical quantification techniques. Future developments will hopefully lead to a greater availability of reference standards and method validation as regulatory bodies create requirements for accurate quantitation of PAs.

# ⟨1601⟩ PRODUCTS FOR NEBULIZATION—CHARACTERIZATION TESTS

Products used for nebulization and intended for pulmonary delivery are characterized using the following tests:

- *Drug Substance Delivery Rate and Total Drug Substance Delivered*;
- *Aerodynamic Assessment of Nebulized Aerosols*.

These tests standardize the approach to the assessment of the dose that would be delivered to a patient but are not intended to provide assessment of the nebulizer device itself.[1] The mass rather than the number-weighted size distribution is more appropriate to evaluate product performance. Drug substance mass as a function of aerodynamic diameter is more indicative of therapeutic effect within the respiratory tract.

## DRUG SUBSTANCE DELIVERY RATE AND TOTAL DRUG SUBSTANCE DELIVERED

These tests are performed to assess the rate of delivery to the patient and the total drug substance delivered to a patient using standardized conditions of volumetric flow rate. Breath-enhanced and breath-actuated nebulizers should be evaluated by a breathing simulator because the output of these types of device is highly dependent on inhalation flow rate. The methodology below describes the use of a standard breathing pattern defined for adults. Should a particular product for nebulization be indicated only for pediatric, i.e., neonate, infant, or child use, then pediatric breathing pattern(s) must be used.[2] Breathing patterns are used, rather than continuous flow rates, to provide a more appropriate measure of the mass of drug substance that would be delivered to patients.

Drug substance delivery rate and total drug substance delivered are appropriate characteristics because they allow the mass delivered to be characterized in a standard way regardless of the nebulizer used. Accordingly, the test methodology described below (a) measures the mass of drug substance delivered in the first period (typically 1 min) consequently giving an assessment of drug substance delivery rate and (b) captures the total drug substance mass delivered.

### Apparatus

#### BREATHING SIMULATOR

A commercially available breathing simulator that is able to generate the breathing profiles specified in *Table 1* is used for the test. The breathing profile indicated for adults is used unless the medicinal product is specifically intended for use in pediatrics, when alternate patterns should be used, as indicated in *Table 1*.

**Table 1. Breathing Simulator Specification**

| Item | Specification | | | |
|---|---|---|---|---|
| | Adult | Neonate | Infant | Child |
| Total volume | 500 mL | 25 mL | 50 mL | 155 mL |
| Frequency | 15 cycles/min | 40 cycles/min | 30 cycles/min | 25 cycles/min |
| Waveform | sinusoidal | sinusoidal | sinusoidal | sinusoidal |
| Inhalation:exhalation ratio | 1:1 | 1:3 | 1:3 | 1:2 |

#### FILTER SYSTEM

A suitably validated low-resistance filter, capable of quantitatively collecting the aerosol and enabling recovery of the drug substance with an appropriate solvent, is used for the test. The dead volume of the filter casing does not exceed 10% of the tidal volume used in the breath simulation.

### Procedure

Attach the filter (contained in the filter holder) (A) to the breath simulator (B) according to *Figure 1*. Fill the nebulizer (C) with the volume of the drug product as specified in the patient instructions. Attach the mouthpiece of the nebulizer to the inhalation filter using a mouthpiece adapter if required, ensuring that connections are airtight. Position the nebulizer in the same orientation as intended for use. This may require tilting the breathing simulator and filter holder. Set the breathing simulator to generate the specified breathing pattern.

A. inhalation filter and filter holder B. breathing simulator C. nebulizer

Figure 1. Experimental Set-Up for Breathing Simulator Testing.

Start the breathing simulator and at the beginning of an inhalation cycle, start the nebulizer. Operate the nebulizer for a defined initial time period. The length of the time interval ensures that sufficient drug substance is deposited on the inhalation filter for quantitative analysis. A time of 60 ± 1 s typically enables direct determination of the drug substance delivery rate. The time chosen, usually 60 ± 1 s, must allow sufficient drug substance deposition on the inhalation filter to allow quantitative analysis. If the quantity of drug substance deposited on the inhalation filter in 60 s is insufficient for this analysis, the length of the time interval for aerosol collection can be increased. If the filter is soaked with the product, this time can be decreased. At the end of this initial period, stop the nebulizer.

Place a fresh filter and filter holder in position and continue until nebulization ceases. Interrupt nebulization and exchange filters, if necessary, to avoid filter saturation.

## Results

Using a suitable method of analysis, determine the mass of drug substance collected on the filters and filter holders during each time interval. Determine the drug substance delivery rate by dividing the mass of drug substance collected on the first inhalation filter by the time interval used for collection. Determine the total mass of drug substance delivered by summing the mass of drug substance collected on all inhalation filters.

## AERODYNAMIC ASSESSMENT OF NEBULIZED AEROSOLS

Nebulized products need to be size-characterized at flow rates lower than the range that is typically used for powder inhalers and metered-dose inhalers. The CEN standard recommends a flow rate of 15 L/min because this value represents a good approximation to the mid-inhalation flow rate achievable by a healthy adult breathing at 500 mL tidal volume.

Although low-angle laser light-scattering instruments (laser diffractometers) can provide rapid size-distribution measurements of nebulizer-generated aerosols, these techniques do not detect the drug substance. Rather, they measure the size distribution of the droplets irrespective of their content. This may not be a problem with homogeneous solutions, but it can result in significant error if the product to be nebulized is a suspension, or if droplet evaporation is significant, as can be the case with certain nebulizer types. Cascade impactors enable the aerosol to be characterized unambiguously in terms of the mass of drug substance as a function of aerodynamic diameter. Laser diffraction may be used if validated against a cascade impaction method.

▲The Next Generation Impactor without pre-separator used with inhalation aerosols, inhalation sprays, and nasal aerosols is described in▲ (ERR 1-Aug-2021) *Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩. ▲An archival version of this cascade impactor▲ (ERR 1-Aug-2021) has been calibrated at 15 L/min specifically to meet the recommendation of the CEN Standard and ▲this configuration▲ (ERR 1-Aug-2021) is therefore used for this test.[3] Determining mass balance in the same way as for powder inhalers and metered-dose inhalers is not straightforward because the dose is being captured as a continuous output and hence is not included. Recovery experiments must be performed as part of method development and validation. Control of evaporation of droplets produced by nebulizers may be critical to avoid bias in the droplet size assessment process. Evaporation can be minimized by cooling the impactor to a temperature of about 5°, typically achieved by cooling the impactor in a refrigerator for about 90 min.

Typically, at least after each day of use, the apparatus must be fully cleaned, including the inter-stage passageways, because of the greater risk of corrosion caused by the condensation/accumulation of saline-containing droplets on inter-stage metalwork associated with cooling the impactor. All surfaces of the apparatus should be dried after each test, e.g, with compressed air. [NOTE—The micro-orifice collector (MOC) should not be dried with compressed air.]

## Apparatus

▲*Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩*, C.4 Next Generation Impactor without Pre-separator for Inhalation Aerosols, Inhalation Sprays, and Nasal Aerosols*▲ (ERR 1-Aug-2021) includes details of critical dimensions and the qualification process for the impactor (stage mensuration).

A back-up filter in addition to the MOC must be used to ensure quantitative recovery of drug substance from the nebulized aerosol at the specified flow rate of 15 L/min. The filter is located below the MOC (internal filter option), or a filter in holder external to the impactor is used to capture any fine droplets that pass beyond the last size fractionating stage. A pre-separator is not used for testing nebulizer-generated aerosols.

## Method Validation

### IMPACTOR STAGE OVERLOADING

During method development and validation, confirm that the volume of liquid sampled from the nebulizer does not overload the impactor. Visual inspection of the collection surfaces on stages collecting most of the droplets may reveal streaking if overloading has occurred. This phenomenon is usually also associated with an increase in mass of drug substance collected on the final stage and back-up filter. Reducing the sampling period ($T_o$) is the most effective way to avoid overloading in any given system, balancing overloading with analytical sensitivity.

### RE-ENTRAINMENT

Droplet bounce and re-entrainment are less likely with nebulizer-produced droplets than with solid particles from inhalers, thus coating would not normally be required.

## Procedure

Pre-cool the assembled impactor and induction port in a refrigerator (set at about 5°) for not less than 90 min, and start the determination within about 5 min of impactor removal from the refrigerator. Other methods that maintain the impactor at a constant temperature (e.g, use of a cooling cabinet) can also be employed when validated.

Set up the nebulizer with a supply of driving gas (usually air or oxygen), or use a compressor at the pressure and flow rate specified by the manufacturer of the nebulizer. Ensure that the gas supply line does not become detached from the nebulizer when under pressure. Fill the nebulizer with the volume of the medicinal product as specified in the patient instructions.

Remove the impactor from the refrigerator. Attach the induction port to the impactor, and connect the outlet of the impactor/external filter to a vacuum source that is capable of withdrawing air through the system at 15 L/min, as specified in *Figure 2*. Turn on the flow through the impactor.

▲

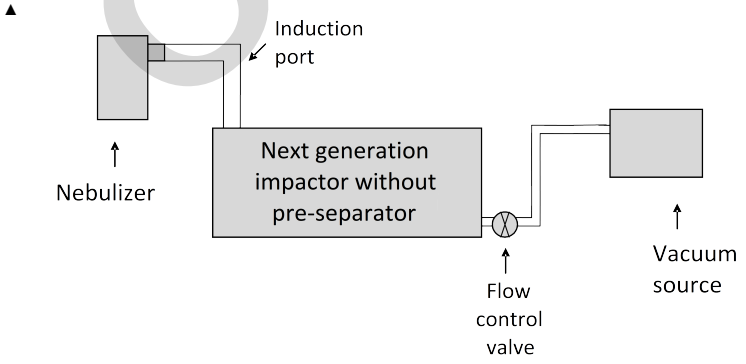

Figure 2. ▲Next Generation Impactor without Pre-separator▲ (ERR 1-Aug-2021) for Measuring the Size Distribution of Products for Nebulization.

Connect a flow meter, calibrated for the volumetric flow leaving the meter, to the induction port. Adjust the flow control valve located between the impactor and the vacuum source to achieve a steady flow through the system at 15 L/min (±5%). Remove the flow meter.

Position the nebulizer in the same orientation as intended for use, then attach the mouthpiece of the nebulizer to the induction port, using a mouthpiece adapter if required. Switch on the flow/compressor for the nebulizer. Sample for a predetermined time ($T_o$). Once determined, this time ($T_o$) must be defined and used in the analytical method for a particular drug product to ensure that mass fraction data can be compared. At the end of the sampling period, switch off the driving gas flow/compressor to the nebulizer, remove the nebulizer from the induction port, and switch off the flow from the vacuum source to the impactor. Dismantle the impactor and, using a suitable method of analysis, determine the mass of drug substance collected in the induction port on each stage and on the back-up filter as described ▲in *Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩*, C.4 Next Generation Impactor without Pre-separator for Inhalation*

Official

https://nhathuocngocanh.com/

*Aerosols, Inhalation Sprays, and Nasal Aerosols*.▲ (ERR 1-Aug-2021) Add the mass of drug substance collected in the MOC to that deposited on the back-up filter/external filter and treat as a single sample for the purpose of subsequent calculations.

Calculate the fine particle mass of the drug substance based on the predetermined time ($T_o$). Calculate the mass fraction ($F_{m,comp}$) of the drug substance deposited on each component of the impactor, commencing with the induction port and proceeding in order through the impactor, using the following expression:

$$F_{m,comp} = m_{comp}/M$$

$m_{comp}$ = mass associated with the component under evaluation;

M = total mass collected by the system.

Present $F_{m,comp}$ in order of location within the measurement equipment, beginning at the induction port and ending with the back-up filter of the impactor (see *Figure 3*). $F_{m,comp}$ values for adjacent stages of the impactor may be combined in order to report the mass fraction collected on a group of stages as a single value.

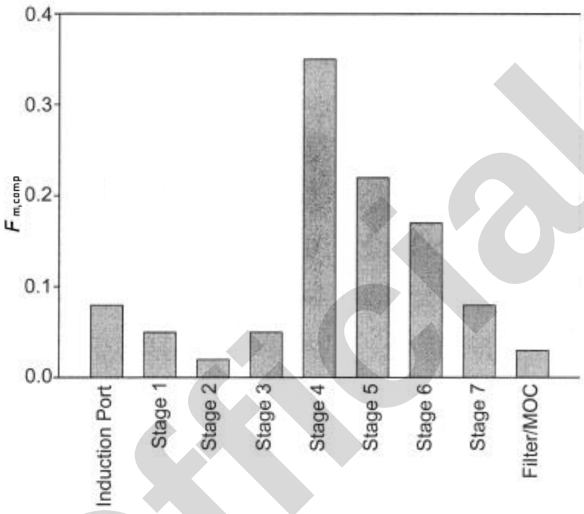

Figure 3. Example of Mass Fraction of Droplets Presented in Terms of Location within the Sampling System.

Determine the cumulative mass-weighted particle-size distribution of the aerosol size-fractionated by the impactor in accordance with the procedure given in ▲*Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩*, C.4 Next Generation Impactor without Pre-separator for Inhalation Aerosols, Inhalation Sprays, and Nasal Aerosols*▲ (ERR 1-Aug-2021). Starting at the filter, derive a cumulative mass versus effective cut-off diameter of the respective stages (see *Table 2* for the appropriate cut-off diameters at 15 L/min). Plot the cumulative fraction of drug substance versus cut-off diameter in a suitable format, e.g, logarithmic or log-probability format. Where appropriate, use this plot to determine by interpolation the fraction either less than a given size or between an upper and lower size limit.

**Table 2. Cut-off Sizes for ▲Next Generation Impactor without Pre-separator▲ (ERR 1-Aug-2021) at 15 L/min**

| Stage | Cut-off Diameter (µm) |
|---|---|
| 1 | 14.1 |
| 2 | 8.61 |
| 3 | 5.39 |
| 4 | 3.30 |
| 5 | 2.08 |
| 6 | 1.36 |
| 7 | 0.98 |

If necessary, and as appropriate, use this plot to determine values for the mass median aerodynamic diameter (MMAD) and the geometric standard deviation (GSD).

***Change to read:***

## 1. INTRODUCTION

### 1.1 Background

Spacers and valved holding chambers (VHCs) are widely used in conjunction with inhalation aerosols [commonly known as pressurized metered-dose inhalers (MDIs)]. When used correctly, VHCs assist with the administration of inhalation aerosols to patients who have poor coordination of MDI actuation and inhalation, and VHCs reduce oro-pharyngeal deposition of the drug. Patients using these spacers/VHCs in general breathe tidally when inhaling their medication, regardless of any delay, and this is particularly true for young and elderly users. Also, spacers and VHCs often come with a facemask instead of the mouthpiece normally supplied for inhalation aerosols. These add-on devices (spacers/VHCs) interface with the actuator/mouthpiece of the MDI and provide additional volume for the aerosol plume to develop. In this chapter, these aspects are addressed by providing patient-use appropriate scenarios that have been evaluated extensively.

Although existing methods for evaluating inhalation aerosols rely on sampling at a constant flow rate, spacers and VHCs may be used by patients who have poor inhalation technique (i.e., they delay inhalation after actuating the MDI). This chapter describes tests that are intended to provide information on how the spacer/VHC modifies the aerosol emitted by the MDI.

### 1.2 Purpose

The purpose of this chapter is to define potential standardized methods for characterizing the in vitro performance of a given MDI drug product with a specific spacer and VHC. It is recognized that spacer/VHC configurations will deliver a modified particle-size distribution and dose compared with the dose indicated on the label by the manufacturer of the MDI product, chiefly by collecting almost all of the portion of the dose contained in particles too large to be available for inhalation by the patient and potentially reach the lungs. This chapter does not advise on the outcome of such changes, rather the interpretation of data obtained using the methods described should be developed by the user after discussion with the appropriate receiving organization.

### 1.3 Rationale

This chapter includes separate testing by a multi-stage cascade impactor to determine aerosol aerodynamic particle size distribution (APSD) and tests mimicking fully coordinated and fully uncoordinated use, with tidal breathing simulated to establish emitted mass (EM) with the MDI-spacer/VHC coupled to a breathing simulator. ▲▲ (USP 1-Dec-2019) It is now possible to combine both APSD and EM measurements by means of a mixing inlet. ▲▲ (USP 1-Dec-2019) However, the more conservative approach adopted herein reflects the absence of method validation data for multiple marketed drug products delivered by MDI. Spacers and VHCs modify the APSD substantially from what is emitted by the MDI when used alone. In particular, almost all of the mass fraction of drug associated with particles having ballistic trajectories, by virtue of propellant expansion upon actuation, is contained within the add-on device. The user should refer to the Canadian Group standard for further interpretation of changes in APSD brought about by the presence of a spacer or VHC.

## 1.4 Recommendations

The use of the induction port identified in *Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩ is recommended for compliance with the pharmacopeial standard. However, it is acknowledged that alternative designs of the induction port, as yet to be included as pharmacopeial standards, offer unique testing opportunities. These are either anatomically correct or idealized to have aerosol transport properties similar to an anatomically correct induction port. Given the widespread use of spacers/VHCs for infants and small children, it is important to note that many of these anatomically appropriate induction ports are scaled in terms of such potential users (e.g., the "Alberta" idealized throats, ▲▲ (USP 1-Dec-2019) developed at the University of Edmonton, Canada). The user is free to adopt such an induction port but should specify the induction port design and age group with which the induction port will be used.

The evaluation of facemask performance requires a model face of the appropriate age range specified in the labeling for the add-on device (i.e., infant, small child, or adult). This arrangement is necessary because there is no other way to accurately simulate the magnitude of the dead space or test for the possibility of leak pathways between facemask and face, both of which are known to influence efficiency of the drug delivery. Some face models are available commercially.▲▲ (USP 1-Dec-2019) Therefore, because the use of a face model is an appropriate way to test these add-on devices, the user will need to either acquire a model from a source where age-appropriate face models have been developed and validated, or develop and validate his or her own design. Whichever pathway is chosen, a description of the model, in particular the dimensions of the face where the facemask comes into contact, should be provided in the data report to the recipient.

## 1.5 Definitions of Key Terms Relating to This Chapter

**Spacers:** Open tubes that do not have a valve at the exit nearest the patient interface (either the mouthpiece or facemask) to retain the aerosol before the user can inhale (see *Figure 1*). Spacers simply increase the distance between the MDI mouthpiece and the mouth of the patient. If the patient exhales instead of inhaling, the medication will be blown out of the spacer and lost.

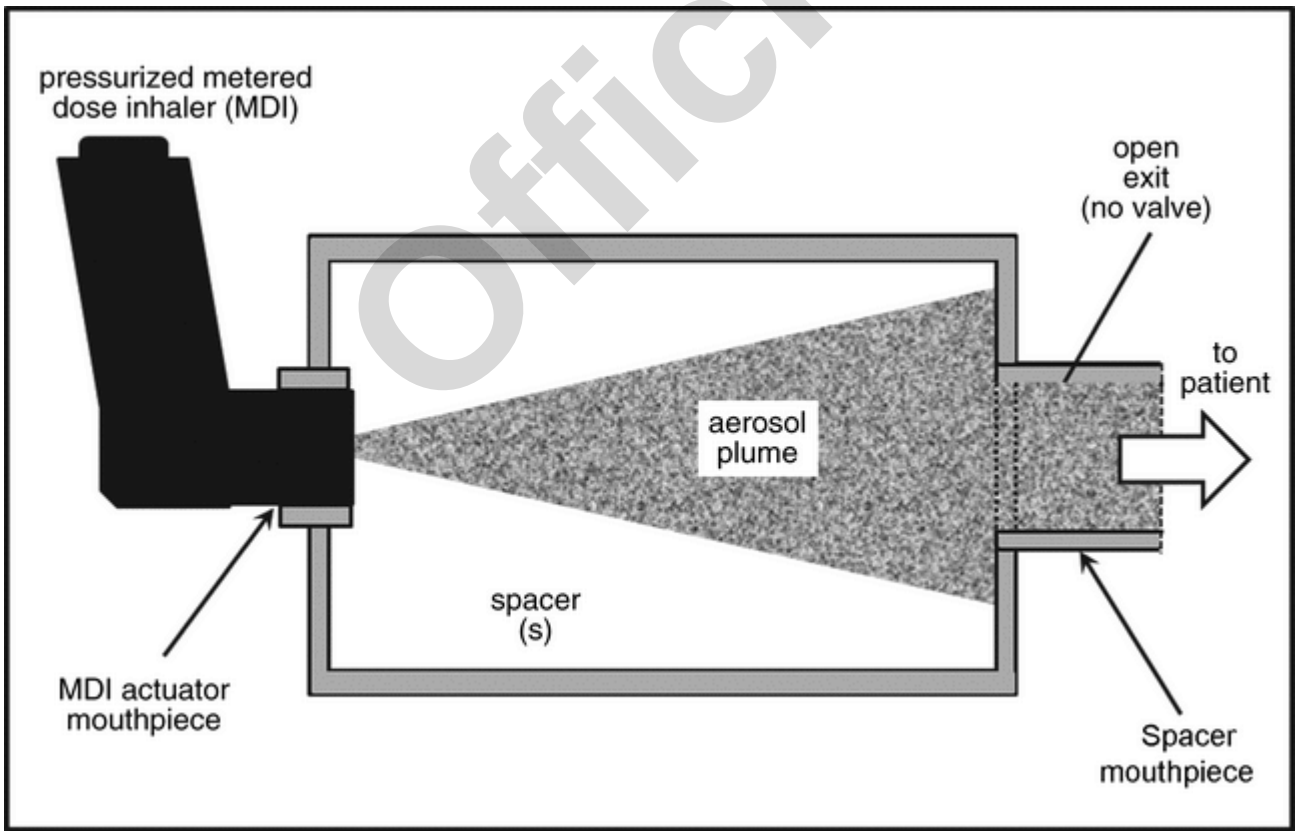

Figure 1. Open-tube spacer with no mechanism for aerosol conservation during exhalation.

**VHCs:** Contain at least one valve that opens to allow the patient to inhale aerosol on inspiration. This inhalation valve remains closed at other times during each breathing cycle (see *Figure 2*). Some VHCs may also contain an exhalation valve that is open only during exhalation to direct the exhaled flow away from the inhalation valve.

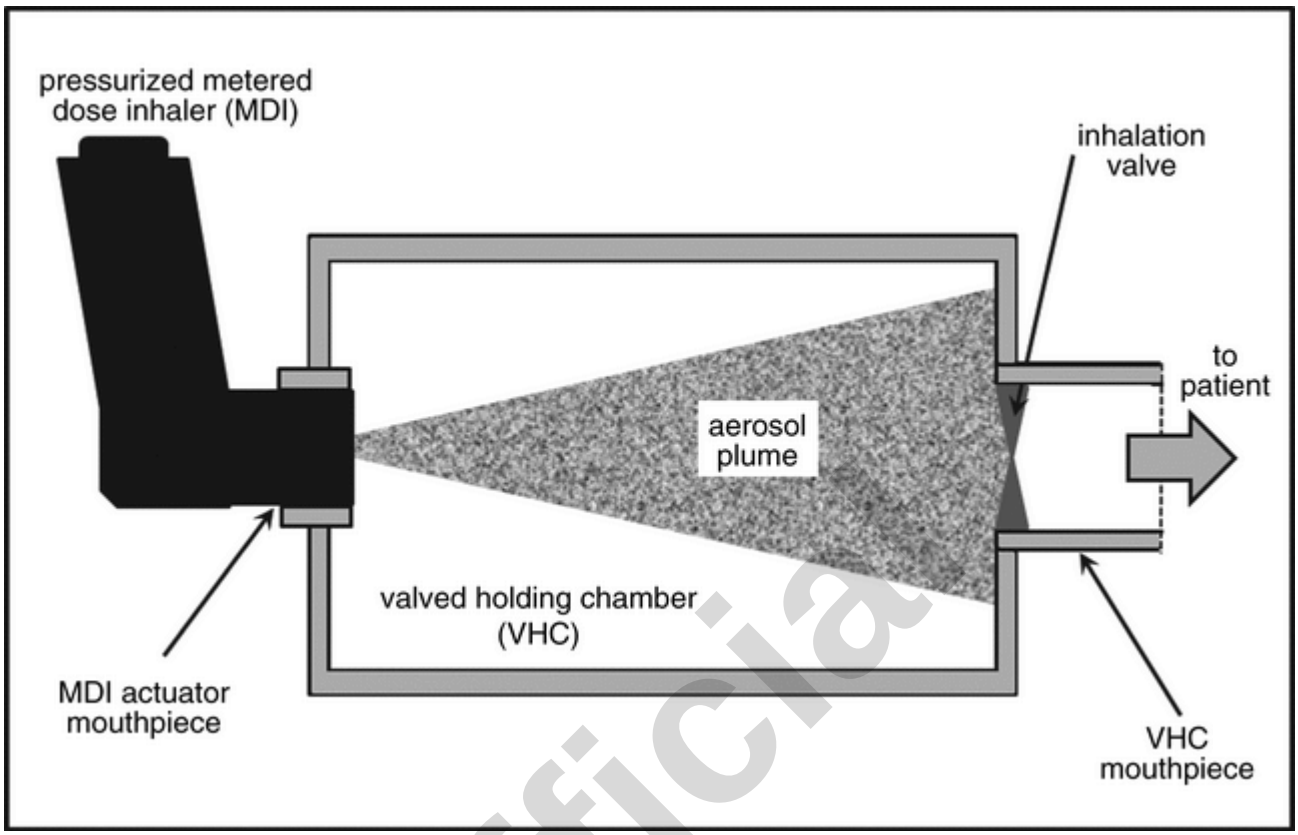

Figure 2. Conventional VHC with valve opening upon inhalation, accepting MDI with forward-firing actuator mouthpiece.

**Integral actuator:** A companion piece with some spacers and VHCs that accepts a MDI canister removed from its actuator-mouthpiece. A "reverse firing" feature may enable the design to be modified such that the built-in actuator faces away from rather than toward the user. In the example illustrated in *Figure 3*, the spacer operates in this way. It has some of the characteristics of a VHC, in that an air dam is created by closure of the valve located distally from the user on exhalation into the chamber. This type of spacer can therefore be evaluated as if it were a VHC, because the aerosol released on MDI actuation is conserved during exhalation.

## 2. TEST METHOD SELECTION

### 2.1 Spacer/VHC Configurations

Four spacer/VHC configurations have been identified that require different test methods to complete the evaluation process (see *Table 1*).

**Table 1. Identification of Test Configurations of the Spacer/VHC**

| Configuration | Spacer | VHC | Mouthpiece | Facemask |
|---|---|---|---|---|
| A | +[a] | –[b] | + | – |
| B | + | – | – | + |
| C | – | + | + | – |
| D | – | + | – | + |

[a] + denotes that this item was part of the condition.
[b] – denotes that this item was not part of the condition.

In *Configuration A*, the device being tested is a spacer with a mouthpiece. Likewise, in *Configuration B*, the device under test is a spacer with a facemask. In *Configuration C*, the device is a VHC with a mouthpiece, and in *Configuration D* the device is a VHC with a facemask. The evaluation of devices without patient interface (i.e., those intended for use by patients on mechanical ventilation) is outside the scope of this chapter.

## TESTS FOR CONFIGURATION A

*Configuration A*, spacer with mouthpiece (see *Figure 4*), comprises two tests: 1) APSD measurement with no delay (see *Part 1A*); and 2) EM by breathing simulation—fully coordinated (see *Part 2A*). Testing with a delay would be inappropriate for this configuration because the medication cannot be retained within the spacer because it has no valving mechanism.

## TESTS FOR CONFIGURATION B

*Configuration B*, spacer with facemask (see *Figure 4*), comprises one test with the facemask in place: 1) EM by breathing simulation—fully coordinated (see *Part 3A*). ▲ [NOTE—The facemask should NOT be removed for this test, because it is important to be able to evaluate the effect of dead space between facemask and face, as well as the correct function of an exhalation valve, if provided.]▲ (USP 1-Dec-2019) It is recommended that this class of device be evaluated for APSD measurement with no delay (see *Part 1A*) by removing the facemask and coupling the spacer on-axis to the induction port entry with a suitable connector. Testing with delay would be inappropriate for this configuration, because the medication cannot be retained within the spacer because it has no valving mechanism. ▲ [NOTE—Removal of the facemask is acceptable for APSD determination, because the entire bolus of medication leaving the spacer is sampled in the continuous vacuum that is required to operate the cascade impactor.]▲ (USP 1-Dec-2019)

## TESTS FOR CONFIGURATION C

*Configuration C*, VHC with mouthpiece (see *Figure 4*), comprises four tests: 1) APSD measurement with no delay (see *Part 1A*); 2) APSD measurement with delay (see *Part 1B*); 3) EM by breathing simulation—fully coordinated (see *Part 2A*); and 4) EM by breathing simulation—fully uncoordinated (see *Part 2B*).

## TESTS FOR CONFIGURATION D

*Configuration D*, VHC with facemask (see *Figure 4*), comprises two tests with the facemask in place: 1) EM by breathing simulation—fully coordinated (see *Part 3A*); and 2) EM by breathing simulation—fully uncoordinated (see *Part 3B*). ▲ [NOTE—The facemask should NOT be removed for this test, because it is important to be able to evaluate the effect of dead space between facemask and face, as well as the correct function of an exhalation valve, if provided.]▲ (USP 1-Dec-2019) It is recommended that this class of device be evaluated for APSD measurement with and without delay (see *Parts 1A* and *1B*) by removing the facemask and coupling the VHC on-axis to the induction port entry with a suitable connector. ▲ [NOTE—Removal of the facemask is acceptable for APSD determination, because the entire bolus of medication leaving the spacer is sampled in the continuous vacuum that is required to operate the cascade impactor.]▲ (USP 1-Dec-2019)

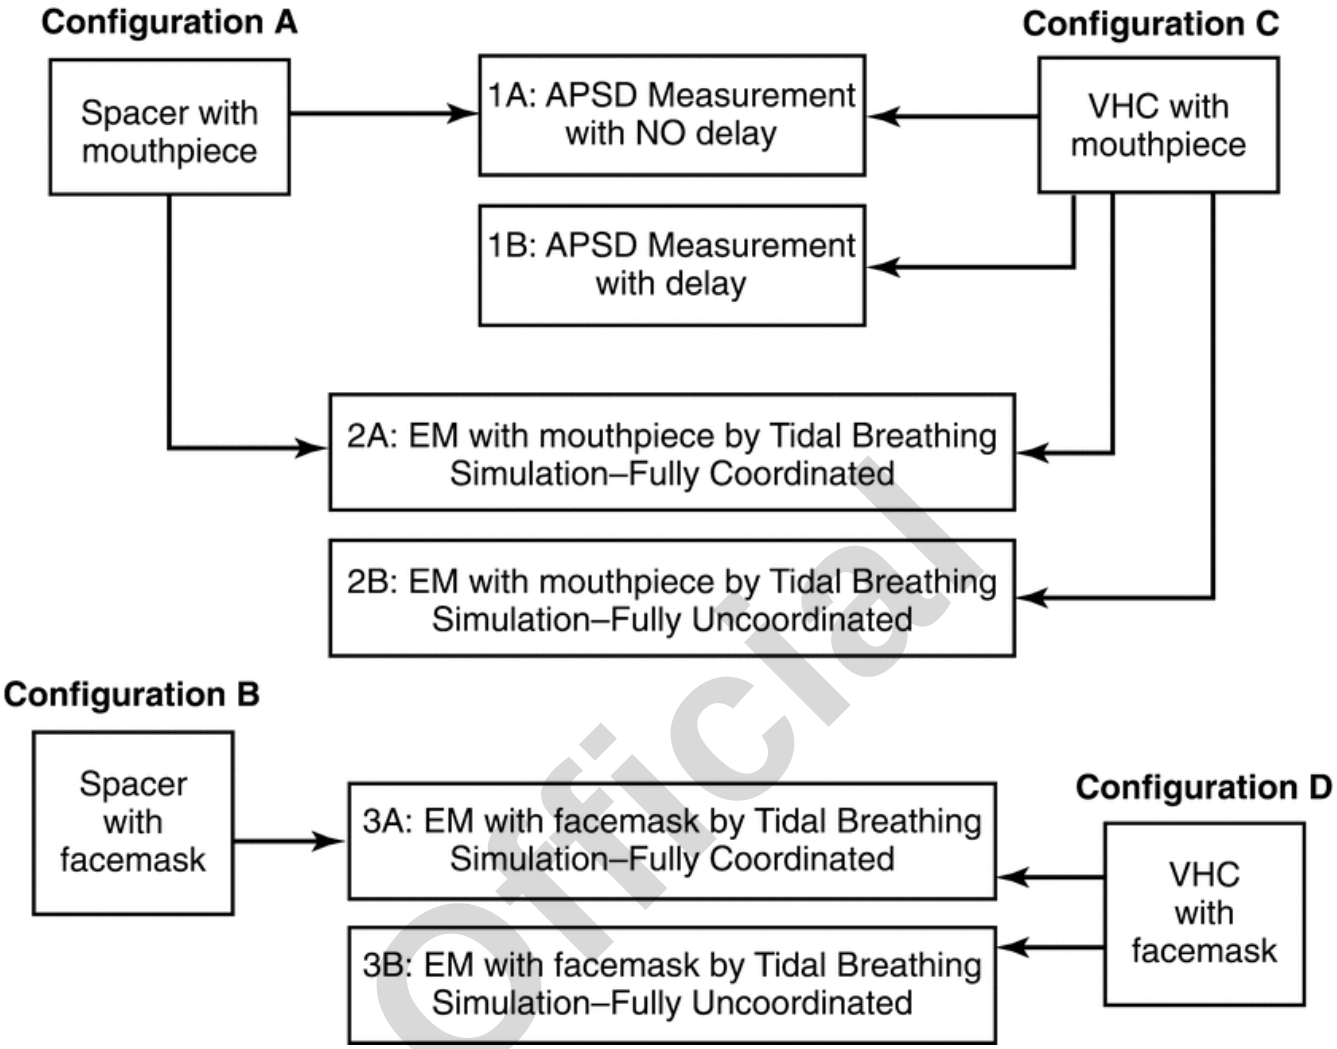

Figure 4. Decision tree for test selection by add-on device type.

## 2.2 Comments on Test Methods

The tests in *Parts 1A* and *1B* (see *Table 2*) are an extension of the procedures described in ⟨601⟩. However, sampling at a constant flow rate via a cascade impactor does not do more than enable the assessment of the APSD of the emitted aerosol. In the later parts of *Products for Nebulization—Characterization Tests* ⟨1601⟩, tests are described in which tidal breathing is simulated to assess spacer/VHC performance in terms of the delivered dose (equivalent to EM) in situations that are more representative of patient use. In *Part 1A* (see *Table 2*), the purpose is to enable the determination of metrics for which a direct comparison can be made with and without the add-on device. This methodology is the same as that described using either ▲the Andersen Cascade Impactor without pre-separator or the Next Generation Impactor without pre-separator (see ⟨601⟩)▲ (USP 1-Dec-2019) and is therefore not repeated here. In *Part 1B* (see *Table 2*), delayed sampling is introduced because add-on devices, especially VHCs, are widely prescribed for individuals who, for whatever reason, are unable to coordinate MDI actuation with the onset of inhalation as described for the MDI alone in "patient information" and "instructions for use". All of the tests in *Part 1* are undertaken with the facemask removed from the spacer/VHC equipped with this type of patient interface. This modification is allowed so that the device can be readily interfaced by fitting the facemask adapter directly to the entry of the induction port without the complication of a direct facemask-to-induction port connection, where internal dead space would likely be both ill-defined and unrepresentative of the "in-use" condition.

**Table 2. In Vitro Tests for Spacers and VHCs**

| Test | Delay at Constant Flow Rate | Breathing Simulation | Suitability | Relevance to Patient Use Scenarios |
|---|---|---|---|---|
| Part 1A: Measurement of APSD with 4-L sample volume | None | Not applicable | Spacers and VHCs | Baseline performance compared with MDI alone |

Simulation of use with facemask applied with a 1.6-kg force[c]▲ (USP 1-Dec-2019) |

[a] Other delay intervals may also be used as required, if justified.
[b] Representative breathing patterns for different patient ages are listed in *Table 3*; other patterns may be used as required, if justified.
[c] 1.6-kg applied force has been shown to be clinically appropriate, but the force used may differ from this value if justified.

The tests in *Parts 2* and *3*, depending on whether a mouthpiece or facemask is present as the patient interface, respectively (see *Table 2*), evaluate the performance of the inhalation valve (and exhalation valve, if equipped) of the add-on device. This evaluation is accomplished by simulating tidal breathing, with parameters that are appropriate for the intended user group (e.g., infant, small child, or adult). This testing approach creates the continually varying flow conditions that are expected in use. Note that in the determination of EM, a sufficient number of inhalations should be taken in accordance with the instructions for use of the VHC, to ensure that the intended amount of drug is delivered.

Spacers/VHCs using a facemask as the patient interface should be evaluated ideally with the facemask in place (see *1.3 Rationale*). The desirable approach is such that in vitro testing makes use of a model face that is representative of the age range for which the spacer/VHC is intended. There are currently limited commercially available model faces; however, the peer-reviewed literature contains several articles providing the necessary technical information to enable suitable age-appropriate model(s) to be created for the purpose of testing spacer/VHCs. It is also important that the surfaces of the face coming into contact with the facemask have mechanical characteristics (e.g., deformability) that are representative of the skin and underlying soft tissues when the facemask is applied to the face with an appropriate force. In *Part 3* (see *Table 2*), the spacer/VHC is evaluated by a breathing simulation with the facemask fitted, mimicking similar fully coordinated use as defined in *Part 2A* and also fully uncoordinated use as defined in *Part 2B* (see *Table 2*). By comparing the EM of the drug with and without the use of a facemask, it is possible to assess the influence of the facemask.

[NOTE—Not all of the tests described in this chapter are applicable to open-tube spacers because such devices require fully coordinated use; otherwise, drug delivery will be significantly reduced. *Figure 4* shows the decision tree to be followed so that the tests chosen are appropriate to the type of add-on device being evaluated.]

*Table 2* further defines the test, method, applicable device, and relevance to patient use scenarios of the procedures that are described in this chapter. Example delay intervals of 2, 5, and 10 s are noted in the table, although other delay intervals may be substituted or added as required and justified. For the testing in *Parts 3▲A* and *B*▲ (USP 1-Dec-2019) (see *Figure 4*), it is recognized that currently there are limited commercially available face models representing the most widely recognized age categories, which may be required (i.e., infant, small child, and adult). The user is advised to select an appropriate commercial model or develop his or her own, providing justification for the selection as required. Additionally, *Table 3* shows representative tidal-breathing patterns for the various patient age categories from neonate to adult.

▲Testing is undertaken (see *3.1 No Delay between the MDI Actuation and Sampling Onset*) to ensure that there are no leakages of ambient air into the measurement apparatus. The purpose is not to evaluate leakages associated with the spacer/VHC. Such testing would be impractical because of the variety of adapters that would be needed to interface the flow meter with the different designs associated with these add-on devices.▲ (USP 1-Dec-2019)

# 3. MEASUREMENT OF APSD

## 3.1 No Delay between the MDI Actuation and Sampling Onset

### BACKGROUND

In *Part 1A* (see *Figure 4*), the measurement of APSD from the spacer or VHC with no delay following actuation of the inhaler is defined as an important test of the optimum performance of the device. This test also provides information with which to compare the in vitro performance of the MDI with and without the add-on device present.

### TEST PROTOCOLS

If the spacer/VHC is intended for adult use, and comparison is being made with the MDI alone, follow ▲one of▲ (USP 1-Dec-2019) the procedures given for ▲inhalation aerosols and sprays,▲ (USP 1-Dec-2019) as required. Alternatively, ▲the pediatric version of▲ (USP 1-Dec-2019) the Marple-Miller Cascade Impactor ▲(Model 150P)▲ (USP 1-Dec-2019) may be used.

If the spacer/VHC is intended for neonates, infants, or small children, it may be appropriate to use an alternative apparatus that operates at the reduced flow rate(s) more appropriate for these classes of patients. Examples are ▲the Next Generation Impactor (without pre-separator)▲ (USP 1-Dec-2019) operated at 15.0 L/min or the pediatric version of ▲▲ (USP 1-Dec-2019) the Marple-Miller Cascade Impactor (Model 150P) that functions at either 4.9 or 12.0 L/min.

▲Set up the cascade impactor as described in the manufacturer's literature. To ensure efficient particle capture, coat appropriately the particle collection surface of each stage with glycerol, silicone oil, or other suitable liquid unless this has been demonstrated to be unnecessary. Connect an induction port with internal dimensions as defined in ⟨601⟩ to the impactor inlet. Connect the impactor to a vacuum pump via a suitable flow control valve.

Attach a flowmeter capable of providing volumetric flow rate, within the range of operation leaving the meter, to the induction port, ensuring an airtight seal. Verify that the flow rate for the test is within ±5% of the specified flow rate. This is achieved by applying a vacuum to the test apparatus by means of the flow control valve located between the cascade impactor and vacuum source. Turn off the source of vacuum to this apparatus after this check has been completed and remove the flow meter.

Attach a suitable coupling for the spacer/VHC to the induction port.▲ (USP 1-Dec-2019) Conduct the ▲remainder of the▲ (USP 1-Dec-2019) evaluation with the mouthpiece of the spacer or VHC, if so equipped, connected to the test apparatus. If the spacer or VHC is equipped with a facemask, remove the facemask and perform the evaluation with the add-on device connected to the test apparatus by means of the facemask adapter.

▲Prepare the spacer/VHC▲ (USP 1-Dec-2019) for the test by washing in accordance with the manufacturer's instructions, if so indicated. If no instructions for preparation are provided, test the device out of the package without prewashing, and note this information in the test report.

Connect the spacer or VHC via the mouthpiece or facemask adapter to the entry to the induction port described in ⟨601⟩. This connection can be made either with a short piece of flexible tubing or with a purpose-built coupling that ensures on-axis alignment with the entry to the induction port. If flexible tubing is used for this connection, ensure that the add-on device is supported in such a way that its long axis aligns with the axis of the induction port entry. Care should be taken to ensure that the coupling, however constructed, does not result in a significant loss of the drug and/or change in measured APSD.

▲▲ (USP 1-Dec-2019)

Official

https://pharmacopeia.cn/v-download/

The practice of actuating the MDI with the spacer or VHC initially disconnected from the induction port and then rapidly connecting the add-on device after MDI actuation is not recommended, because there is always a small delay interval and medication will be lost in an uncontrolled manner from an open-tube spacer if this procedure is followed.

Follow the directions in the patient information and instructions for use for the MDI to prime it before inserting into the MDI adapter of the spacer/VHC. In the case of an add-on device equipped with an integral actuator, after priming the MDI canister in its mouthpiece adapter as supplied, remove the canister from the adapter and clean the external valve stem with a suitable wipe. Insert the canister valve stem into the receptacle following the instructions for use for the particular add-on device, taking care to avoid premature actuation.

In cases where more than one actuation of the MDI is needed to collect sufficient mass of drug product, follow the directions in the patient information and instructions for use; if no directions are provided, allow a minimum of 30 s between actuations. Turn on the vacuum to the cascade impactor before delivering any actuations. It is important to deliver the minimum number of actuations to obtain an adequate sample of the size-fractionated drug mass for measurements to be made to the same degree of precision as would be the case if the MDI was evaluated alone.

After the MDI actuation and aerosol sampling are completed, recover the drug from each component of the cascade impactor, including the induction port, and also from within the spacer/VHC by using a validated method appropriate to the product being measured. Carefully remove the backup filter of the cascade impactor, whose purpose is to capture the drug mass passing the last impaction stage, from its location and place it in a suitable container. For each sample, add a predetermined volume of a suitable solvent to the container and agitate to dissolve the collected drug. Transfer a sample to a cuvette or vial for drug assay using a syringe equipped with an in-line filter to retain any suspended material. Care must be taken with the recovery of a drug retained by the add-on device, because a greater volume of solvent may be needed, compared with volumes needed for recovery from each impaction plate/cup of the impactor. Perform separate assays to measure the mass of drug recovered from each component, using a validated procedure.

Repeat the measurement with the required number of devices and replicates per device. Typically, five separate spacers or VHCs are each tested once, but other testing protocols may be adopted as required, if justified. These protocols may include replicate measurements per device to obtain information about intra- as well as inter-device performance.

MEASUREMENTS

**Total mass of drug collected:** This procedure is not a test of the product or add-on device but serves as a system suitability test to ensure that the results are valid. The total mass of drug collected comprises the sum of the drug mass in all of the components, including the MDI mouthpiece and from within the spacer/VHC [material balance (MB)] divided by the number of actuations of the MDI. Note that typically up to 5% of the target-delivered label claim may be retained by the cascade impaction apparatus as inter-stage wall losses.

**Total mass of drug emitted:** The total mass of drug emitted from the spacer/VHC with zero seconds delay (delivered dose, equivalent to EM) is determined from the sum of the values for the mass of drug collected in all of the components of the test apparatus divided by the number of actuations of the MDI. Spacers and VHCs are intended to reduce the mass of coarse particles inhaled by the patient; therefore, an important part of data interpretation of the APSD should involve separate assessments of the pertinent subfractions relevant to the inhalation aerosol product. The precise size limits for these subfractions will agree with the recipient of the test data. However, to provide initial guidance on this matter, it is suggested that the following be considered as a minimum:

- Determination of the mass of drug retained by the spacer/VHC together with the mass recovered from the induction port
- Stage-by-stage profile of the remaining EM

Further interpretation of these data is at the discretion of the user. The performance of the spacer/VHC is compared with that of the MDI alone, following the procedure described in ⟨601⟩.

## 3.2 Delay between the MDI Actuation and Sampling Onset

[NOTE—This test is inappropriate for spacers.]

BACKGROUND

This test requires the adaptation of ▲the Andersen Cascade Impactor without pre-separator and the Next Generation Impactor without pre-separator (see ⟨601⟩)▲ (USP 1-Dec-2019) to accept a means by which the delay interval can be realized. The actuation of the MDI into the VHC on test with its mouthpiece or facemask adapter disconnected from the entry to the induction port, followed by connection to the port with the vacuum applied to the apparatus immediately after the delay interval has elapsed, is difficult to perform accurately and may result in leakage or an inaccurate realization of the delay interval. For these reasons, an apparatus of the type described in *Figure 5* is recommended, because it enables the VHC mouthpiece/facemask adapter to remain in position throughout the measurement. The methodology for delay testing is based on the apparatus illustrated, but other equipment offering similar capability may be used if justified.

TEST PROTOCOLS

The vertically mounted shutter plate comprises a circular opening in its upper half and is mounted at setup such that the gap between the VHC mouthpiece/facemask adapter and induction port entry is closed, as illustrated (see *Figure 5*). The induction port and VHC adapter fit tightly into the mounting block. In this position, when vacuum is applied to the test apparatus, air is sampled by the apparatus at the desired flow rate via a bypass channel on the side of the adapter facing the induction port. This arrangement avoids the need to start the flow through the apparatus after the delay interval has elapsed, so that the cascade impactor is always operated at a constant flow rate.

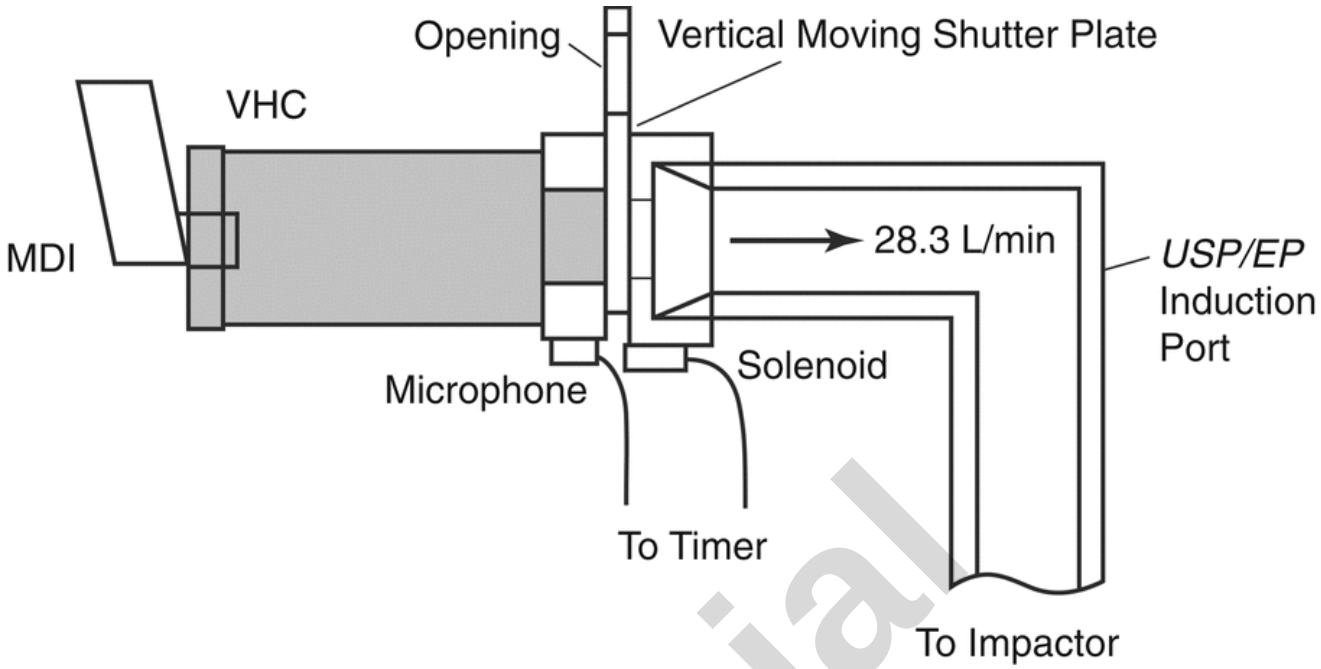

Figure 5. A configuration for an apparatus to assess the effect of a delay between the MDI actuation and sampling onset.

In the configuration described in *Figure 5*, when the MDI is actuated, a microphone located on the adapter block detects the sound emitted at actuation of the MDI, starting a timer that operates a solenoid valve that retracts a pin immediately after the preset delay interval has expired. This process permits gravity to operate on the shutter, which drops to the lower position in which the aperture is aligned with the VHC mouthpiece/facemask adapter and induction port entrance. The aerosol retained within the VHC is sampled as soon as the shutter moves to the "open" position. This procedure avoids the risk of capturing any "blow-by" aerosol that might escape the VHC as the propellant expands immediately following MDI actuation but would not be inhaled by a user. If blow-by is observed, it should be noted in the test report. In the configuration shown in *Figure 5*, the adapter introduces <5 mL of additional volume to the aerosol pathway from the VHC to the filter, and the minimum delay interval achievable is 1 s.

Example delay intervals of 2, 5, and 10 s have been noted earlier in this chapter, although other delay interval(s) may be substituted or added if required and justified.

▲Connect the impactor to a vacuum pump via a suitable flow control valve.

The delay apparatus, if constructed in accordance with *Figure 5* will introduce leakage into the apparatus, once attached to the induction port because the bypass flow passage is open in order that in-flow comes in via this passage rather than through the VHC before the shutter drops after the prescribed delay period. The flow rate verification test is therefore conducted before the delay apparatus is attached. Connect an induction port with internal dimensions as defined in ⟨601⟩ to the impactor inlet. Attach a flowmeter capable of providing volumetric flow rate, within the range of operation leaving the meter, to the coupling, ensuring an airtight seal. Verify that the flow rate for the test is within ±5% of the specified flow rate. This is achieved by applying a vacuum to the test apparatus by means of the flow control valve located between the cascade impactor and vacuum source. Turn off the source of vacuum to this apparatus after this check has been completed and remove the flow meter.▲ (USP 1-Dec-2019)

Securely attach the exit port from the delay apparatus to the entry of the induction port. ▲Conduct the remainder of the evaluation with the mouthpiece of the spacer or VHC, if so equipped, connected to the test apparatus. If the spacer or VHC is equipped with a facemask, remove the facemask and perform the evaluation with the add-on device connected to the test apparatus by means of the facemask adapter. If this is the first testing of the spacer/VHC or the intention is to evaluate the add-on as new for each delay condition, prepare it for the test by washing in accordance with the manufacturer's instructions, if so indicated. If no instructions for preparation are provided, test the device out of the package without prewashing, and note this information in the test report.▲ (USP 1-Dec-2019) Connect the VHC via the patient interface (mouthpiece or facemask adapter) to the entry port of the delay apparatus. ▲▲ (USP 1-Dec-2019)

Before actuating the MDI for the first time into the VHC being tested, ensure that the delay apparatus is set such that the shutter is in the "up" or "closed" position. Select the desired delay interval for the timer.

Follow the directions in the patient information and instructions for use before inserting the actuator/mouthpiece of the MDI into the MDI adapter of the VHC before the first actuation into the test apparatus. If the spacer/VHC is designed with an integral actuator, after priming the MDI canister in its mouthpiece adapter as supplied, remove the canister from the adapter and clean the external valve stem with a suitable wipe. Insert the canister valve stem into the receptacle following the instructions for the particular add-on device, taking care to avoid premature actuation.

In cases where more than one actuation of the MDI is needed to collect sufficient mass of drug product, follow the directions in the patient instructions, or if no direction is provided, allow a minimum of 30 s between actuations. Deliver the minimum number of actuations needed to obtain an adequate sample of the size-fractionated drug mass so that measurements can be made to the same degree of precision as if the MDI was evaluated alone. Reposition the shutter of the delay apparatus in the

@2024 USPC

up or closed position, and check that the timer is set for the desired delay after each MDI actuation. Maintain the vacuum through the entire sequence until all actuations are completed.

After the sampling part of the measurement is completed, recover the drug from each component of the cascade impactor, including the induction port, and from within the spacer/VHC by using a validated method appropriate to the specific product. In the configuration shown in *Figure 5*, the surface area of the shutter that is exposed to aerosol particles is minimal. Therefore, recovery of drug from this component needs to be done only for the most accurate work; in which case, the inner surfaces of the aperture in the shutter plate and the exit port are washed with recovery solvent. Care should be taken with the recovery of drug retained by the VHC, because a greater volume of solvent than is needed for recovery from each impaction plate/cup of the impactor may be needed to be sure that drug is quantitatively recovered. Assay for the mass of drug recovered from each component separately by using a validated procedure.

Repeat the measurement with the required number of devices and replicates per device. Typically, five separate spacers or VHCs are each tested once, but other designs, including replicate measurements per device, may be adopted as required.

MEASUREMENTS

**Total mass of drug collected:** The total mass of drug collected in all of the components, including the MDI mouthpiece and from within the spacer/VHC (MB) is divided by the number of actuations of the MDI. The component of the dose that may escape past the inhalation valve of the VHC on MDI actuation (due to momentary pressurization of the interior of the chamber) is termed "blow-by", and it may not be captured for the assay. If this phenomenon is observed, it must be noted.

[NOTE—Quantification of blow-by is not a practical proposition because the act of collecting the aerosol will inevitably apply back-pressure to the valve, reducing or eliminating the phenomenon altogether.]

The performance of the spacer/VHC tested with delay (see *3.2 Delay between the MDI Actuation and Sampling Onset*) is compared with that of the spacer/VHC tested with no delay (see *3.1 No Delay between the MDI Actuation and Sampling Onset*).

VHCs are intended to reduce the mass of coarse particles inhaled by the patient, so an important part of data interpretation of the APSD should involve separate assessments of the pertinent subfractions relevant to the inhalation aerosol product. The precise size limits for these subfractions will agree with the recipient of the test data. However, to provide initial guidance on this matter, it is suggested that the following be considered as a minimum:

- Determination of the mass of drug retained by the spacer/VHC together with the mass recovered from the induction port
- Stage-by-stage profile of the remaining EM

Further interpretation of these data is at the discretion of the user.

***Change to read:***

## 4. MASS OF DRUG DELIVERED FROM A SPACER/VHC WHILE SIMULATING PATIENT TIDAL BREATHING

### 4.1 Without Facemask

Cascade impactors used in the assessment of APSD are designed to operate at fixed flow rates. However well the add-on device may perform during an in vitro test of function using such an apparatus, the operation of critical moving components (i.e., inhalation and exhalation valves of VHCs) is not evaluated in the way that these components would perform when the VHC is used by the patient. An additional test that simulates tidal breathing is therefore included, because this type of respiratory pattern is most commonly encountered with patients using an add-on device, particularly neonates, infants, and children who are incapable of a forced inhalation maneuver. Several representative, age-related breathing patterns are listed in *Table 3*.

There is no breathing simulator recognized in ⟨601⟩. However, ⟨1601⟩ provides for the use of a commercially available breathing simulator that is able to generate the same breathing profiles as those specified in *Table 3*. The methodology provided assumes that equipment meeting this standard is available. *Figure 6* illustrates schematically a setup that has been effective for these measurements, but other configurations may be used as required.

The filter system used to collect the aerosol at the mouthpiece/facemask adapter of the spacer/VHC should be a suitably validated, low-resistance filter capable of quantitatively collecting the aerosol and enabling recovery of the drug substance with use of an appropriate solvent. If the filter is contained in its own housing, the dead volume of the filter casing must not exceed 10% of the tidal volume used in the breath simulation. This restriction will likely make it necessary to use filters without a separate housing when performing tests that simulate neonatal or infant use.

The first part of the test is suitable for both spacers and VHCs, because it simulates the delivery of medication mimicking a fully coordinated user actuating the MDI at the onset of inhalation. However, the second part of the test is only suitable for VHCs because the MDI is actuated at the onset of exhalation to simulate a fully uncoordinated user.

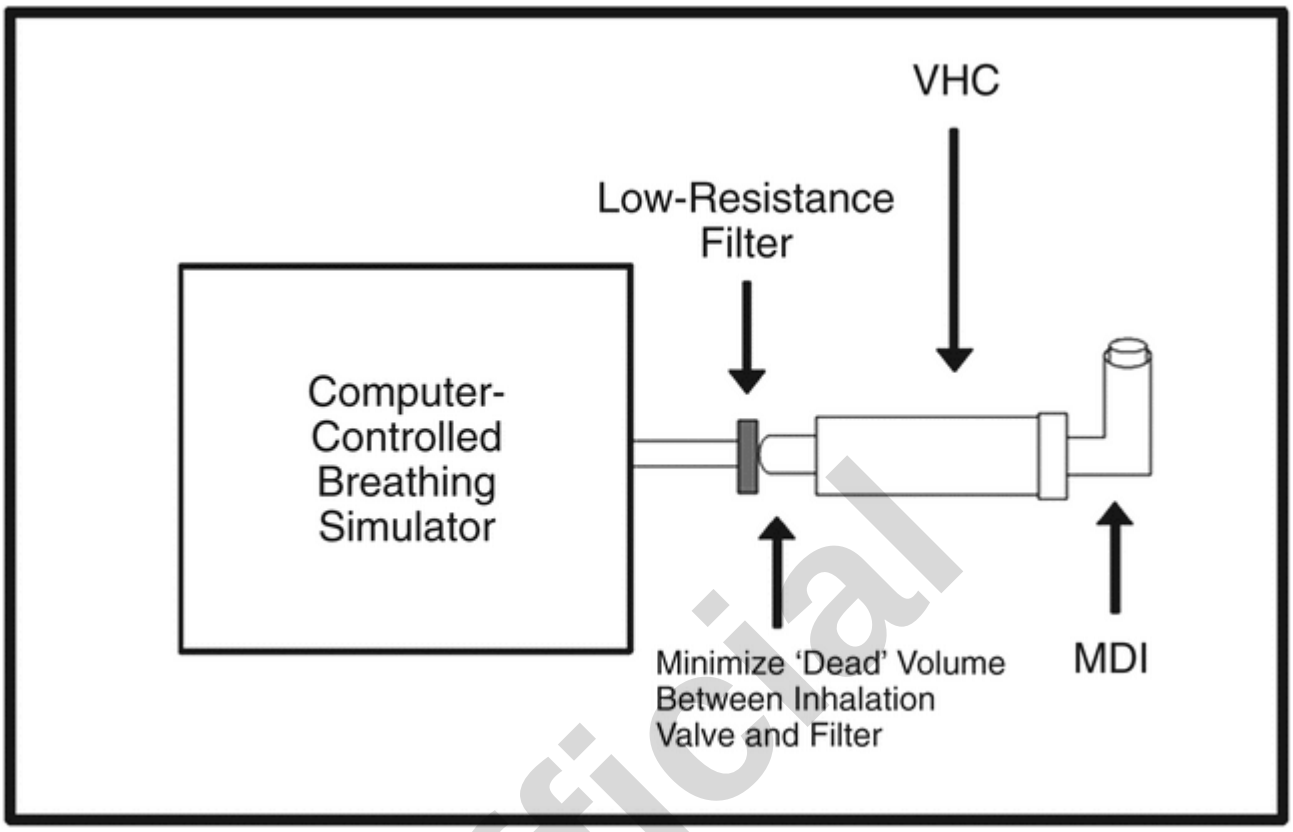

Figure 6. VHC evaluation by breathing simulator.

TEST, PART 1

Set the breathing simulator to the required breathing pattern (identified from *Table 3*) in accordance with the manufacturer's instructions. Alternative breathing patterns may be used if required. Ensure that the simulator has been calibrated before use so that the actual volumes and frequency are within ±5% of the indicated value during each breathing cycle. Calibration syringes are available from various suppliers of mechanical ventilation equipment to verify volumes. To verify frequency, the method varies among breathing simulator manufacturers, and therefore the advice of the particular supplier/manufacturer should be sought if the method is not explicitly stated in the operating instructions for the apparatus.

Ensure that the selected flow waveform from the computer-controlled breathing simulator (*Figure 6*) is stable before proceeding. Prepare each device in the group of spacers or VHCs to be tested by washing in accordance with the manufacturer's instructions, if indicated. If no instructions for preparation are provided, test the devices out of package without prewashing and note this fact in the test report.

Connect the mouthpiece or facemask adapter of the spacer/VHC to the breathing simulator by means of a short length of flexible hose. Locate the aerosol filter as close as possible to the mouthpiece of the spacer/VHC using an adapter or other means that will enable a leak-tight seal to be formed with the minimum amount of space (dead volume) between the device and the filter. Ensure that the adapter does not restrict the path of the aerosol.

Filtrete is a suitable electret filter medium ▲▲ (USP 1-Dec-2019) that readily releases collected drug quantitatively upon addition of a suitable solvent during the assay procedure. However, other suitable filter media may be used provided that the tester is satisfied that the filter is capable of collecting the entire emitted dose and that drug recovery for assay is quantitative.

Follow the directions in the patient information and instructions for use for the MDI to prime it before inserting into the MDI adapter of the spacer/VHC before the first actuation into the test apparatus. In the case of an add-on device equipped with an integral actuator, after priming the MDI canister in its mouthpiece adapter as supplied, remove the canister from the adapter and clean the external valve stem with a suitable wipe. Insert the canister valve stem into the receptacle by following the instructions for use for the particular add-on device, taking care to avoid premature actuation. This test typically should require only one actuation of the MDI into the spacer/VHC per determination. However, for certain highly potent products delivering low unit mass of drug per actuation, more than one actuation of the MDI may be needed to collect a sufficient mass of drug product. Under such circumstances, follow the directions in the patient information and instructions for use for the MDI, or allow a minimum of 30 s between actuations if no direction is provided. It is important to deliver the minimum number of actuations to obtain an adequate sample of the drug mass for measurements to be made with acceptable precision.

For the first part of the test, perform a single actuation timed to coincide with the *beginning* of an inhalation. Allow sampling to occur for five additional breathing cycles for the actuation. If additional actuations are required to improve analytical sensitivity, ensure that the sampling time is of sufficient length for the spacer/VHC to be emptied of remaining aerosol before the next actuation is delivered, and do not disconnect the spacer/VHC from the breathing simulator between actuations.

@2024 USPC

Remove the filter carefully from its location and place it in a suitable container. Add a predetermined volume of a suitable solvent to the container and agitate to dissolve the collected drug. Transfer a sample to a cuvette or vial for drug assay using a syringe equipped with an in-line filter to retain any suspended material. Recover the mass of drug from the filter by using a validated procedure appropriate to the specific product, and assay for the mass of drug collected by using a validated procedure. Calculate the total mass of drug per actuation; this is the emitted mass in the fully coordinated condition ($EM_c$). Repeat the measurement with the required number of devices and replicates per device.

TEST, PART 2

[NOTE—This part of the test is inappropriate for spacers.] For the second part of the test, either clean the VHC between measurements or evaluate a new VHC out of its packaging, as required and justified. Report whether cleaning or replacement of the VHC was carried out. Repeat the procedure above in *Test, Part 1* with the same VHC, this time actuating the MDI timed to coincide with the onset of exhalation. Calculate the total mass of drug per actuation; this is the EM in the fully uncoordinated condition ($EM_{uc}$). Repeat the measurement with the required number of devices and replicates per device.

Calculate the ratio of $EM_c$ with the $EM_{uc}$.

## 4.2 With Facemask

TEST, PART 1

The purpose of this test is to compare the EM from a spacer/VHC equipped with a facemask to that obtained in the fully coordinated simulation with the facemask removed. Facemasks are widely prescribed for infants, small children, and adults who lack coordination to use a mouthpiece-based product. The evaluation of spacers/VHCs supplied with a facemask, rather than a mouthpiece, requires additional attention beyond the methods described previously, because the facemask itself has a major part to play in the transport of the drug-containing aerosol particles from the add-on device to the patient (*Figure 7*). It is therefore important that the facemask be tested in situ as part of the add-on device, rather than separately. A critical component of the test apparatus is the representation of a human face appropriate to the age range for which the add-on device is intended (e.g., neonate, infant, small child, or adult). There are few models that can be defined as an apparatus in a way that is similar to what is done for cascade impactors in the aerodynamic particle size analysis of MDI-generated aerosols, although some face models are currently available commercially. Ideally, standardized, age-appropriate models would be preferred. ▲▲ (USP 1-Dec-2019)

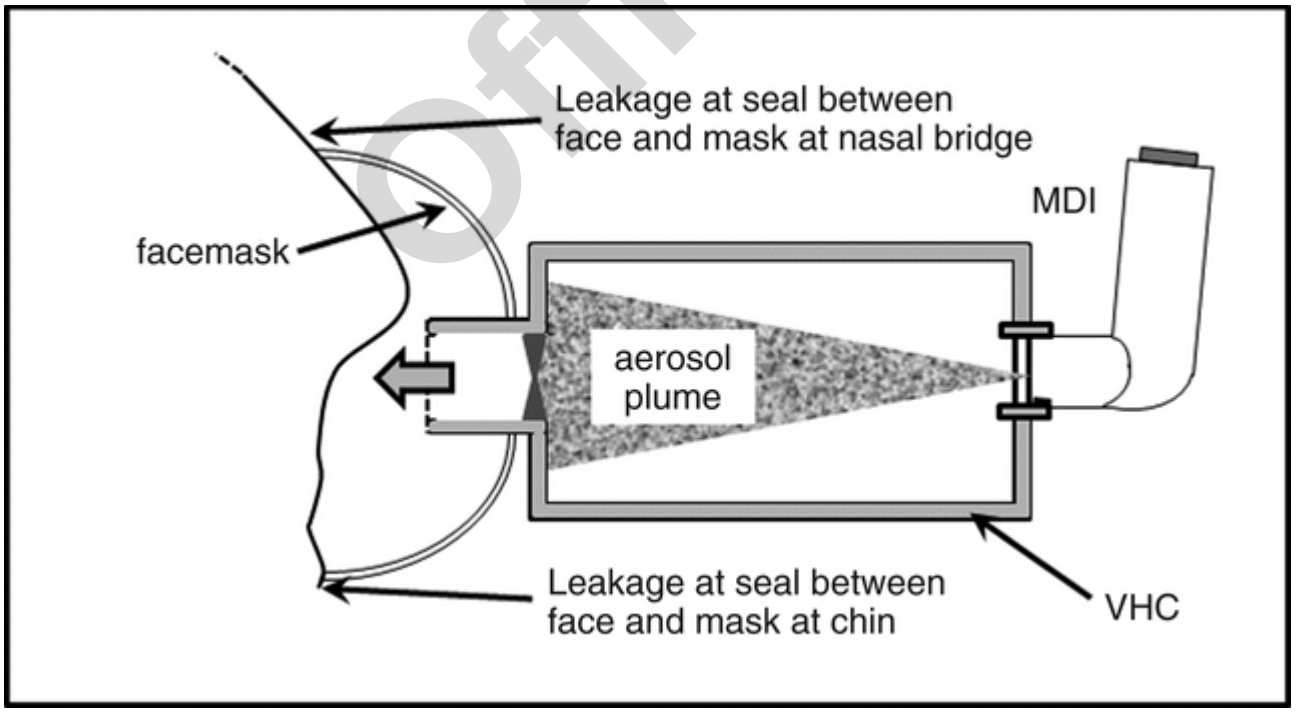

Figure 7. VHC with facemask applied to face.

Ideal attributes for face models are the following:

- Appropriate facial dimensions for the intended user age range
- Ability to apply the facemask with the predicted amount of dead space when it is applied with a clinically appropriate force to the model
- Physiologically accurate soft facial tissue modeling around the chin, cheeks, and nose where the facemask makes contact

https://pharmacopeia.cn/v-download/

- Means of correctly mounting the spacer/VHC so that the facemask is oriented with the correct alignment to the face, as would occur when in use by a patient

[NOTE—Some models may include anatomically accurate realization of the upper airway (naso- or oropharynx), with the aerosol collection filter located at the distal port of the model representing the entry to the lungs.]

For the sake of simplicity and to realize a measure of spacer/VHC performance comparable to the measure obtained with facemask removed in *Parts 2*▲*A* and *B*▲ (USP 1-Dec-2019) (see *Figure 4*), the default assumption is that the model face simulates open-mouth breathing without an anatomically accurate upper airway, and that the aerosol collection filter is located in a cavity immediately behind the lips of the model. Alternatively, if an obligate nasal breathing infant model is being used, then the filter can be placed behind the nares. The mass of drug is reported as the emitted mass ($EM_{facemask}$).

Select a face model appropriate to the intended age range for the spacer/VHC facemask, and mount the face model in an appropriate fixture. The fixture should enable the facemask to be located at an appropriate angle to the face model, such that an effective seal between the facemask and face model is created with a clinically appropriate force. This is typically a loading force of 1.6 kg but may differ from this value if justified by the design of the facemask. The arrangement shown schematically in *Figure 8* is one way of achieving the desired result, but other approaches may be adopted as required, if justified.

Locate and secure the filter media in the cavity behind the lips of the face model. Filtrete is a suitable electret filter medium ▲▲ (USP 1-Dec-2019) that readily releases collected drug quantitatively upon addition of a suitable solvent during the assay procedure. However, another suitable filter medium may be used, provided that the tester is satisfied that it is capable of collecting the entire emitted dose, and that drug recovery for the assay is quantitative.

Verify that a seal has been obtained between the facemask and face model. This is conveniently done by connecting the outlet (distal) port of the face model, using a short length of flexible hose, to an in-line calibrated gas flow meter whose distal port is in turn connected to the vacuum source via a regulating valve capable of setting the flow rate to a suitable value, typically 30 L/min. Connect a similar flow meter to the port for the MDI (MDI adapter) on the spacer/VHC, and ensure that the mask is positioned in order to maximize flow rate. ▲▲ (USP 1-Dec-2019)

[NOTE—Leakage from the facemask to face seal, as detected by lower flow rate, is known to reduce drug delivery.]

Turn off the vacuum source after this check has been completed, and disconnect the flexible hose from the in-line flow meter. Remove the upstream flow meter from the MDI adapter of the spacer/VHC.

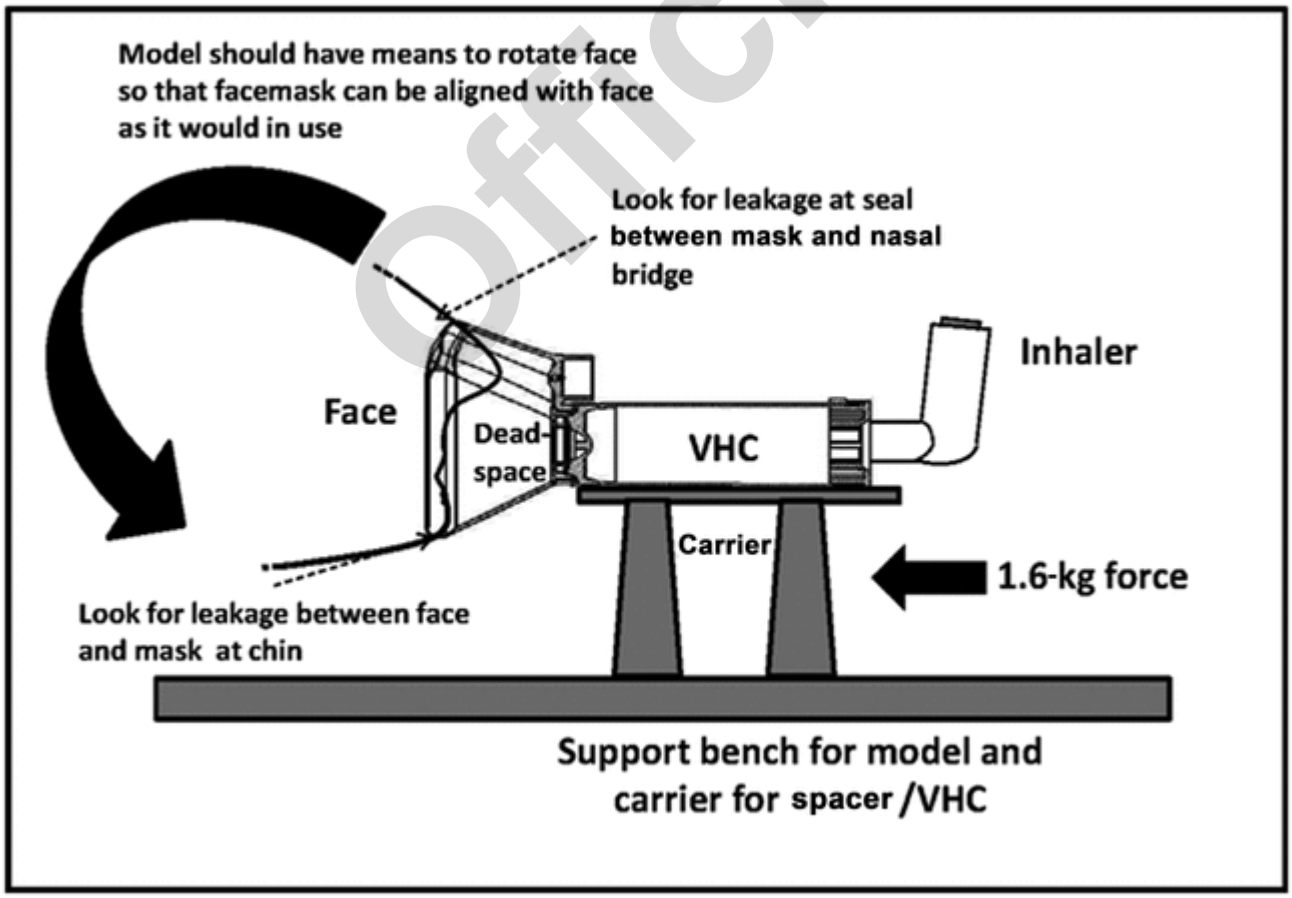

Figure 8. Mount for face model with alignment fixture including carriage for spacer/VHC; a fixed (i.e., 1.6-kg) weight acts on the pulley below the VHC and draws the carriage toward the face with the required force.

Connect the outlet (distal) port of the face model to the appropriate port of the breathing simulator using a short length of flexible hose. Set the breathing simulator to the required breathing pattern (identified from *Table 3*) in accordance with the manufacturer's instructions. Alternative breathing patterns may be used if required. Ensure that the simulator has been

Official

https://pharmacopeia.cn/v-download/

calibrated before use so that the actual volumes and frequency are within ±5% of the indicated value during each breathing cycle. Calibration syringes are available from various suppliers of mechanical ventilation equipment to verify volumes. To verify frequency, the method varies among breathing simulator manufacturers, and therefore the advice of the particular supplier/manufacturer should be sought if the method is not explicitly stated in the operating instructions for the apparatus. Ensure that the selected flow waveform from the breathing simulator is stable before proceeding.

Follow the directions in the patient information and instructions for use for the MDI to prime it before inserting it into the MDI adapter of the spacer/VHC before the first actuation into the test apparatus. In the case of an add-on device equipped with an integral actuator, after priming the MDI canister in its mouthpiece adapter as supplied, remove the canister from the adapter, and clean the external valve stem with a suitable wipe. Insert the canister valve stem into the receptacle according to the instructions for use for the particular add-on device, taking care to avoid premature actuation. Typically, it should require only one actuation of the MDI into the spacer/VHC per determination. However, for certain highly potent products delivering a low-unit mass of drug per actuation, more than one actuation of the MDI may be needed to collect a sufficient mass of drug product. Under such circumstances, follow the directions in the patient instructions or allow a minimum of 30 s between actuations if no direction is provided. Deliver the minimum number of actuations needed to obtain an adequate sample of the drug so that mass measurements can be made with acceptable precision.

Perform a single actuation in the spacer/VHC, timed to coincide with the beginning of an inhalation (see *Figure 4*, *Part 3A*). Allow sampling to occur for five additional breathing cycles for the actuation. If additional actuations are required to improve analytical sensitivity, ensure that the sampling time is of sufficient duration for the spacer/VHC to be emptied of remaining aerosol before the next actuation is delivered, and do not disconnect the spacer/VHC from the breathing simulator between actuations.

Following the tests, remove the filter carefully from its location and place it in a suitable container. Add a predetermined volume of a suitable solvent to the container and agitate to dissolve the collected drug. Transfer a sample to a cuvette or vial for drug assay using a syringe equipped with an in-line filter to retain any suspended material. Recover the mass of drug from the filter by using a validated method appropriate to the specific product, and assay for the mass of drug collected by using a validated procedure. Calculate the total mass of drug per actuation; this is the emitted mass in the fully coordinated condition with facemask fitted to the spacer/VHC ($EM_{c–fm}$). Repeat the measurement with the required number of devices and replicates per device.

The values of $EM_c$ from the test undertaken in *Part 2*▲*A*▲ (USP 1-Dec-2019) (see *Figure 4*) in which the facemask adapter was removed for comparison of EM, simulating fully coordinated use by a breathing simulator can be compared to the $EM_{c–fm}$ in order to understand the impact of the facemask on drug delivery.

## TEST, PART 2

For a VHC only, the same process can be repeated, but with the MDI actuation(s) timed to coincide with the beginning of exhalation (rather than inhalation) (see *Figure 4*, *Part 3B*). In this instance, the mass of drug collected per actuation is the emitted mass in the uncoordinated condition ($EM_{uc–fm}$). The ratio of $EM_{c–fm}$ from *Part 1* ▲of this test▲ (USP 1-Dec-2019) and the $EM_{uc–fm}$ can now be calculated.

## 1. INTRODUCTION

### 1.1 Background and Rationale

The multi-stage cascade impactor is the mainstay methodology for the determination of aerodynamic particle size distribution (APSD) of aerosols emitted by Inhalation Aerosols and Sprays, and Inhalation Powders, as described in *Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩. This equipment is also recommended for APSD assessment associated with the use of drug products dispersed by nebulizing systems in *Products for Nebulization—Characterization Tests* ⟨1601⟩ as well as for the assessment of add-on devices for use with inhalation aerosols in *Spacers and Valved Holding Chambers Used With Inhalation Aerosols—Characterization Tests* ⟨1602⟩. Both chapters provide instructions on how to determine APSD, but due to necessity are focused on the measurement process itself, and are therefore limited in the advice given to assist in obtaining consistent measurements by these apparatuses. The cascade impactor is a complex apparatus to set-up, use, and maintain correctly. This chapter provides guidance to optimize the accuracy and precision of the methods described in ⟨601⟩, ⟨1601⟩, and ⟨1602⟩ for the determination of APSD.

Regulatory activity in the mid-1990s that led to the 1998 publication of a draft US FDA Guidance for Industry on metered dose inhaler (MDI) and dry powder inhaler (DPI) drug products chemistry, manufacturing, and controls documentation obviated the need for an informational chapter covering good cascade impactor practice (GCIP). This draft Guidance (Metered Dose Inhaler (MDI) and Dry Powder Inhaler (DPI) Products—Quality Considerations) was updated in 2018. Following the release of this document, the International Pharmaceutical Aerosol Consortium on Regulation and Science (IPAC-RS) and later the Product Quality Research Institute (PQRI), recognized that there was a need to define a method of addressing a failure to achieve a mass balance in the quality testing of orally inhaled products (OIPs). After the PQRI working group was concluded, the Cascade Impactor Working Group of the IPAC-RS continued to address reports from stakeholders that the cascade impactor method was complex, resulting in measurement failures that were not attributable to product quality. Later, the European Pharmaceutical Aerosol Group (EPAG) established the acceptability of stage mensuration as a means for a regular check on aerodynamic size-separating performance of the component stages and exploring methods of collection surface coating, eliminating leakage into the apparatus and setting the volumetric flow rate correctly.

The purpose of GCIP is therefore:

1. To ensure appropriate size-fractionation of the inhaled product;
2. To establish the APSD profile of the delivered dose reliably, minimizing sources of potential bias and optimizing measurement precision;
3. To obtain adequate resolution of the fine particle mass component of the delivered dose;

@2024 USPC

4. To establish the precision of manufacture of impactor apparatuses and accessories with consideration for allowed tolerances and material of construction; including information on calibration, verification, and mensuration-related issues of the apparatus upon receipt and after use.

The rationale for the chapter is to guide both new and existing cascade impactor equipment users as to industry best practices in connection with set-up, use, maintenance, and storage between uses. The ultimate goal is to establish and maintain the capability to determine the APSD and quality consistency of drug product batches.

## 1.2 Purpose and Scope

The purpose of this chapter is to define a series of measures that should be taken to improve the likelihood of reliably making valid measurements of APSD from a product for inhalation by any of the cascade impactor apparatuses described in ⟨601⟩. Its focus is on the measurement apparatus itself.

The scope is in four main parts:

1. Generic description of the operating principle of the cascade impactor;
2. Apparatus maintenance, including ancillary equipment such as the pre-separator (PS), used for some APSD measurements and the induction port entry to the measurement system;
3. Method development for inhaler APSD determinations, providing guidance on how to structure a series of measurements to obtain information regarding the variability associated with the determination, as well as advice regarding the mitigation of common causes of measurement bias;
4. In-use aspects, in particular the step-by-step checks that should be made before each measurement, addressing cleaning and storage of the apparatus components, maintaining the integrity of individual apparatus sets where more-than-one cascade impactor and the associated equipment is in service, and lastly advising on checks that should be made to provide assurance of component interchangeability following appropriate component validation procedure(s) (for example, the use of a common PS with several different impactors or the use of the same collection plate or cup in several different impactors of the same type).

This chapter is not intended to provide a line-by-line guide to APSD measurement, as some of this information is provided in ⟨601⟩, ⟨1601⟩, and ⟨1602⟩ for the various inhaler product types. Neither does it provide detailed procedures, because in many cases, such information will be product-specific. Rather, the information presented is meant to summarize current thinking as to the implementation of best practices in cascade impactor maintenance and use in terms of robust protocols for the laboratory making these measurements. When developing such protocols, users are also advised to consult with current regulatory guidance documents that address inhaler APSD measurement, for example, those published from time to time by the FDA.

## 1.3 Specific Information Regarding Impactor Stage Mensuration

In *4.1 Stage Mensuration, Measurement Traceability, and Mensuration Interval*, information regarding the stage optical mensuration of nozzles associated with the sizing stages of cascade impactors is given to aid the user in identifying the critical aspects of the process and how mensuration provides traceability of the measures of size ultimately to the international length standard via intermediate calibrated objects, such as optical reticles or orifices of known diameter, having a circular profile. However, since specialized optical inspection equipment is required to acquire the mensuration data, it is assumed likely that the user will employ a specialized service in order to undertake the task, so detailed methodology is not provided.

# 2. DEFINITIONS OF KEY TERMS RELATING TO THIS CHAPTER

**Aerodynamic diameter ($D_{ae}$):** The aerodynamic diameter of an irregular particle is defined as the diameter of the spherical particle with a density of water [1000 kg/m$^3$ ($\rho_0$)] and having the same settling velocity under the influence of gravity as the irregular particle. $D_{ae}$ is related to the microscopy-measured physical diameter (volume equivalent diameter, $D_p$) in accordance with:

$$D_{ae}C_{ae} = \left[\frac{\rho_\rho}{\rho_0 \chi}\right]^{1/2} D_\rho C_\rho \quad [1]$$

$C_{ae}$ and $C_p$ = slip correction factors corresponding to $D_{ae}$ and $D_p$, respectively, both of which can be regarded as being close to unity for the sizes of aerosol particles from inhalers for which APSD is being determined
$\rho_p$ = particle density
$\chi$ = dynamic shape factor[1] (1.00 for spherical solid particles or liquid droplets, >1.00 for non-spherical particles)

**Effective diameter ($W_{eff}$):** The representative diameter for a collection of nozzles forming a multi-nozzle stage of a multi-stage cascade impactor. Effective diameter is defined analytically as the product of the area mean diameter ($W^*$) raised to the power of 2/3 and the area median diameter ($W_{median}$) raised to the power of 1/3:

$$W_{eff} = (W^*)^{2/3}(W_{median})^{1/3} \quad [2]$$

$W^*$ = area mean diameter
$W_{median}$ = area median diameter

For a single-nozzle stage, $W_{eff}$ defaults to the mensurated diameter of that nozzle.

**Stage cut-point size ($d_{50}$):** The size on the aerodynamic diameter scale at which a given impactor stage collects incoming particles with 50% efficiency. The relationship between collection efficiency and $D_{ae}$ is described further in *3. Cascade Impactor Operating Principles*.

**Stokes number (*St*):** The dimensionless term characterizing the behavior of solid or liquid particles suspended in a fluid flow, such as air. A particle with a low Stokes number follows the air streamlines. In contrast, a particle possessing a large Stokes number is dominated by its inertia and so that it continues along its initial trajectory when the flow passes an obstruction, for example, as it diverges upstream of the collection surface of an impactor stage (see *Figure 1*). $St_{50}$ is the Stokes number corresponding to the cut-point size at which the impactor stage is 50% efficient at collecting the incoming particles.

**Stage mensuration:** The process of establishing the representative diameter at the exit of each nozzle of a stage forming part of a multi-stage impactor. Although pin or go/no gauges can be used to mechanically measure nozzles having diameters in excess of about 2 mm, it is more common currently to make the determination non-invasively by using automated optical microscopy combined with image analysis.

## 3. CASCADE IMPACTOR OPERATING PRINCIPLES

A cascade impactor size-fractionates incoming aerosol particles into several sub-fractions on the basis of their differing inertia. A typical design, such as the apparatuses described in ⟨601⟩, comprises several consecutive stages, each of which functions as an inertial size-separator or fractionator of the incoming aerosol in a gas stream moving at constant velocity (flow rate). The basic component is a single stage that comprises a nozzle plate containing one or more circular orifices located a fixed distance from an impaction plate/cup surface that is usually horizontal (see *Figure 1*). The following characteristic dimensions describe the operating property of the stage:

$W_{eff}$: effective nozzle diameter—most stages will contain *n* nozzles machined to be as close to identical as possible
*T*: thickness of the nozzle plate
*S*: separation distance between exit plane of nozzle plate and the collection surface

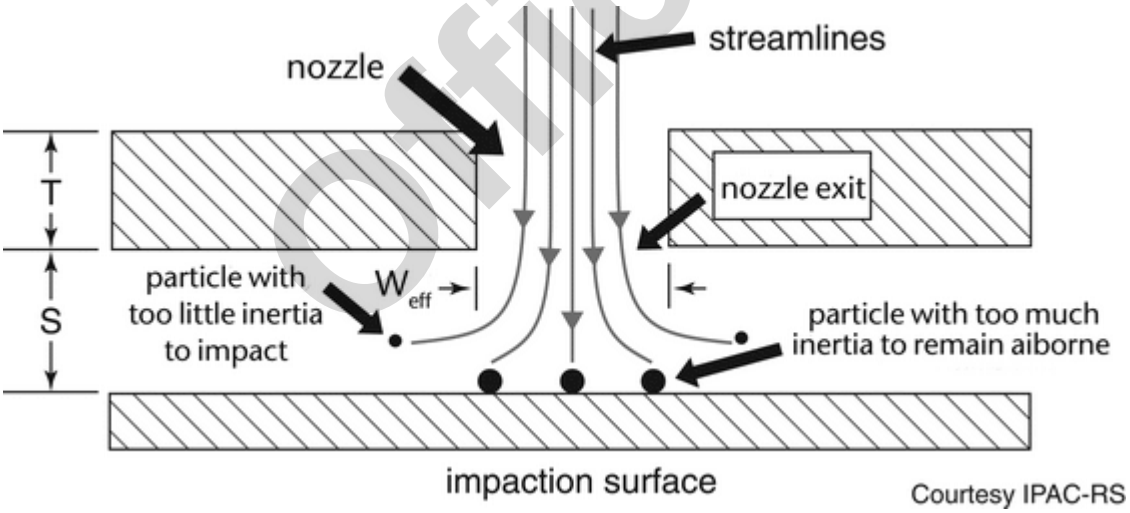

Figure 1. Generic single-stage impactor showing nozzle plate and collection surface located immediately below the plane of the nozzle exit. Several consecutive stages connected together with nozzle sizes that progressively get smaller constitutes a cascade impactor.

The stage functions by fractionating incoming particles of various sizes on the basis of their differing inertia, the magnitude of which reflects the resistance to a change in direction of the laminar flow streamlines passing through each nozzle. As the incoming flow passes through the nozzle plate, the streamlines diverge on approach to the collection surface, whereas the finite inertia of the particles causes them to cross the streamlines. Depending upon how far a given particle diverges from the streamlines, its trajectory may cause it to collide (impact) with the collection surface located at a distance, *S*, close to the exit plane of the nozzle set.

The magnitude of *T* is set by the manufacturer during design of the impactor stage, and in general, does not change measurably in use. In contrast, the size of *S* can be reduced by coating of the collection surface to mitigate particle bounce (see *5.4 Mitigation of Particle Bounce and Re-Entrainment*), as well as by the accumulation of deposited particles on the collection surface. The ratio, $S/W_{eff}$, can vary widely in the range 1–10 for effective size fractionation to occur, and therefore changes in this ratio are unlikely to influence stage performance, given typical mass loadings associated with inhaler APSD measurements, even on the stages where most of the particulate deposits.

The dimensionless Stokes number (*St*), which is the ratio of the stopping distance of a particle to a characteristic dimension, in this case the nozzle diameter, $W_{eff}$, describes the size fractionation process by defining a critical particle size that will reach

@2024 USPC

the collection surface for a particular stage geometry. *St* is defined in terms of the stage effective diameter by the following relationship:

$$St = \frac{\rho_\rho C_{\text{ae}} d_{ae}^2 u}{9\mu W_{eff}} \text{ [3]}$$

$C_{ae}$ = designated as unity from this point onwards
$d_{ae}$ = particle aerodynamic diameter
$u$ = air velocity through the nozzle plate
$\mu$ = air viscosity

In a cascade impactor, several stages are connected together such that $u$ progressively increases through the cascade by reducing $W_{eff}$ (see *Figure 2*).

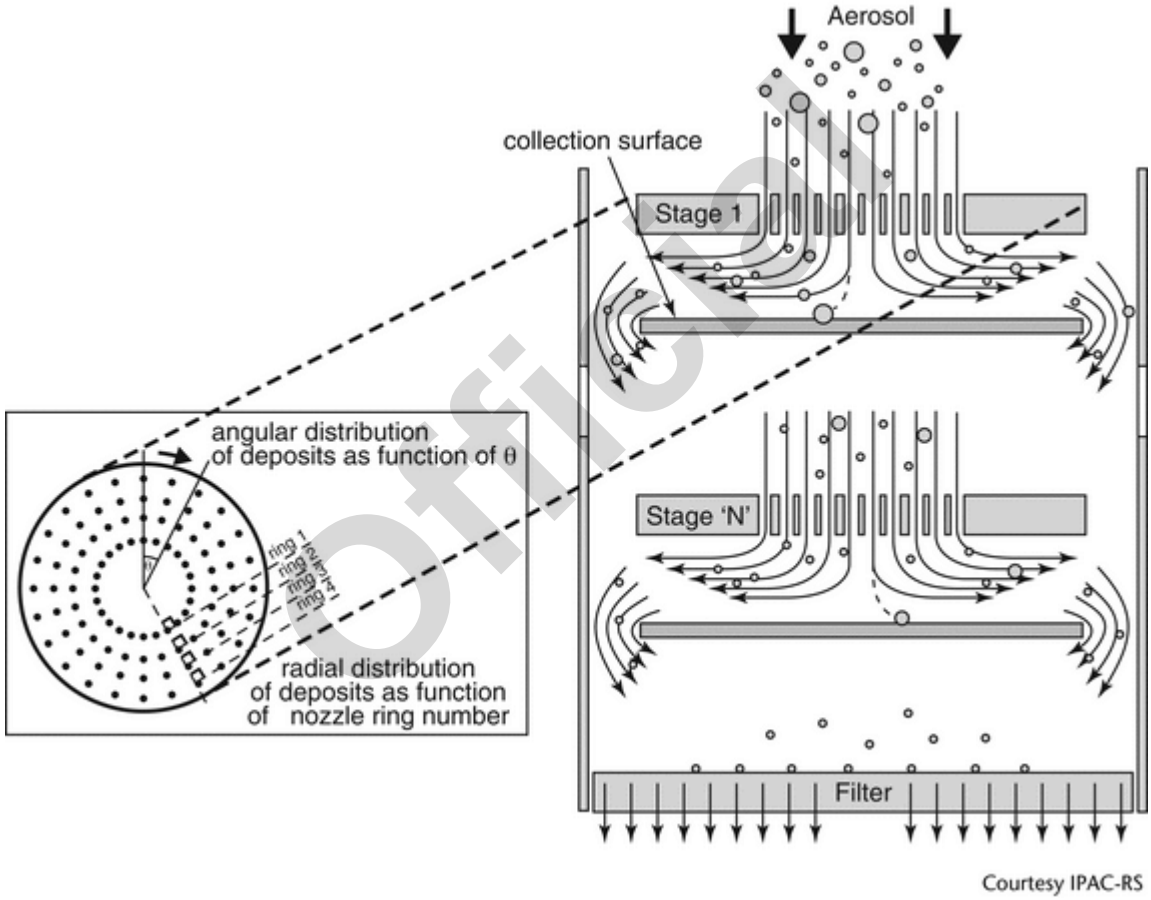

Figure 2. Conceptual multi-stage cascade impactor—Typically there are 7 or 8 stages from the entry to the back-up filter or micro-orifice collector (MOC) in the case of the Next Generation Impactor; the function of the filter/MOC is to capture any particles that have penetrated beyond the lowermost stage 'N'.

*Equation 4* predicts that the particle collection efficiency of an ideal impactor stage, $E_{stage}$, expressed as a percentage, will increase in a step-wise manner between limits of 0%–100%, as $d_{ae}$ increases. In practice, for a well-designed stage, $E_{stage}$ is a monotonic sigmoidal function of $d_{ae}$ that increases steeply from $E \approx 0\%$ to >95%, reaching its maximum steepness when $E_{stage}$ is 50% (see *Figure 3*). At this location, defined as the stage cut-off diameter ($d_{50}$), this equation also defines the relationship between $d_{50}$, $St_{50}$, and volumetric flow rate ($Q$) for a multi-orifice stage comprising $n$ circular nozzles:

$$d_{50} = \left[\frac{9\pi\mu n W_{eff}}{4\rho_0 Q}\right]^{1/2} \sqrt{St_{50}} \text{ [4]}$$

$\sqrt{St_{50}}$ is close to 0.49 at $d_{50}$ for all stages of each cascade impactor type described in ⟨601⟩.

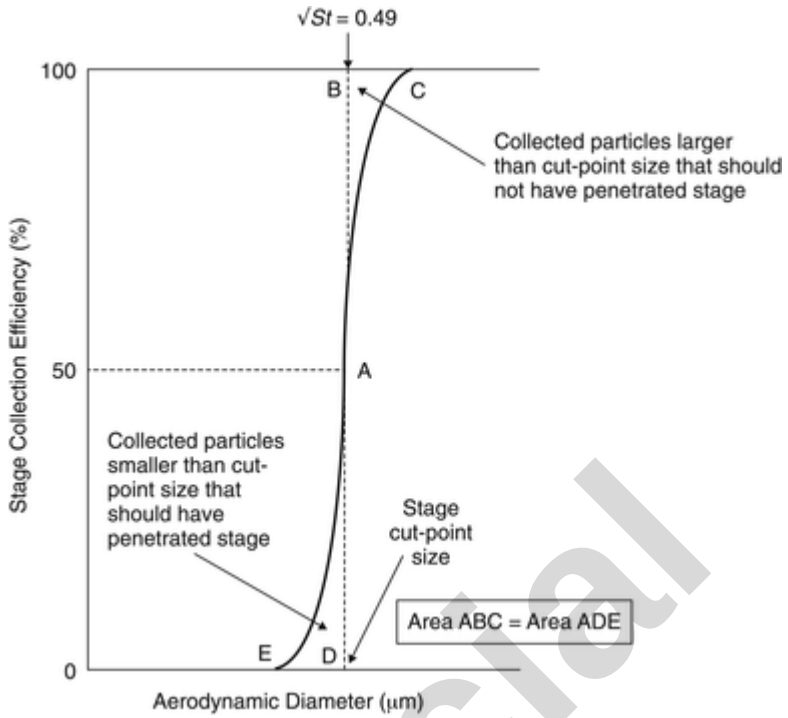

Figure 3. Generic impactor stage collection efficiency curve—The ideal step function at the size corresponding to the cut-off diameter is shown together with the sigmoidal curve representing normal behavior.

In a well-designed stage, the area ABC of *Figure 3*, representing the portion of the incoming aerosol contained in particles larger than the cut-point size that should have been collected, but instead bypassed the collection plate/cup, equals the corresponding area ADE that represents the portion of the aerosol contained in particles smaller than the cut-point size that should have penetrated the stage, but instead were collected there. The result is that $d_{50}$ for a given stage can be used to define its size-fractionating performance as if it was ideal in this respect.

An important outcome arising from *Equation 4* is that the cut-off diameters of all the stages in a given cascade impactor are constant only when $Q$ is also constant. It follows that for the testing of dry powder inhalers in accordance with the methodology in ⟨601⟩, the stage cut-points will not be at their final steady state values until the volumetric flow rate is constant after initiation of sampling from no flow by opening the two-way solenoid valve located between the exit from the impactor and the vacuum source. This process can take up to 400 ms for impactors having large internal volume, in particular, the Next Generation Impactor (NGI) with its PS. In practice, this finite start-up time is ignored in such assessments on the basis that it represents a small fraction of the total time during which the 4.0-L volume is sampled for inhalation powders. More importantly, however, any leakage of ambient air into the impactor at locations other than via the induction port, will increase the local value of $Q$ after the leakage point, and in consequence result in an uncontrolled decrease in $d_{50}$ for stages downstream. Bias arising from leakage into the impactor is therefore discussed further in *6.5 Mitigation of Air Leakage into the Apparatus*.

## 4. APPARATUS MAINTENANCE

### 4.1 Stage Mensuration, Measurement Traceability, and Mensuration Interval

The performance of a specific stage of a cascade impactor depends primarily upon the physical integrity of the nozzles. It follows that the precision of manufacture of these critical components is a factor that may contribute to variability of APSD results when measurements of the same inhaled product are made with more than one impactor. Furthermore, use-related changes to the nozzle dimensions of a given impactor may result in the development of APSD measurement bias during time in service. Mensuration is therefore appropriate both for new impactors and at intervals during their lifetime in service.

Nozzles can become partially plugged by deposited particles or through corrosion of the metal from which the stage nozzle plate is manufactured. Alternatively, they can become widened with time, either through corrosive action or by mechanical damage, for instance during cleaning if a sharp object is used to penetrate the nozzles. In the past, stage performance was determined by calibrating the stage with uniform-sized (monodisperse) particles of known aerodynamic diameter. However, the process is time-consuming as many different sizes of calibration particles are required to define the collection efficiency curve to the required precision. Since the advent of automated microscopy-image analysis, the procedure of stage mensuration has replaced particle calibration. In stage mensuration, the diameter of each nozzle exit is directly measured to a high degree of accuracy and precision, and the effective diameter ($W_{eff}$) is calculated to represent the entire group of nozzles where more than a single nozzle is present. In the latter case, the single nozzle diameter is identical with $W_{eff}$. The calculated value of $W_{eff}$ is compared with the tolerance range established for that stage for either the Andersen Cascade Impactor or the NGI in ⟨601⟩ to establish if the stage is within specification. The mensuration equipment is in turn calibrated with reference objects that are

@2024 USPC

traceable ultimately to the international length standard. It is anticipated that the cascade impactor user will have the procedure undertaken by an external provider, who will typically be the supplier of the impactor, so the focus here is on establishing a regimen for maintaining assurance that any given stage of any cascade impactor remains within the manufacturer's specification as defined in ⟨601⟩.

The scheme shown in *Figure 4* illustrates the components of a mensuration protocol for initial receipt and subsequent assessment of any of the impactors described in ⟨601⟩. The following checks are recommended:

1. Installation qualification (IQ): At receipt of a new impactor, ensure, as part of IQ, that each stage is compliant with the manufacturer's dimensional specifications. These initial measurements are intended to establish baseline data for each stage of each individual cascade impactor. Undertake mensuration for each and every nozzle of each stage and determine its $W_{eff}$. Compare this measurement against the critical dimensions specified for that stage/cascade impactor in ⟨601⟩. Reject any stage whose $W_{eff}$ is outside the specification. For the ACI, it may be appropriate to substitute the equivalent rejected stage(s) with alternative stages of the same number(s), whose $W_{eff}$ value(s) are within specification. However, in the case of the NGI, the entire unit will need to be returned to the supplier for remedial action to provide stage(s) whose $W_{eff}$ values are within specification. Once values of $W_{eff}$ for all stages are ascertained to be within specification, the entire cascade impactor can be accepted for use.

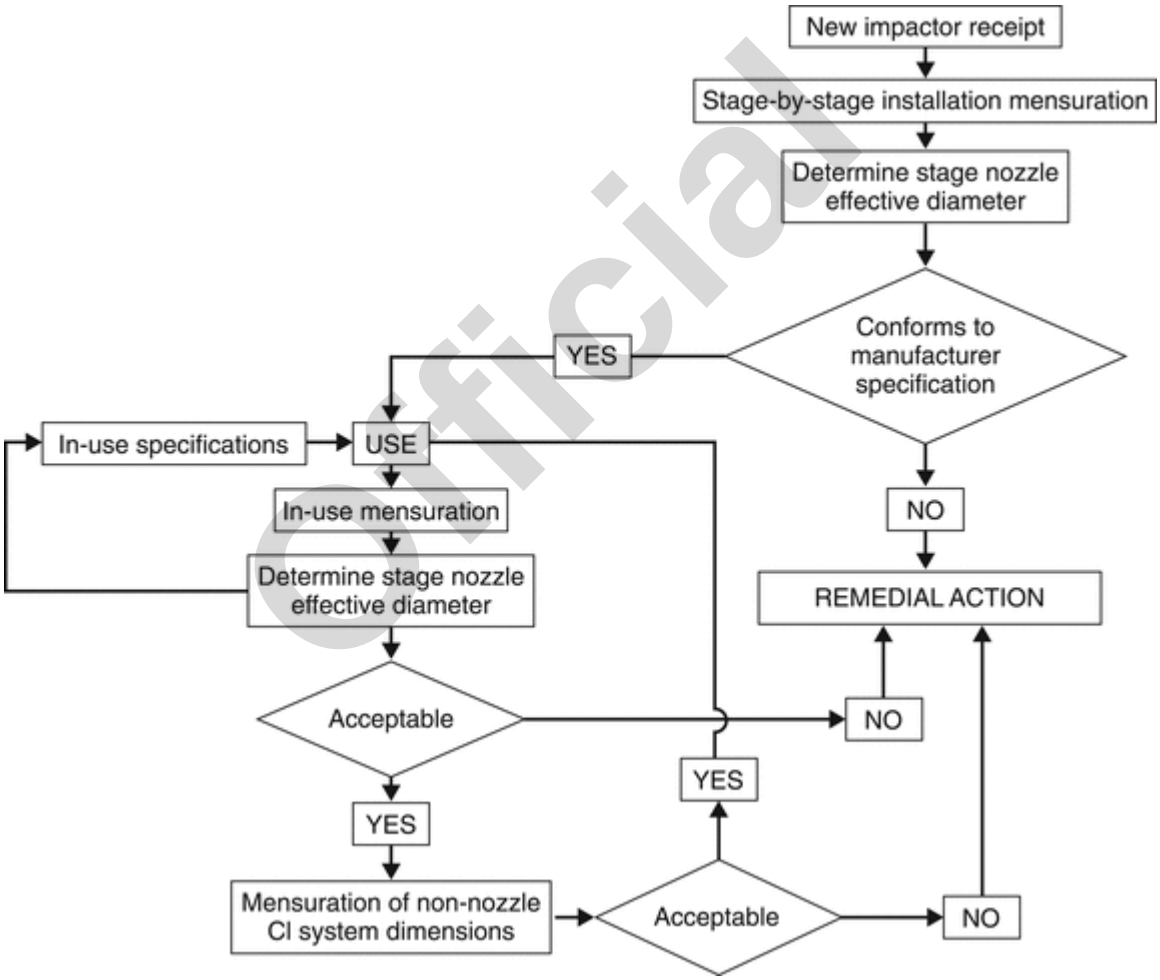

Figure 4. Scheme for the application of stage mensuration to confirm suitability for use of a cascade impactor at initial receipt and at subsequent performance assessment.

[NOTE—The frequency of the "In-use mensuration" check is determined by the amount of impactor use, the material from which the impactor is constructed, the product ingredients, and recovery solvent characteristics.]

2. For stages that are deemed acceptable in terms of the specifications in ⟨601⟩, establish the in-use stage mensuration regimen, whose frequency is determined by the amount of impactor use and the product/active pharmaceutical ingredient solvent chemical characteristics. Each in-use mensuration will always include measuring the individual stage nozzle diameters, determining $W_{eff}$ as the performance metric. The specifications established at initial acceptance will normally be used as benchmarks to judge whether the stage(s) may continue in service or require remediation or replacement. Note that remediation could be as simple as careful cleaning to remove deposits that may be plugging nozzles. Acquisition of data from several subsequent mensuration exercises after exposure to the product(s) being evaluated in the typical testing environment may also provide the opportunity to develop meaningful in-service "at

Printed by: USP NF
Do Not Distribute

mensuration" limits for $W_{eff}$ for a given stage that will likely be chosen to be tighter than those used to begin with. These internal limits can subsequently be used to indicate the need for remediation before the stage $W_{eff}$ breaches either the upper or lower boundary of the tolerance range provided in ⟨601⟩.

3. Following mensuration failure of an impactor, undertake the following:
   A. In the case of the ACI, remove those stages from service that are not acceptable in terms of the manufacturer's specifications, and either recondition them or replace the affected stages altogether.
   B. In the case of an NGI, the entire unit will need to be returned to the supplier for remedial action, if $W_{eff}$ for one or more stages is/are found to be out of specification.
4. Performance qualification (PQ): Establish the frequency between mensuration events. Although annual evaluation will be sufficient for most users, the duration between mensuration exercises should ideally be governed by the frequency of cascade impactor use, the type of compounds being collected, and the solvents used to recover the collected active pharmaceutical ingredient(s) particulate matter as well as the end user established cleaning procedures.
5. Ensure that other non-nozzle dimensional data for the cascade impactor apparatus are checked and confirmed as being acceptable through a mensuration or appropriate visual inspection process. Guidance on the important dimensions for ancillary equipment, such as the induction port and PS (if used), has been provided by Nichols, et al.[2] In the unlikely event that any of the critical dimensions (e.g., entry and exit diameters for the induction port, or nozzle diameters for the PS) are deemed to be unacceptable, remedial action may be as simple as cleaning the affected component. Under such circumstances, discussion with the manufacturer to establish the most appropriate procedure beforehand is strongly recommended. However, if remedial action does not resolve the problem, then the individual component should be replaced before the ancillary apparatus is placed back into service.
6. If any impactor stage or item of ancillary equipment fails specification, establish an appropriate remediation strategy, most likely involving the supplier/manufacturer of the affected equipment.

## 4.2 Internal Losses

Internal losses of particles on surfaces of the cascade impactor, other than the intended collection plates or cups, as well as losses associated with ancillary equipment, in particular the induction port and the PS (if used), are likely to result in a divergence in the recovered mass balance from the ideal label claim value. The magnitude of so-called wall losses, or inter-stage losses, if located within the impactor, is related to the issue of particle bounce covered in *5.4 Mitigation of Particle Bounce and Re-Entrainment*, since particles having adhesive surfaces that have trajectories which graze internal surfaces of the apparatus are more susceptible to be retained there by virtue of their increased ability to adhere once initial contact is made. Furthermore, electrostatic charge associated with the aerosol/dry powder particles being sampled may also result in increased internal losses. Chapter ⟨601⟩ therefore sets an upper limit of 5% of the total delivered drug mass per actuation from the inhaler as a validation requirement to limit the impact of such internal losses on measurement accuracy.

The magnitude of internal losses is also likely to be dependent on the physicochemical properties of the particles being sampled (e.g., surface roughness) that are in turn formulation dependent. Likewise, these losses are dependent upon the internal geometry of the passageways between stages of the impactor and are therefore different from one impactor design to another. In the initial development of a method for a new drug product or when a new design of cascade impactor is placed in service, it is recommended that internal surfaces of the induction port, PS (if used) and cascade impactor (entrance cone and nozzle plates for the ACI or inter-stage passageways for the NGI) be washed from both each other and from the collection surfaces separately with the established minimum necessary volume of recovery solvent to determine the magnitude of the associated internal losses as well as their location. In the product development stage, if the overall losses in APSD determination exceed 5% of the mass balance, and steps to mitigate particle bounce in the cascade impactor (see *5.4 Mitigation of Particle Bounce and Re-Entrainment*) and electrostatic charge (see *5.5 Mitigation of Electrostatic Charge Accumulation*) prove ineffective at reducing such losses, the user may wish to consider an alternative cascade impactor (e.g., replace the ACI with the NGI) to investigate if losses can be reduced below 5%. If this outcome is not possible, the inhaler aerosol APSD measurement procedure can be performed including the total internal wall losses in the assessment of mass balance to confirm that the mass recovery is within the recommended range of label claim for mass of active pharmaceutical ingredient delivered per actuation. In defining the ASPD profile, it is important to note that it is not possible to apportion wall losses from stage to stage within the cascade impactor in an attempt to assign specific size ranges to these losses. The wall loss deposition processes lack the requisite size selectivity associated with each impaction stage.

## 4.3 Inspection of Damaged/Deformed Collection Surfaces

Cascade impactors are typically manufactured from durable materials that are less prone than their predecessor materials (often aluminum) to chemical attack by solvents used in recovery of collected deposits. Nevertheless, the possibility remains that accidental damage may take place in use, especially to the more vulnerable components such as the collection plates (ACI) or collection cups/MOC (NGI). In the case of accidental damage, such as dropping during transit from one location to another, immediate physical inspection for superficial damage should be undertaken. The component should be taken out of use and replaced if damage/deformation is apparent, and is likely to affect performance.

# 5. CASCADE IMPACTOR METHOD DEVELOPMENT

## 5.1 Initial Considerations

The development of a cascade impactor-based method for evaluating the APSD of a specific inhaler product is typically undertaken in consultation with the appropriate regulatory authority. These authorities from time-to-time publish guidance to industry relating to the determination of APSD for inhaled products. The information provided in this part of this chapter is therefore intended to provide underlying information associated with good practice that is intended to assist in the process of establishing an acceptable methodology.

## 5.2 Number of Inhaler Actuations per Determination

Ideally, only one actuation from the inhaler product would be necessary for the APSD determination, and this situation may be possible for products having a high drug mass unit-dose delivery. In practice, more than one actuation may be needed to achieve the required deposition profile throughout the stages of the cascade impactor to enable acceptable measurement precision to be achieved by the drug recovery and assay procedure. However, repeated actuations may disguise any underlying variability in APSD that occur from one actuation of the inhaler to the next, and therefore it is recommended that determination for each inhaler should be performed with the minimum number of actuations justified by the sensitivity of the analytical procedure used to quantitate the deposited drug. The amount of drug deposited on the critical stages of the cascade impactor should be sufficient for reliable assay, but not so excessive as to bias the results by masking individual actuation variability. Here, critical stages are those that collect the smallest particle mass per actuation, where the sensitivity of the recovery method and subsequent assay for the active pharmaceutical ingredient are often limiting factors.

## 5.3 Number of Replicate APSD Determinations

Although the cascade impactor-based method for determining inhaler APSD performance is both a labor-intensive and exacting procedure, automated or semi-automated systems are available to assist in the process. It is common to undertake at least five replicate measurements at each condition being assessed. However, this number will typically be decided by consultation with the appropriate regulatory agency, involving considerations such as prior knowledge of the variability in delivery associated with the product and the number of actuations required through the delivery life of the inhaler.

## 5.4 Mitigation of Particle Bounce and Re-Entrainment

In normal operation, particles collected by a particular stage of the cascade impactor should be retained on the collection surface until the drug is recovered for assay. For certain inhalation aerosols containing surfactant as an excipient as well as products for nebulization that are generated as aqueous droplets, it is likely that the collection surfaces will not need coating with a viscous substrate to mitigate bounce of incoming particles and their subsequent re-entrainment in the flow passing further into the impactor. However, for inhalation powders, coating of collection surfaces other than the filter/MOC will almost certainly be necessary. Such pre-coating is normally used for inhalation powders where the incoming drug particles are accompanied by larger carrier particles.

Particle bounce and associated re-entrainment is easily diagnosed by the presence of a larger than expected mass of drug recovered from the back-up filter/MOC, because once re-entrained, the particles have sufficient velocity to bounce off the collection surfaces of subsequent stages. In method development, it is therefore recommended that evaluation of such behavior be undertaken in a validation study with and without collection surface coating present.

There are numerous methods for collection surface coating, all of which involve the deposition of a thin layer of a viscous substance, such as glycerol, silicone oil, or other suitable substance, such as the surfactant, polyoxyethylene lauryl ether.[3] The coating substance is typically prepared as a solution in a volatile solvent which subsequently evaporates, leaving behind a uniform deposit. The choice of coating material will depend upon the physicochemical properties of the drug product being sampled as well as the subsequent recovery and analytical procedure. Whatever method is chosen for applying the coating substance, each collection surface should be visually inspected for non-uniformities in the coating, and the procedure repeated after cleaning the collection surface, if imperfections are found.

The interior surfaces of the induction port are not normally coated in the procedures described in ⟨601⟩. However, an appropriate pre-defined volume of an appropriate solvent may be dispensed when the PS is used (up to 10 mL to coat the PS interior used with the ACI or up to 15 mL to the central cup of the PS used with the NGI). Alternatively, it may be appropriate to coat the particle collection surfaces with a viscous substance as described for the stage collection surfaces in order to prevent re-entrainment of impacted particles therein.

## 5.5 Mitigation of Electrostatic Charge Accumulation

Acquisition of electrostatic charge can affect the measured APSD by modifying the particle size properties of the aerosol delivered from the device (intrinsic aerosol electrostatic charge) or by changing the deposition of the aerosolized particles within the cascade impactor test assembly (delivery device/apparatus-acquired charging). Both processes result in an increase of variability of APSD measurements, especially when seasonal changes in relative humidity are not controlled, and such behavior is more likely with inhalation powders rather than inhalation aerosols or products for nebulization.

@2024 USPC

Appropriate setup and handling of the inhaler as well as the entire measurement apparatus can significantly reduce variability in test results caused by electrostatics, and practical steps include grounding the measurement equipment as well as the operator (typically via use of a wrist strap and an antistatic laboratory coat). Controlling the local environmental conditions such that testing is undertaken at values of relative humidity in the range 40%–60% is also recommended to avoid variability from electrostatic effects.

***Change to read:***

# 6. IN-USE ASPECTS

## 6.1 Initial Considerations

There are several precautions that should be taken for each and every cascade impactor measurement. The purpose of this section is to provide an ordered sequence of verifications [Operational Qualification (OQ)] for the user to follow to avoid bias associated with errors associated with apparatus set-up (i.e., incorrect impactor assembly) and also in the establishment of the correct operating conditions (i.e., flow rate setting). From a regulatory science perspective, the mass of active pharmaceutical ingredient deposited on a stage-by-stage basis is initially reported to establish the APSD profile of the drug product. At the appropriate time, stage groupings may be proposed based on agreement with the regulatory agency.

## 6.2 Inspection of Cascade Impactor Components Susceptible to Deterioration

Regardless of incidents involving accidental damage, a regimen should be established for periodic visual inspection of all cascade impactor apparatus components, including the induction port and PS (if used), connection tubing, and related flow control equipment. This physical examination is in addition to the stage mensuration of the nozzles of individual stages described in *4.1 Stage Mensuration, Measurement Traceability, and Mensuration Interval*. The frequency of such inspections will depend upon the amount of use the components receive, as well as experience gained with time in service; however, as a start an annual inspection is recommended. Inspected components that are deemed damaged or marginally functional should be identified as such and removed from service. Visual inspection of the seal body and inter-stage passageways of the NGI can be difficult, and may therefore best be undertaken by the supplier/manufacturer. The component should be replaced or repaired to the manufacturer's specification, if any damage/deformation is apparent.

The external 'O'-ring seal associated with each stage of the ACI is particularly susceptible to crack formation in normal use. Each seal should therefore be visually inspected for cracking, scratch marks, and gross deformation on each occasion of use and replaced if damaged. The corresponding elastomer rings located in the seal body of the NGI should likewise be visually inspected before use and replaced if damaged.

## 6.3 Assurance of Stage Collection Surface Coating

Coating of the stage collection plates (ACI) or cups (NGI) may be necessary to mitigate bias in the APSD measurement caused by particle bounce and re-entrainment (see *5.4 Mitigation of Particle Bounce and Re-Entrainment*). Since the coating procedure can be highly operator dependent, even if semi-automated, once a suitable coating method has been established and validated, each coated collection plate or cup should be visually inspected before assembly into the impactor to be sure that the applied coating is uniform and that no locations are apparent that remain uncoated.

## 6.4 Assertion of Correct Assembly

### 6.4.1 ANDERSEN CASCADE IMPACTOR

The individual stages are separated when the impactor is disassembled fully between determinations. The manufacturer may identify each nozzle plate with its stage number. However, if there is more than a single impactor in service, nozzle plates should be further identified as belonging to a particular impactor assembly, either by embossing the impactor serial number on the underside of each plate (so as not to affect the particle deposition surface), or by an acceptable means of identification, in order to preserve the integrity of the stage mensuration process by linking it to a specific cascade impactor assembly (see *4.1 Stage Mensuration, Measurement Traceability, and Mensuration Interval*).

If an inhalation aerosol or spray is being tested, the stage order is as illustrated for configuration A in *Table 1*, and the cascade impactor is operated at 28.3 L/min for evaluating an inhalation aerosol or spray (see also ⟨601⟩, *Table 4* for critical nozzle dimensions). If an inhalation powder is under evaluation, there are three configurations A, B, and C of *Table 1* for stage ordering, depending upon the target flow rate of 28.3 L/min, 60 L/min, or 90 L/min, respectively (see also ⟨601⟩, *Table 3a* for stage cut-point sizes).

The annular collection plates for the uppermost two stages are interchangeable, as are the solid surfaced plates for the following 6 stages so there is no need to identify each collection plate to belong to a specific impactor. However, during assembly it is important not to mix the order in which the two types of collection plate are assigned to each stage.

Following completion of the collection plate coating procedure (see *5.4 Mitigation of Particle Bounce and Re-Entrainment*), set out the individual stages, each with their collection plate in the order in which they will be assembled (see *Table 1*) on the bench-top. Starting with the base-plate, insert a suitable filter disk into the recess of the filter stage and secure with the 'O'-ring provided. Secure the filter stage on top of the base-plate. Locate the collection plate for the bottom-most size-fractionating stage on the three supports at the periphery of the filter stage, then secure the bottom-most stage nozzle plate to the filter stage. Continue assembling the stack vertically, first positioning the collection plate for the next stage, followed by securing

the corresponding nozzle plate. Attach the inlet cone to the uppermost nozzle plate if an inhalation aerosol or spray is being tested, or the PS, assembled in accordance with the instructions in ⟨601⟩, if the impactor is being used to assess an inhalation powder, unless justified by data that PS is not necessary. Finally, secure the induction port to the entry of the inlet cone (inhalation aerosol or spray assessment) or PS (inhalation powder assessment) to complete the assembly of the impactor stack.

**Table 1. The Three Configurations of the Andersen Cascade Impactor—Configuration A is Used at 28.3 L/min for the Evaluation of Inhalation Aerosols and Sprays; Configurations A, B, or C are Used for Evaluation of Inhalation Powders Depending Upon the Target Flow Rate (28.3, 60, or 90 L/min, Respectively)**

| Stage Configuration | | |
|---|---|---|
| **A** | **B** | **C** |
| 28.3 L/min | 60 L/min | 90 L/min |
| 0 | –1 | –2 |
| 1 | –0 | –1 |
| 2 | 1 | –0 |
| 3 | 2 | 1 |
| 4 | 3 | 2 |
| 5 | 4 | 3 |
| 6 | 5 | 4 |
| 7 | 6 | 5 |
| Filter | Filter | Filter |

[NOTE—Stage '0' is modified to accept stage '–1' for operation at 60 L/min or stages '–1' and '–2' together for operation at 90 L/min. In either case, the inlet cone is replaced by the modified stage '0' and used above either stage '–1' or stage '–2' depending upon the chosen flow rate.]

### 6.4.2 NEXT GENERATION IMPACTOR

There is only a single configuration of the NGI that can be operated at 15 L/min for the assessment of products for nebulization (see ⟨1601⟩, *Table 2*), at 30 L/min for inhalation aerosols and sprays or at flow rates between 30 and 100 L/min for the assessment of inhalation powders (see ⟨601⟩, ▲*Table 3b*▲ (CN 1-May-2021) for stage cut-point sizes).

There are two sizes of collection cups; the two larger cups are located beneath the collection plate for stage 1 and under the MOC (or internal filter, if used), the six smaller cups are located beneath stages 2–7. Cups of a given size are interchangeable. Although this impactor can be operated without the cup tray, it is normal practice to insert the cups into the tray before each determination, since their order with respect to the stage number is easily preserved after each measurement by removing the tray and cups as a single unit from the bottom frame for transfer to the station where drug recovery takes place. Alternatively, multiple cup-sets may be used with a single cup tray or each cup set can be assigned to a particular cup tray, depending on the number of APSD determinations that need to be made per day, as well as the operating regimen in force within the laboratory. For instance, assigning cup sets to a particular tray is useful if separate operators are responsible for the APSD determination and subsequent drug recovery/assay processes. Nevertheless, it is advisable to mark the base of each cup so they are identified as a single set.

In typical use, following completion of the collection cup coating procedure (see *5.4 Mitigation of Particle Bounce and Re-Entrainment*) and inspection of the seals in the seal body, each cup is located in the appropriate order in the cup tray. The MOC is normally present to capture any particles that penetrate beyond stage 7. However, for some inhaled products (i.e., inhalation aerosols dispersing a plume in which a significant portion of the particles have sizes finer than about 1.0 μm in aerodynamic diameter), the MOC is replaced by either an internal filter and/or a separate external filter assembly which can be inserted between the impactor body and the vacuum source. Next, insert the cup tray into the impactor, such that the cup bases fit into the corresponding spaces of the bottom frame. Close and secure the seal body containing the stages nozzle plates over the cup tray using the external lever located at the front of the impactor. Insert the tapered fitting of the induction port to the entry port located on the uppermost surface of the seal body if an inhalation aerosol or spray is being tested. Alternatively, insert the tapered fitting of the PS, assembled in accordance with the instructions in ⟨601⟩, if the impactor is being used to assess an inhalation powder, unless justified by data that PS is not necessary, and secure the induction port to the entry of the PS to complete the assembly of the impactor.

## 6.5 Mitigation of Air Leakage into the Apparatus

*Equation 4* in *3. Cascade Impactor Operating Principles* illustrates the relationship between impactor stage cut-point sizes and volumetric flow rate of the air through the cascade impactor. Since the source of the air flow through the measurement apparatus is by the creation of a vacuum downstream of the impactor exit and the flow rate is set at the entry to the induction port (see *6.6 Setting of Flow Rate*), it follows that any leakage of ambient air into the sampling train at the time of setting the flow rate for the determination, other than via the intended entry of the induction port will result in an unintended increase in flow rate through stages downstream of the leak. In consequence, such leakage will result in bias of part or all of the APSD towards coarser sizes. Avoidance of air leakage is therefore a paramount requirement that should be verified before every APSD measurement.

@2024 USPC

Leakage testing is most conveniently undertaken immediately following assembly (see *6.4 Assertion of Correct Assembly*) by connecting the set-up, including the induction port, PS (if used), and external filter (if used with the NGI), to the vacuum source. This procedure also serves to check the leakage integrity of the entire set-up including tubing and flow control equipment before use. The entry of the induction port is temporarily plugged with an elastomeric bung for the duration of the test. *Figure 5* illustrates the configuration for the ACI without PS, but the external components, if equipped with its PS or for the NGI with/without PS, are similar. A side-connection via a gate valve (G2) is made to a sensitive differential pressure transducer (0–50 kPa and capable of determining a change of ±0.5 kPa at 20.0 kPa) that is located immediately after the exit port from the cascade impactor or the external filter assembly if the NGI is used with this additional equipment. Another gate valve (G1) is located between the side-connection and the variable flow control valve that, in turn, is connected to the vacuum source/pump.

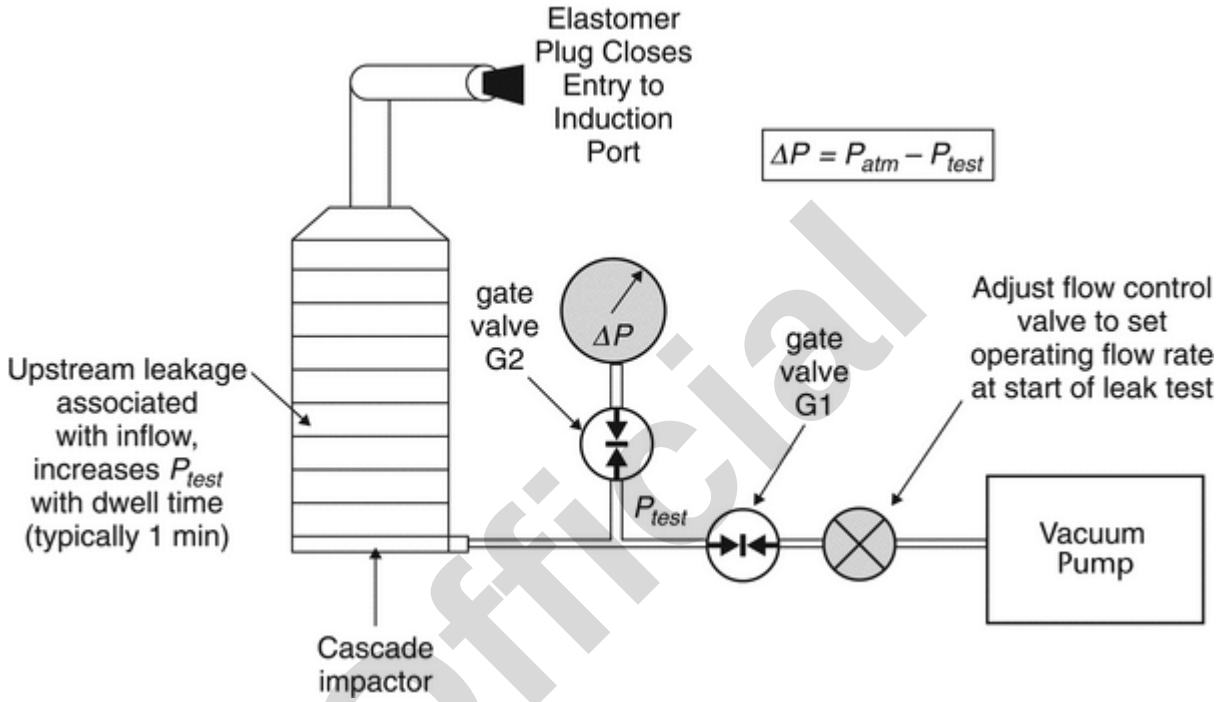

Figure 5. Set-up for leak testing impactor and associated equipment before use—the Andersen Cascade Impactor is shown without its PS, but the set-up is similar if the PS is present or the Next Generation Impactor is substituted.

[NOTE—The system is shown for inhalation aerosols, but the same procedure will work by substituting the appropriate flow control equipment for testing inhalation powders in place of the flow control valve.]

The following procedure is then followed:

1. With the flow control valve closed, the gate valves, G1 and G2, are opened, and the vacuum source is activated;
2. A partial vacuum is applied to the test system by adjusting the flow control valve to set $P_0$ to 20.0 ± 0.5 kPa observing the reading of the output from the differential pressure meter. The differential pressure is measured by connecting the differential pressure transducer at its negative pressure port to the side-connection from the test system;
3. After the required vacuum is displayed on the meter of the pressure gauge, the gate valve, G1, is fully closed to isolate the test apparatus from the vacuum source, and a timer is started;
4. The initial differential pressure ($P_0$) is documented;
5. Allow at least 1 min to elapse, then observe and record the displayed pressure ($P_1$);
6. Carefully remove the rubber bung from the inlet, ensuring not to disturb the apparatus, close the gate valve, G2, and open the gate valve, G1, to isolate the differential pressure meter and to bring the entire test system back to atmospheric pressure conditions, ready for next use;
7. The vacuum source can be deactivated at this stage;
8. The leak rate ($L$) is calculated in accordance with *Equation 5*:

$$L = \frac{P_0 - P_1}{t} \quad [5]$$

$P_0$ = initial differential pressure
$P_1$ = displayed pressure
$t$ = time (min)

Use the leak test specification from the manufacturer. If this is unavailable, then $L$ should be ≤10 kPa/min.

Official

https://nhathuocngocanh.com/

If *L* exceeds this limit, examine the components of the assembly for leakage(s). Begin by inspecting the seals associated with the stages, then the connections from the induction port to PS (if used) or to cascade impactor, and finally from the impactor to the vacuum source. Replace defective components as necessary and reassemble. Repeat the leak test above until *L* is lower than the specified limit.

## 6.6 Setting of Flow Rate

In *3. Cascade Impactor Operating Principles*, *Equation 4* links the stage cut-point sizes of the cascade impactor to the air volumetric flow rate through the apparatus. It follows that the accuracy of a measured APSD is critically dependent upon the flow rate setting. The flowmeters supplied by some impactor manufacturers that are located between the impactor exit and the vacuum source should be treated as flow indicators and NOT used as a means of setting flow rate.

The volumetric flow rate is set at the entry of the induction port, as illustrated in *Figure 6*.

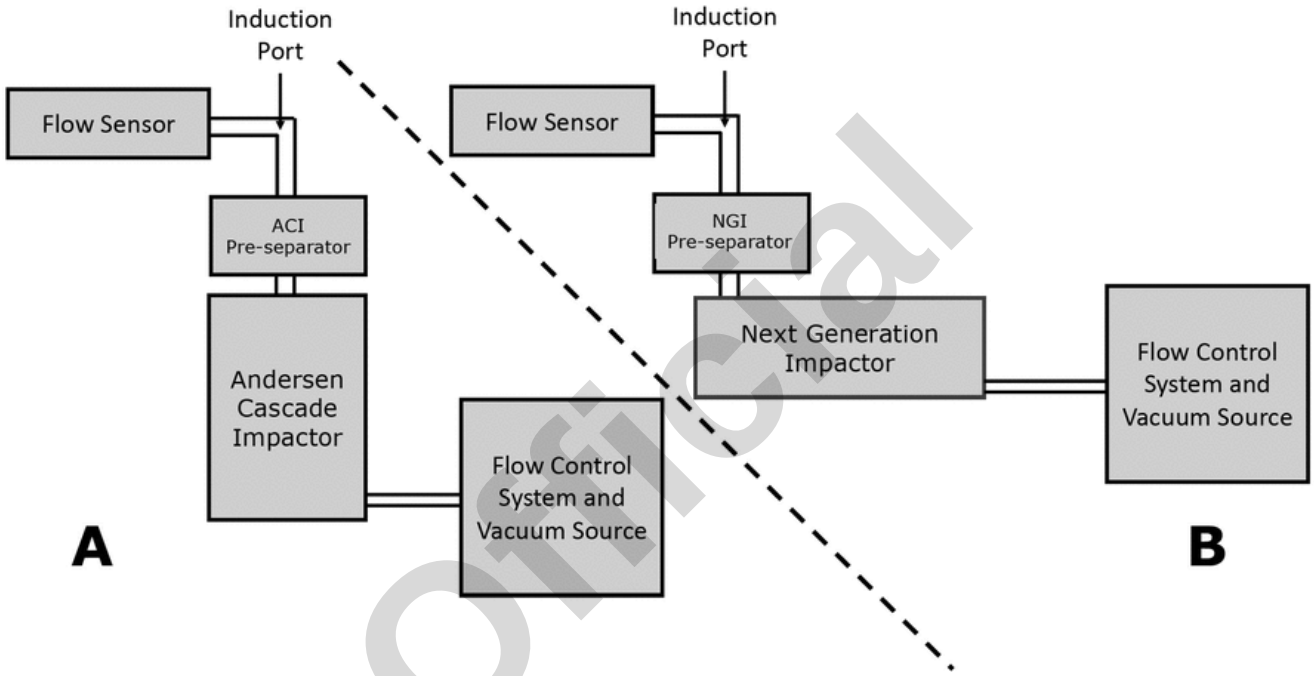

Figure 6. Flow rate setting for (A) Andersen Cascade Impactor with PS, (B) Next Generation Impactor with PS; the flow sensor location at the entry to the induction port remains the same if the PS is not used.

Set the volumetric flow rate to the target value for the inhaler being tested immediately before making the APSD determination. Note that a low flow resistance mass flowmeter may be used to make this measurement, as the air pressure at the point of flow measurement is close to room ambient.

## 6.7 Cleaning and Storage Between Uses

Although cascade impactors and their related equipment are constructed from durable materials, careful storage between uses will prolong the life of vulnerable components, such as seal rings and collection plates/cups. A regimen should be established that ensures that all components are cleaned periodically, especially the nozzle plates (ACI) and the inter-stage passageways of the seal body (NGI). The frequency of cleaning will depend upon the chemical properties of the formulations being assessed as well as the drug recovery solvent(s).

If cascade impactor equipment is not in continuous use, it should be stored at room ambient temperature, in a dry environment, and protected from airborne contaminants. The collection plates/cups should be stored separately from the impactors and also protected from airborne contaminants.

## 6.8 Assertion that Individual Cascade Impactor Assemblies of the Same Type (i.e., Andersen Cascade Impactor or Next Generation Impactor) are Interchangeable

In many laboratories, there are likely to be many cascade impactor assembles of the same type in service. There may therefore be a desire to interchange different impactors when making APSD performance measurements on the same inhaler product in order to speed up the process. Provided that stage mensuration (see *4.1 Stage Mensuration, Measurement Traceability, and Mensuration Interval*) has demonstrated that $W_{eff}$, determined as the representative measure of the diameter of the nozzles of each stage is within the manufacturer's specification, as provided in ⟨601⟩, *Table 4* (ACI) and ⟨601⟩, ▲*Table 6*▲ (CN 1-May-2021) (NGI), and checks have been made to ensure that seals are intact (see *6.2 Inspection of Cascade Impactor Components Susceptible to Deterioration*), and other considerations as discussed in *4. Apparatus Maintenance*. The impactors may be interchangeable.

However, it is advisable to perform comparative testing to validate equivalence. Nevertheless, it is recommended that the stages together with their collection surfaces are uniquely identified to a particular cascade impactor assembly for the purpose of traceability as to the source for each APSD determination.

A similar consideration applies to the PS used with the NGI, because there is a specification for the nozzle diameters in ⟨601⟩, *Table 6*. The situation is less clear for the PS for the ACI, although a manufacturer-supplied specification for the diameter of the three exit tubes, where available, would fulfill the same purpose as the PS specification for the NGI PS.

The specifications for the critical dimensions (entry and exit tube internal diameters) of the induction port are provided in ⟨601⟩, ▲*Figure 6b*▲ (CN 1-May-2021) and should be used to check for the interchangeability of this component, where multiple induction ports are in service.

# ▲⟨1604⟩ PRESENTATION OF AERODYNAMIC PARTICLE SIZE DISTRIBUTION (APSD) MEASUREMENT DATA FOR ORALLY INHALED PRODUCTS

## INTRODUCTION

Aerodynamic particle size distribution (APSD) is a critical quality attribute of all orally inhaled drug products (OIP). Characterization of the delivered mass of drug from the inhaler is important to assess product safety and efficacy. This mass includes both (and is the sum of) the sized and non-sized fraction emitted from the patient interface (e.g., the inhaler mouthpiece) (see *Figure 1*).

The delivered mass excludes drug product deposited on the mouthpiece and is consistent with the target delivered dose as specified in *Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩.

Although nasal drug products can produce particles whose size can be measured by multistage cascade impactors (CIs), almost all the emitted particulates of a well-designed nasal spray drug product are larger than the normal operating size ranges for CIs (see ⟨601⟩).

For determination of aerodynamic particle size distribution, the number of actuations should be minimized but sufficient to allow quantification of drug deposited on the stage with lowest deposition without overloading the stage with highest deposition. For details on performing determination of aerodynamic particle size distribution, see ⟨601⟩.

[NOTE—All figures in this chapter are for illustrative purposes.]

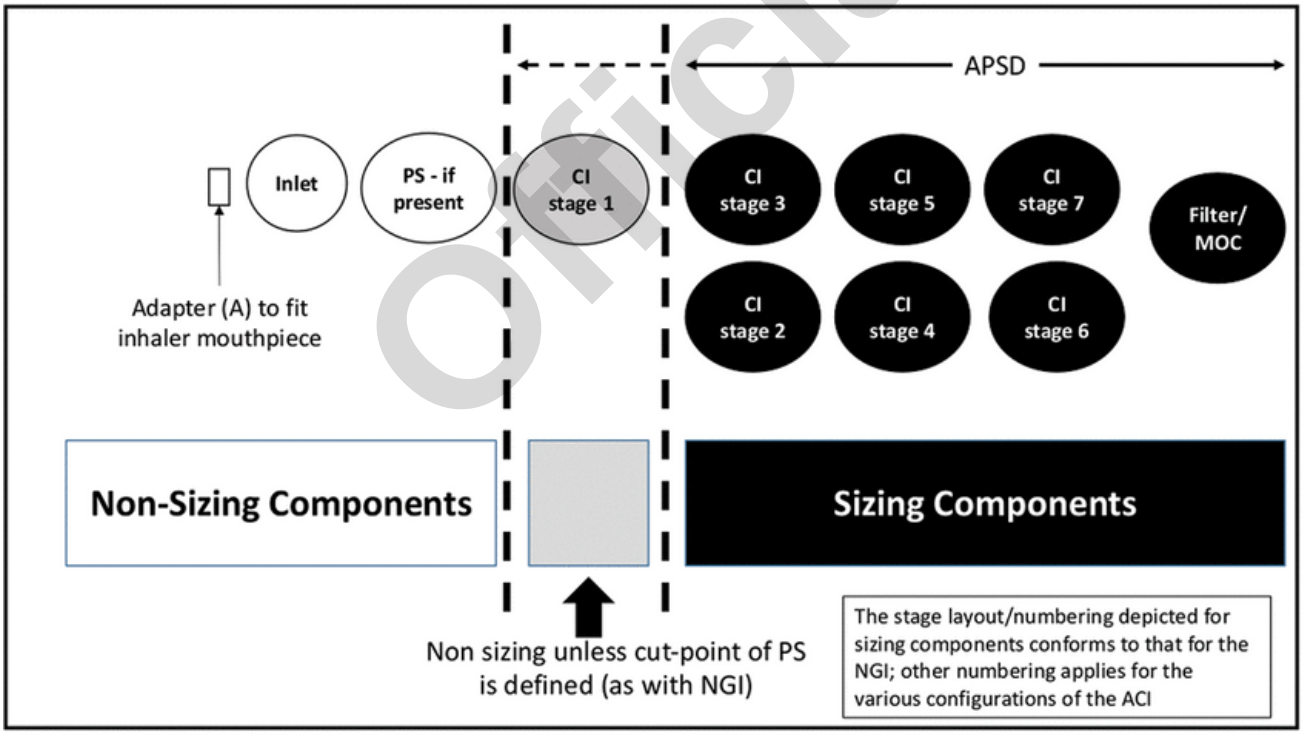

Figure 1. CI sizing and non-sizing components of the sampling apparatus used for determination of APSD for OIPs.

[NOTE—A filter may replace the micro-orifice collector (MOC), which is used with the Next Generation Impactor (NGI), or may be used in addition to the MOC.]

It is not the intention of this chapter to provide guidance on the assessment of comparability of APSDs.

This chapter presents two pharmacopeial approaches that may be used to evaluate CI analysis data, collected as per ⟨601⟩ (i.e., at a single flow rate):

- Representation of the deposition profile for the entire delivered mass of drug product per actuation, sampled as an aerosol from the inhaler mouthpiece (combination of sized and non-sized particles)
- Assessment of the deposition profile of the delivered mass of drug product per actuation from the inhaler mouthpiece by grouping CI stages

Optional uses for APSD data, which are developmental in nature, include:

- Representation of the cumulative APSD for the portion of the emitted aerosol sized aerodynamically and determination of associated moments [e.g., mass median aerodynamic diameter (MMAD) and, where appropriate, geometric standard deviation (GSD)] (*1*)
- Assessment of the APSD in terms of pertinent sub-fractions (e.g., when comparing APSD data collected at different flow rates)

The approach used depends on the question being addressed. It might be appropriate to use more than one approach.

### Choice of CI and Sampling Flow Rate for the APSD Measurement

The effective cutoff diameters that define the aerodynamic diameters associated with the sizing components at the CI operational flow rate differ between impactor types [e.g., NGI versus the Andersen Cascade Impactor (ACI)]. The same impactor must be used for stage grouping comparisons; comparison of data for different impactors of the same type can be established through a cumulative distribution curve or sized fractions. Furthermore, comparative measurements should normally be undertaken at the same flow rate unless the intent is to investigate flow rate-dependent changes to the APSD. However, when inhalers with different flow resistances are compared, measurements should be made at the same pressure differential, which will require operating at different flow rates. For some passive inhalation systems [e.g., breath-actuated dry powder inhalers (DPIs)], it is difficult to make meaningful comparisons of aerosol metrics such as fine particle dose (FPD), fine particle fraction (FPF), or MMAD between measurements collected on an NGI versus those collected using an ACI due to the differences in the two impactors' internal volumes. The difference in internal volume alters the initial acceleration and aerosolization of particles emitted from the inhaler early in the profile before the peak flow rate is achieved. Additionally, the NGI and ACI differ because of different stage effective cutoff diameters (ECDs), further prohibiting a direct comparison between the two impactors. [See sections on the ACI or NGI with pre-separator (PS) in ⟨601⟩, *C. Aerodynamic Particle/Droplet Size Distribution—Inhalation Aerosols, Inhalation Sprays, Inhalation Powders, Nasal Aerosols, and Nasal Powders* and sections on Apparatus B in ⟨601⟩, *A. Delivered Dose Uniformity*.]

## APPROACHES FOR PHARMACOPEIAL APSD DATA PRESENTATION

### System Suitability

As part of the CI system suitability verifications during standardized quality control testing, it is required that the mass balance (delivered amount from the inhaler through the impactor as a percentage of the target delivered label claim) for each determination is within 85%–115% (see ⟨601⟩). However, where losses due to internal non-sizing components (also commonly referred to as *wall losses*) are known to be ≤5% of the total delivered drug mass into the impactor, the procedure may be simplified by assaying only drug on the collection plates. [NOTE—For testing nonstandard flow rates, the method must be validated.]

### Deposition Profile

From the analysis of the solutions recovered from the entire apparatus including the patient interface, induction port, pre-separator if used, and all stage collection surfaces of the CI including the back-up filter or MOC (NGI only), calculate the mass of drug substance per actuation deposited on each of the components of the apparatus. Do not include the mass of the drug substance recovered from the interior walls of the CI, as the aerodynamic particle size of such deposits is undefined. The mass of drug substance recovered from the internal walls may, however, be used in calculations to estimate the total mass of drug substance recovered from the apparatus (mass balance; see *System Suitability*).

Construct a graph with the mass of drug substance per actuation as the ordinate (*y*) and the collection site within the sampling train as the abscissa (*x*) (see *Figure 2*).

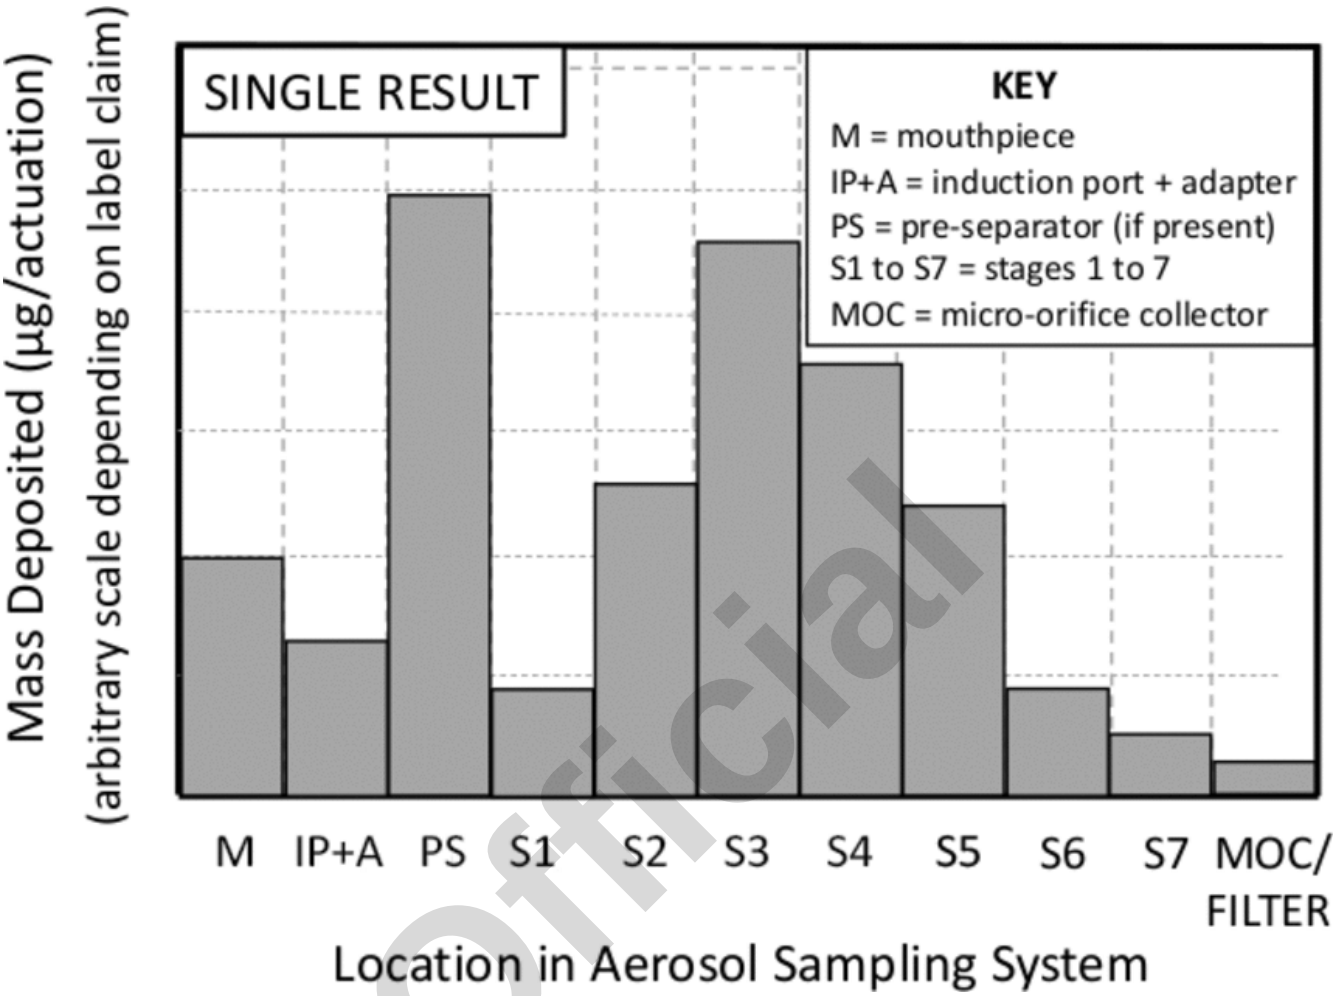

Figure 2. CI deposition profile (NGI with PS as example) for a single measurement.

## MULTIPLE DETERMINATIONS

In certain situations, it may be appropriate to compare the mean of several CI determinations. To do so repeat the data analysis procedure for the number of multiple determinations (i.e., *X*-replicate measurements), by calculating the mean mass of drug substance per actuation for each component together with its standard deviation (SD). Construct a graph with the average mass of drug substance per actuation as the ordinate and the collection site within the sampling apparatus as the abscissa; moreover, error bars may be added, typically representing ±1 SD (see *Figure 3*). It is also recommended that when presenting data based on multiple determinations that the sample size be noted (i.e., N = *X*, where *X* is the number of samples). Additionally, for each component, individual data can be grouped as shown in *Figure 4*.

See ⟨601⟩ for more details regarding multiple determinations.

## The APSD: Sized Deposition Profile

The sized deposition profile (SDP) is a representation of the mass of drug substance per actuation versus particle size, expressed in terms of aerodynamic diameter (*Figure 5*). [NOTE—Some distributions may not conform to the illustration in *Figure 5*, which is specific to an NGI.] The SD associated with each measurement may also be presented. Only the mass collected on each of the sizing components of the apparatus contributes. Hence, the mass recovered from the initial stage of either the ACI or the NGI when a PS is not present does not contribute to the SDP because there is no maximum size associated with either component. In contrast, when the PS is used with the NGI, mass on the initial stage 1 (S1) does contribute to the SDP because the effective cutoff diameter of the PS is defined through the archival calibration of this apparatus.

## Stage Grouping of the Deposition Data

For quality control purposes, the mass deposition data from both non-sizing and sizing components of the sampling apparatus can be consolidated into nonoverlapping groups to summarize the distribution of the mass of drug substance emitted from the inhaler. An illustration of this concept is presented in *Figure 6*. Other groupings are possible and the user should therefore seek guidance on this matter from the appropriate regulatory agency. In the illustration provided, the groups have been defined in terms of four relative categories:

- Group 1: Mass of drug substance recovered from non-sizing components
- Group 2: Mass of drug substance recovered from stages that might be taken as representing the “coarse” particle fraction of the mass
- Group 3: Mass of drug substance recovered from stages that might be taken as representing the “fine” particle fraction of the mass
- Group 4: Mass of drug substance recovered from stages that might be taken as representing the “extra-fine” particle fraction of the mass

The words "coarse", "fine", and "extra-fine" are intended to illustrate sizes only for discussion in this chapter.

Discussion and agreement with the relevant regulatory authority regarding the definition of the boundary sizes of each of the groupings and the related specification setting is strongly encouraged.

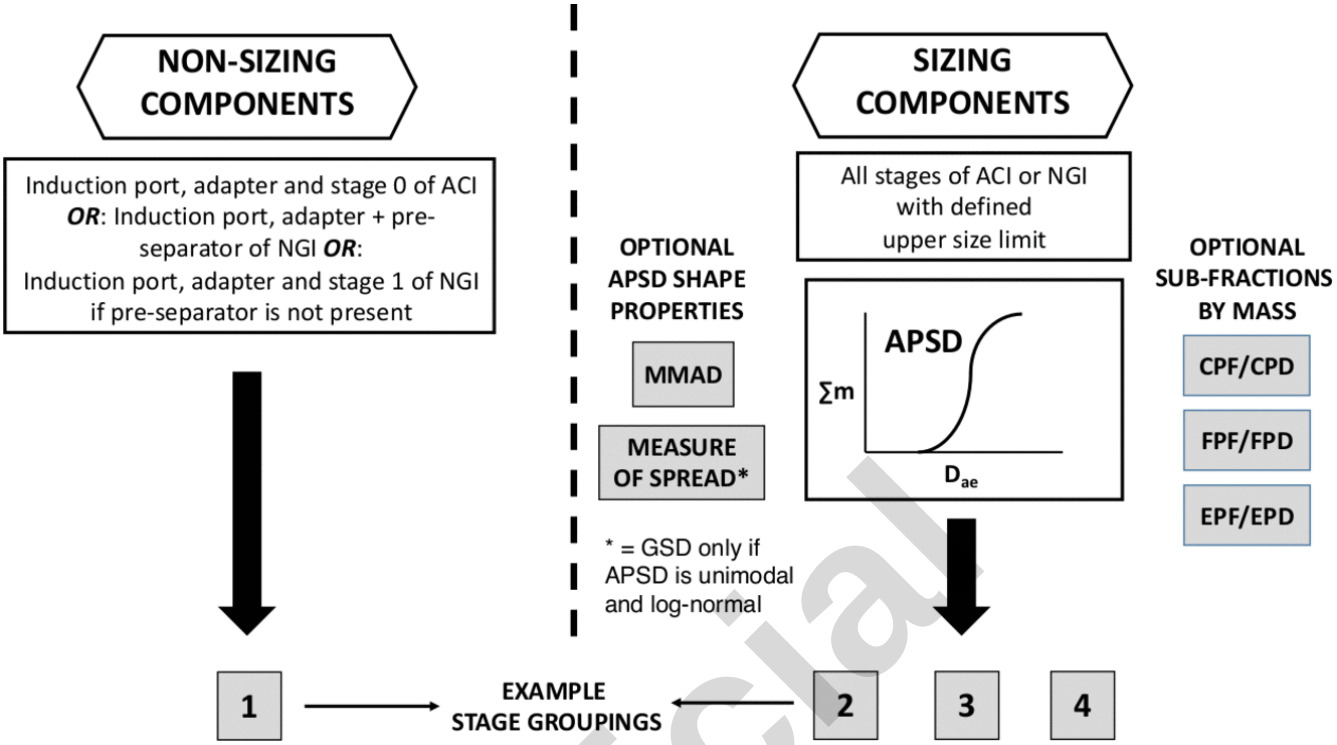

Figure 6. The left side shows the contribution from the non-sizing components of the sampling train to example stage group 1 together with the contributions from the sizing components to example stage groups 2, 3, and 4; the cumulative mass distribution and derived metrics are shown on the right side. CPF: "coarse" particle fraction; CPD: "coarse" particle dose (mass); FPF: "fine" particle fraction; FPD: "fine" particle dose (mass); EPF: "extra-fine" particle fraction; EPD: "extra-fine" particle dose (mass). If the size distribution is unimodal and log-normal, it is optionally permissible to calculate GSD as a measure of spread in addition to MMAD.

Official

## FURTHER TREATMENTS OF APSD DATA

### The APSD: Cumulative Distribution Profile

The cumulative distribution profile (CDP) is a representation of the cumulative mass of the drug substance less than or equal to the stage cutoff diameter versus the stage cutoff diameter.

[NOTE—For comparative purposes, the use of percent CDP alone would be misleading in absence of comparable impactor sized mass (ISM).]

The CDP is commonly expressed as a percentage of the ISM. The sum of the mass collected starting from the first stage, where the upper bound size is defined by virtue of the cutoff diameter of the stage immediately preceding, or of the PS in the case of the NGI, and all stages including the back-up filter or MOC. Starting at the final collection site (filter or MOC), derive a table of cumulative mass versus cutoff diameter of the respective stage. *Figure 7* shows how such data can be plotted.

## Sized Fractions

The total mass of particles in a particular size range is sometimes of interest, for example, when investigating flow dependence or when comparing inhalation powders (DPIs) with different flow resistances. This amount can be expressed in micrograms or milligrams depending on the product (e.g., FPD) and in percentage (e.g., FPF). The normalizing factor can either be labeled delivered dose (*or* target delivered dose) by the CI or ISM, depending on purpose. For example, FPD may be considered to be <5 μm aerodynamic diameter and, similarly, extra fine particle dose (EPD) may be considered to be <2 μm aerodynamic diameter because these parameters may be used for quality control purposes in regions outside the United States and may also be believed to correlate to clinical responses.

The $FPD_{<X\mu m}$, where $X$ is an aerodynamic diameter within the range of the cutoff diameters for the impactor in use at the relevant flow rate, can be estimated from the raw distribution in several ways. The most straight-forward approach is to use linear interpolation of the CDP between stages with cutoff diameters adjacent to $X$. Consider, for example, the estimation of FPD for data from an NGI (with pre-separator) with a test flow of 60 L/min (see *Table 2B*). $FPD_{<5\mu m}$ is then calculated as:

$$\frac{\text{FPD} < 5\mu m - F_3}{F_2 - F_3} = \frac{5 - 4.46}{8.06 - 4.46}$$

where $F_2$ and $F_3$ are the values of the cumulative dose up to stage 2 and 3, respectively, which simplifies to:

$$FPD_{<5\mu m} = F_3 + \left(F_2 - F_3\right)\frac{0.54}{3.60} = 0.15F_2 + 0.85F_3$$

Other sized fractions, also at other flow rates, can be determined in the corresponding manner. For best results, the CDP should be approximately linear in the region for the estimation. If this is not the case, transformation of the CDP and/or the cutoff diameters can be considered. An alternate approach is to fit a growth curve (*F*) to the CDP (microgram scale), so FPD =

*F*(*X*). The advantage with this approach is that all data, not only the data for the stages with cutoff diameters adjacent to *X*, are directly influencing the estimation.

Relevant to, and associated with, the sized fractions is a measure of the central point of the APSD: the MMAD. The USP growth curve method for calculating MMAD (*2*) assumes that the distribution of the CDP raw data has the same form as a log-normally distributed random variable. The pharmacopeial method does not provide an alternative approach when the distribution fails to meet this criterion. If there are significant deviations from log-normality, performing a linear regression over the entire data set could result in considerable bias depending on where and by how much such deviations from log normality occur.

Published data show that for many, if not most, OIPs the CDP does not follow a log-normal distribution; however, several other growth functions, which are not based on an underlying log-normal distribution have been shown suitable for fitting the CDP of OIPs (*2*). As an example, *Figure 7* shows a Morgan-Mercer-Flodin growth curve fit to the CDP in which the median (i.e., 50$^{th}$ percentile) particle size was estimated to be approximately 1.9 μm in aerodynamic diameter. Other percentiles could also be considered. In general, modeling practices should follow the principles outlined in *Analysis of Biological Assays* ⟨1034⟩.

## GLOSSARY

**A:** Adapter
**ACI:** Andersen cascade impactor
**APSD:** Aerodynamic particle size distribution
**CDP:** Cumulative distribution profile
**CI:** Cascade impactor
**CPD:** Coarse particle dose
**CPF:** Coarse particle fraction
**DPI** Dry powder inhaler
**ECD:** Effective cutoff diameter
**EPD:** Extra-fine particle dose
**EPF:** Extra-fine particle fraction
**FPD:** Fine particle dose
**FPF:** Fine particle fraction
**GSD:** Geometric standard deviation
**IP:** Induction port
**IQR:** Interquartile range
**ISM:** Impactor sized mass
**M:** Mouthpiece
**MMAD:** Mass median aerodynamic diameter
**MOC:** Micro-orifice collector
**NGI:** Next Generation Impactor
**OIP:** Orally inhaled product
**PS:** Pre-separator
**Q:** Test flow rate
**S:** Stage
**SD:** Standard deviation
**SDP:** Sized deposition profile
***X*:** Sample size

# ⟨1644⟩ THEORY AND PRACTICE OF ELECTRICAL CONDUCTIVITY MEASUREMENTS OF SOLUTIONS

This general chapter provides information in support of instrumental methods for procedures that measure electrical conductivity. Pharmaceutical applications include: chemical dosing, cleaning in place, fermentation control, and liquid mixing verification, among others. Although the general chapter focuses on aqueous systems, conductivity measurements can be extended to organic fluids. The general chapter also focuses on contacting conductivity measurements and does not cover applications which may use noncontacting inductive conductivity. After an introduction, the general chapter covers the following major topics: theory of operation, operational considerations, calibration, and operation for at-line, in-line, and off-line measurement procedures.

## INTRODUCTION

Conductivity is the measurement of the ability of a fluid to conduct electricity via its chemical ions. The ability of any ion to electrically conduct is directly related to its ion mobility. Some of the common applications of conductivity measurements include water treatment and purification, clean-in-place process fluid management, fermentation process monitoring, dosing applications, nutrient media preparation, buffer production (e.g., distribution and dilution for dialysis and chromatography applications), chromatography detection of gradient and eluent, active pharmaceutical ingredient chemical synthesis, and concentration determination of basic chemicals. Fluids should be measured in a single homogenous phase—i.e., conductivity should not be applied to mixed immiscible fluids unless they are separated. Electrical conductivity measurements cannot be applied to solids or gases, but they can be applied to the condensate of gases.

Besides its use to monitor ionic concentrations of process fluids, conductivity is also useful for the detection of ionic impurities in compendial waters (see *Water Conductivity* ⟨645⟩) and for the detection of ionic impurities in organic matrices.

The measurement is non–ion-specific, and all ions respond with different efficiency or equivalent conductance, λ. Despite the lack of ionic specificity, conductivity is a valuable laboratory and process tool for measurement and control of total ionic content because it is proportional to the sum of the concentration of each ionic species (anions and cations) as described in *Equation 1*:

$$\kappa = 1000 \sum_{i}^{all\ ions} C_i \lambda_i$$

where κ is the conductivity (S/cm), $C_i$ is the concentration of chemical ion *i* (mole/L), and $\lambda_i$ is the specific conductance of ion *i* ($S \cdot cm^2$/mole). Though S/m is the appropriate SI unit for conductivity (i.e., the base SI units are the ampere and the meter) units of S/cm historically have been selected as the accepted unit of expression.

At low ion concentrations (typically $<10^{-3}$ mole/L), the conductivity–concentration relationship is linear and valid because λ is constant for each ion, but there are three notable exceptions to this strict linearity and proportionality. First, at higher concentrations (approximately $10^{-3}$ to 1 mole/L) small negative deviations from linearity (<5% per decade) arise because of the decrease in λ for each ion, and the negative deviations vary from ion to ion. Second, at higher concentrations for weak acids and bases the extent of dissociation into ions decreases depending on their dissociation constants. As the concentration of a weak acid/base increases, the conjugate cation/anion concentration increases as the square root of the acid/base concentration. Third, at high concentrations (>20%) of certain strong acids such as $HNO_3$ and $H_2SO_4$, the negative deviations persist, and, in some cases, the conductivity decreases with increasing concentration. The conductivity of high-concentration acid systems is well documented.

Another variable that influences conductivity measurements is the fluid temperature. A stricter expression of *Equation 1* is shown below as *Equation 2*:

$$\kappa\left(T\right) = 1000 \sum_{i}^{all\ ions} C_i\left(T\right)\lambda_i\left(T\right)$$

where the conductivity measurement, ion concentrations, and specific ion conductances are temperature (*T*) dependent. As fluid temperature increases, the ions become more efficient electrical conduits, making this physicochemical phenomenon the predominant reason for the temperature-compensation requirement when testing conductive fluids. The specific ion conductance of all ions increases with increasing temperature. In addition, the concentration of ions can also change as a function of temperature. For example, the auto-dissociation constant of water, $K_w$, increases with temperature from 0° to 100°, resulting in the increased production of $H^+$ and $OH^-$ .

Strictly speaking, it is challenging to temperature-compensate perfectly the conductivity measurement to a reference temperature unless the ionic species are well known. In many applications the ionic species are well known, and in most other cases simple assumptions make this issue less demanding. Temperature compensation is discussed in further detail in *Temperature Compensation*, below.

# THEORY OF OPERATION

## Alternating Current Measurement Method

Conductivity is measured by applying a voltage (or current) between two conducting electrodes and measuring the resistance of the fluid using Ohm's Law. Various methods are used to apply the voltage/current, but all have the property of using an alternating voltage/current (AC) in order to minimize polarization (or collection of ions) at the electrodes or any electrolytic reaction. If a direct voltage/current (DC) is used, then the positive ions will collect at the negative electrode, and negative ions will collect at the positive electrode. The collection of ions at the electrode prevents the flow of current and adversely affects the accuracy and stability of the conductivity measurement. The measuring frequency of the AC signal depends on the technology and can range from as low as 30 Hz in low-conducting fluids and up to 4 kHz in highly conductive fluids. The specific frequencies are not relevant to operation of the system because the drive frequency is embedded in the instrument's measurement systems and is integrally linked to the supplier's measurement technology. This chapter does not seek to evaluate different measurement technologies because they are usually microprocessor-controlled systems and are proprietary.

The two-electrode AC measurement technique is valid for use with all concentrations of ionic species ranging from acids and bases (high conductivity) to *Water for Injection* and *Purified Water* (low conductivity) and even to organic, weakly ionic species such as alcohols and glycols. The measurement can be sensitive to ion concentrations as low as 0.05 µg/L. For high ion concentrations, analysts can use an alternative 4-electrode measurement method in which the current is applied between two of the electrodes and the voltage is measured between the two other electrodes. Ions are driven to the current electrodes while the voltage electrodes make the measurement with limited polarization effects.

## Units of Expression

There is no difference in the physical measurement of conductivity and resistivity—they are multiplicative inverse measurements of each other. Therefore, if one measurement is known, then the other value is readily calculated by taking the reciprocal of the numerical value and the units. There is also no difference in the instrumentation or the sensors. The only difference is how the measured value is reported or displayed for the convenience of the analyst. For example, 18.2 MΩ · cm = 0.0550 µS/cm and 5.23 kΩ · cm = 0.191 mS/cm = 191 µS/cm. Although the proper SI units are Ω · m or S/m, the traditionally used units are Ω · cm or S/cm.

*Figure 1* shows relationships among conductivity, resistivity, and some example process fluids of various grades of purity. The conductivity of fluids in pharmaceutical systems varies over approximately 8 orders of magnitude. In high-purity water systems, the quantity of ions present in *Purified Water* or *Water for Injection* is very low, resulting in a conductivity <5 µS/cm and often approaching 0.055 µS/cm or less. [NOTE—The conductivity of the purest waters at temperatures less than 25° is less than 0.055 µS/cm.] In drinking waters, the conductivity may vary from 30 to 2000 µS/cm. In chromatographic separations, the conductivity of the eluent may vary from 0.1 to 100 mS/cm. For hot concentrated acids, the conductivity may be as high as 1 S/cm.

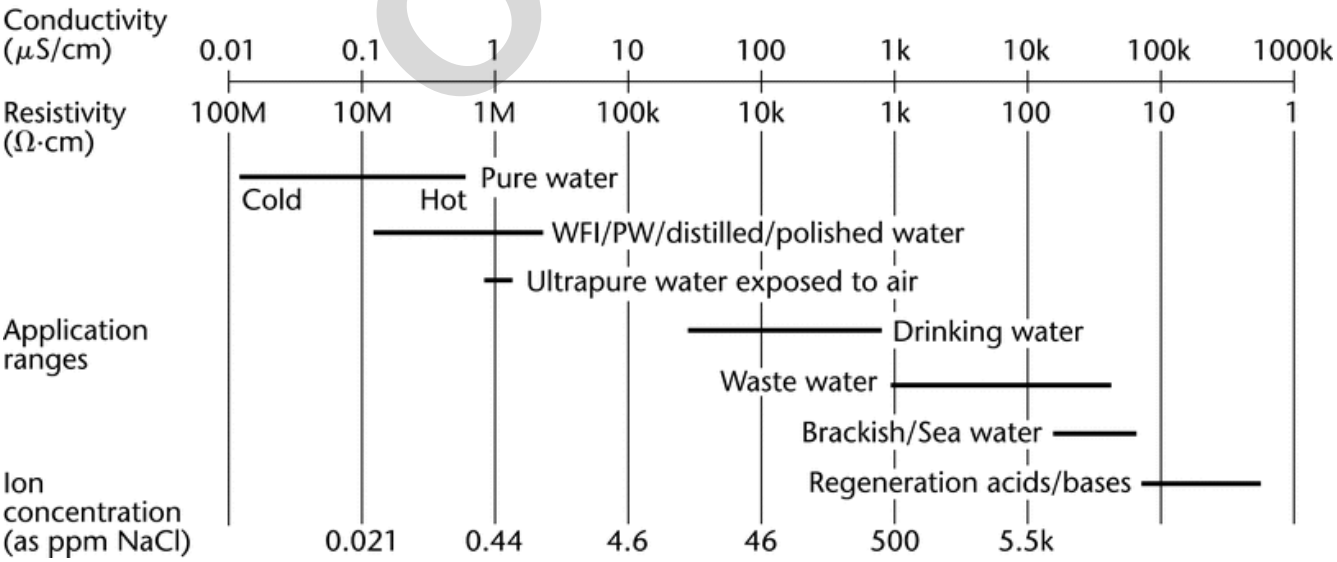

Figure 1. Relationships among conductivity, resistivity, and some example process fluids of various grades of purity.

## Cell Constant Determination

The purpose of the sensor's cell constant is to normalize the conductance/resistance measurement for the geometrical construction of two electrodes. When two electrodes are placed in a conducting fluid and a voltage is applied to them, there is a conductance (resistance) between the electrodes. If the electrodes are placed farther apart, the conductance decreases (resistance increases). If the area of the electrodes increases, then the conductance increases (resistance decreases). In both

@2024 USPC

cases, the ion concentrations between the electrodes do not change, but the geometrical construction of the sensor (cell constant) alters the measured conductance (resistance). The conductivity of a solution ($\kappa$, S/cm) is related to the conductance, $G$ (siemens) according to *Equation 3:*

$$\kappa = G \times \left(\frac{d}{A}\right) = G \times \theta$$

where $A$ is the area of the conducting electrodes ($cm^2$) and $d$ is the distance between the electrodes (cm). The other common unit of expression is the reciprocal of conductivity, or resistivity, $\rho$ ($\Omega \cdot cm$), as described in *Equation 4*:

$$\rho = \frac{1}{\kappa} = \frac{1}{G \times \theta} = \frac{R}{\theta}$$

where $R$ is the resistance of the fluid between the electrodes ($1\ \Omega = 1\ S^{-1}$). The geometrical ratio, $d/A$ (or $\theta$), is known as the cell constant ($cm^{-1}$) of the sensor.

Determination of the cell constant by the direct measurement of $d$ and $A$ is impractical because of variations in the geometrical configurations and the nonuniformity of the electric field between the electrodes. Practically, the cell constant is determined by the measurement of aqueous solutions of known conductivity. See *Calibration* below.

### Temperature Compensation

Temperature compensation is a typical requirement for most conductivity measurements, although there are exceptions such as those contained in *Water Conductivity* ⟨645⟩. As noted previously, the conductivity of a fluid is related to its temperature. As the temperature increases, ions become more mobile and the conductivity increases. The effect of temperature depends on the type and concentration of the ion, but for most solutions >10 µS/cm the impact of temperature is in the range of 1.9%/° to 2.2%/°. For strong acids, this may be as low as 1.5%/°. For high-purity compendial waters, the temperature coefficient varies from 2.0%/° to 7.5%/° depending on the temperature and purity of the water. For each case described here, some knowledge of the type of impurity is needed in order to ensure adequate temperature compensation. If the conductivity vs. temperature function is linear and the temperature coefficient is constant, the equation that relates the compensated conductivity to the non–temperature-compensated conductivity is described in *Equation 5*:

$$\kappa_{25} = \frac{\kappa_T}{[1 + \alpha(T - 25)]}$$

where $T$ is the measured temperature, $\kappa_{25}$ is the conductivity compensated to 25°, $\kappa_T$ is the conductivity at $T$, and $\alpha$ is 0.02 for a temperature coefficient of 2%/°.

Most conductivity measurement systems measure the uncompensated conductivity/resistivity and the temperature, and the temperature-compensated conductivity is determined via mathematical algorithms (e.g., by application of *Equation 5*) in the microprocessor of the transmitter. Depending on the application and knowledge of the content of the fluid, different compensation algorithms may be available. For most process control applications, temperature compensation is recommended because when the uncompensated conductivity changes it is impractical to distinguish whether this change is caused by temperature fluctuation or a change in ionic content. Temperature compensation allows the analyst to distinguish between changes in temperature and ionic content. Compensation to a reference temperature of 25° is standard practice, but some methods specify temperature compensation to 20°.

Most conductivity sensors have temperature devices such as a platinum RTD (resistance temperature device) or NTC (negative temperature coefficient) thermistor embedded inside the sensor, although external temperature measurement is possible.

## OPERATIONAL CONSIDERATIONS

### System Components

The usual components of a conductivity measurement system are the sensor, the transmitter, and the cable that connects the sensor to the transmitter. The sensor is the device that is in direct contact with the fluid. The sensor consists of the electrodes, usually an embedded temperature device, and a process connection (e.g., a tri-clamp if the sensor is intended for in-process sanitary applications). Traditionally, sensors are passive electromechanical devices and do not contain measurement circuitry.The transmitter is the device that measures the resistance between the sensor's electrodes, measures the resistance of the temperature-measuring device, converts the resistance measurement to a conductivity (or resistivity), and performs temperature corrections to compensate the signal to a reference temperature. The cable connects the sensor to the transmitter. In process control or monitoring systems, the cable allows the sensor to be attached to a process tank or pipe, and the transmitter can be located at a control panel or other remote location, if necessary. The distance between the sensor and the transmitter may affect measurement accuracy caused by the added cable resistance and the susceptibility of the cable to external noise. Therefore, this distance should be considered during selection of the measurement system. In some conductivity measurement systems, the measurement circuitry is directly attached to the conductivity sensor, allowing digital transfer of the measurement results to a remote display at greater distances than traditional measuring systems with wire transmission of analog signals.

### Materials of Construction

The sensor's materials of construction are critical when the sensor may be in contact directly or indirectly with the product. For most laboratory applications, materials of construction are less critical. All sensors contain measuring electrodes and an insulating material between the electrodes. Technically, the only requirements are for electrodes to be electrically conducting and to be able to withstand the physical and chemical environment. Electrodes can be made of various grades of stainless steel, titanium, graphite, and many other metals. The insulating materials must isolate the electrodes from each other so that only the fluid conductivity is measured. Insulating materials are usually made of an inert polymer, epoxy, or ceramic.

If the sensor is connected directly to a process vessel or the piping system, then the sensor's materials of construction must meet the thermal and hydraulic (pressure) requirements of the process system. The sensor must have a proper process connection to the vessel/piping. Depending on the application, the sensor also may be required to meet biological compatibility, material, or hygienic design requirements. The sensor must not degrade during installation and operation. The sensor must be able to withstand any other processes that the system may encounter such as clean-in-place or steam-in-place processes. Otherwise analysts may need to remove the sensor from the process. When immersion of the sensor into the process places the process at risk, the sensor should be installed in a housing that is attached to the sidestream. In this case, a fraction of process fluid flows to the housing and sensor and then to drain. This allows indirect measurement of the process fluid without harm to the process or product.

If the conductivity measurement is performed off-line, e.g., in a laboratory environment, then the operating considerations are reduced because the thermal, hydraulic, and other product-contact concerns are reduced or eliminated.

## CALIBRATION

The process of calibrating a complete conductivity measurement system generally consists of three parts. First, the transmitter's electronic circuitry is calibrated. Second, the temperature sensor device is calibrated. Third, the cell constant of the conductivity sensor is determined. In each case, verification may precede any calibration to determine if an adjustment is necessary. In most cases for microprocessor-controlled instrumentation, there is no formal mechanical or electronic adjustment of these subsystems. Instead, these adjustments are usually made in software-controlled calibrations that are computed automatically by the transmitter.

A calibrated transmitter should be used in order to calibrate the temperature sensor and cell constant. The transmitter used to calibrate the temperature sensor and cell constant can be the transmitter used in normal operation, or another transmitter can be used instead. Because of differences in a supplier's wiring and electronic compatibility, it may be necessary to use the same type of transmitter.

As is the case for all instrument-based methods, calibration frequency depends on many factors. Depending on the type of conductivity sensor and transmitter, calibration cycles vary from weekly to annually based on manufacturers' recommendations, historical performance of the instrumentation, internal requirements, and the criticality of the application. For robust process instrumentation, typical calibration cycles for the electronics and the sensor take place approximately every 12 months. When the sensor's cell constant can be altered by the fluid or the process conditions, more frequent calibration may be needed.

### Instrument Calibration

The transmitter's electronic circuitry is calibrated by disconnecting the sensor from the transmitter, connecting precision resistors (resistors of known value) to the transmitter, and comparing the traceable resistance value to the measured resistance value. The resistance values should be traceable to a competent national authority. The resistance values should be selected so that they are in the range of (1) the measurement capability of the transmitter, and (2) the resistance that will be measured during operation. The transmitter may have multiple circuits internally, so verification of the appropriate circuit (or all circuits) and measurement range is necessary. Comparison of the measured resistance to the actual resistance verifies if the transmitter is properly calibrated. The resulting difference must be within a predetermined $x_1$% of the actual resistance, where $x_1$ indicates the desired conductivity circuit electronics performance. Typical conductivity circuit electronics performance is usually in the range of 2% or less of the target value. Otherwise, adjustment of the resistance measurement circuit is recommended.

An example of the transmitter's measurement electronics calibration process follows: A typical operating range for a clean-in-place process may be in the 50 to 75 mS/cm range. A sensor with a cell constant of 5.0 $cm^{-1}$ is used in this example. Based on *Equation 4*, this requires a measuring resistance of 67 to 100 Ω. To verify the conductivity measuring circuit during calibration, analysts should use a resistor(s) with a traceable value in or near this range. When compendial waters are used, typical measurements are in the range of 1 to 20 MΩ · cm and use sensors with a cell constant of 0.1 $cm^{-1}$. This computes to a resistance of 0.1 to 2 MΩ. Resistors with a traceable value in this range should be used. If the recorded values are within the range of the pre-established acceptance criteria ($x_1$%), then adjustment is not required.

### Temperature Measurement and Sensor Calibration

If a temperature measurement circuit is integrated into the transmitter and is used as part of the measurement system, then verification and/or calibration of this circuit is required. Depending on the type of temperature device in the sensor, an appropriate signal source (e.g., resistance) should be input to the transmitter. Comparison of the measured temperature and the simulated temperature verifies if the temperature measurement circuit is properly calibrated. The resulting difference must be within $x_2$° of the simulated temperature where $x_2$ indicates the desired temperature circuit electronics performance. Typical temperature circuit electronics performance usually is in the range of ±1° or less. If the difference meets the pre-established acceptance criteria, no further action is required. Otherwise, adjustment of the temperature measurement circuit is recommended using the protocol in the transmitter's calibration function.

Official

https://mathdocs.globalhistory/

If a temperature sensor is integrated into the conductivity sensor, the temperature sensor can be calibrated by comparison of the sensor's temperature measurement to a reference system. This is accomplished by immersing the process and reference sensors in the same fluid. The reference system can be another traceable temperature measurement device or a fluid system of known temperature such as boiling water (corrected for elevation, if this degree of accuracy is necessary) or an ice-water bath.

The accuracy of the calibration is related to the accuracy of the reference sensor, the thermal homogeneity of the fluid, and the elimination or reduction of any artifacts that can negatively influence accuracy. For example, if the sensor is not fully immersed in the fluid, thermal conduction from the ambient environment can alter the temperature measurement. Careful insulation of the sensor from the ambient environment may improve the accuracy of temperature measurements, particularly if the reference temperature is substantially different than the ambient temperature.

Comparison of the measured temperature and the reference temperature verifies if the temperature sensor is properly calibrated. The resulting difference must be within $x_3$° of the reference temperature where $x_3$ indicates the desired temperature accuracy that is required for the process. Temperature sensor accuracy is usually in the range of ±2° or less. If the difference meets the pre-established acceptance criteria, no further action is required. Otherwise, adjustment of the temperature sensor calibration factors is recommended using the protocol in the sensor's calibration function.

### Cell Constant Calibration

The cell constant of the sensor is determined by comparing the conductivity measurement of the system to that from a reference conductivity system and adjusting the cell constant. Place the sensor in a reference solution of known conductivity whose value is traceable to a competent authority. The reference solution can be a solution of known conductivity in one of three ways:

1. The solution can be produced according to a standard method that is traceable to a competent authority. One method is to prepare one of the solutions listed in ASTM D1125. Another method is to use ultra-pure deionized water with no exposure to air whose conductivity is known.
2. The solution can be procured from a third-party supplier with traceability to an acceptable authority. Cell constant calibration should be performed in the recommended temperature range of the reference solution.
3. The solution can be any fluid whose conductivity is known by measurement from an alternative and traceable reference conductivity measurement system.

In all three cases, regardless of the type of calibration methodology, there are some fundamental requirements. The sensor's cell constant should be calibrated at a conductivity that is in the measurement range of the measuring system. For example, if the system is designed to measure in the 0–100 µS/cm range, then use of a 1000 µS/cm reference solution is not advised.

Because the cell constant is a geometrical property of the sensor and is a constant, the determination and/or calibration of the cell constant does not need to be in the operational range of the pharmaceutical process as long as the conductivity is in the operational range of the measurement system. Also, because the cell constant is a geometrical property of the sensor, a single-point calibration typically is sufficient. In some applications, a 2-point calibration can provide improved accuracy at very high conductivity. Depending on the reference solution, cell constant calibration can be performed with or without temperature compensation. For reference solutions exceeding 10 µS/cm, if temperature compensation is needed a temperature coefficient ($\alpha$) of 2%/° is sufficient over the range of 25 ± 10° unless otherwise specified.

Adjustment of the cell constant is recommended if the difference between the measured and reference conductivity exceeds $x_4$% of the reference conductivity where $x_4$ indicates the conductivity accuracy that is required for the process. Typical conductivity accuracy is 5% or less. If the accuracy measurement meets the pre-established acceptance criteria, no further action is required. Otherwise, adjustment of the sensor's cell constant is recommended using the protocol within the sensor's calibration function.

## OPERATION

### In-line, At-line, and Off-line Measurements

Depending on the application, in-line, at-line, and off-line measurements have specific universal requirements. Each has advantages and disadvantages depending on the application, but the fundamental technologies (AC measurement) supporting each measurement type are constant. The primary differences between the in-line/at-line and the off-line systems are sensor features related to process robustness and transmitter features related to output functions, external communication capabilities, and system installation costs. In-line and at-line systems have added benefits of real-time measurements and continuous data acquisition. They also have added one-time electrical and plumbing installation costs, and the instrumentation is fixed in a specific location for a single process and purpose. Also, sample is diverted to drain, resulting in product loss. Note that the fluid flow velocity should be high enough that the velocity does not affect the measurement. Off-line (or laboratory-based) systems have the benefit of measuring many sample types under controlled conditions. Off-line batch testing has added costs associated with cleaning containers and collecting samples as well as risks of sample contamination.

In-line conductivity measurements are suitable when the following conditions are met: (1) there is a need for or value of real-time, continuous data; (2) the sensor and the application/fluid are compatible and cause no harm to each other; and (3) atmospheric contamination must be avoided. In these cases, continuous process control, decisions, and intervention are available.

At-line (or sidestream) conductivity measurements are used when the following conditions are met: (1) a need exists for or value of real-time, continuous data; (2) the sensor and the application are compatible with each other; (3) the sensor can cause harm to the application and/or fluid; and (4) atmospheric contamination must be avoided. In such cases the measurement is made by delivering the sample from the tank/piping using hydraulic pressure (flow) to the conductivity sensor, and the fluid passes through the sensor and goes to drain. In these cases, continuous process control, decisions, and intervention are available

@2024 USPC

and have no affect on product or application. The only requirement is positive pressure upstream from the sensor to prevent backstreaming of the sample fluid back into the process.

Off-line conductivity measurements are used when the following conditions are met: (1) no need exists for or value of real-time or continuous data; (2) the sensor and the application are compatible with each other, but the sensor can cause harm to the application and/or fluid; and (3) sampling needs are infrequent or are needed on a limited basis.

## Sample Preparation and Off-line Measurement

When performing off-line measurements, analysts must ensure that the container used to collect the fluid sample(s) is sufficiently clean so that the container does not alter the result. Collect an amount of fluid needed for rinsing and measuring. For samples such as *Purified Water* where the analysis can be affected by gasses, containers should be filled completely to reduce headspace. The volume of fluid needed to make a measurement depends on the design of the sensor and can range from <10 mL to 1 L. Transfer a portion of the sample fluid to the clean measuring container to rinse the container walls. Discard the fluid. The sample container also can be used as the measuring vessel. The sensor should be rinsed with a suitable quality of water or other appropriate fluid before use so the measurement is not affected and then rinsed at least once with the solution to be measured, which then is discarded. This rinse with sample solution removes any residue or fluids with which the conductivity sensor previously was in contact. The exact procedure varies depending on the solution tested. For example, when testing very low conductivity samples such as *Purified Water*, analysts must do more rinsing to remove any remaining residue from the sensor. Maximum holding time, temperature, and container type must be controlled for some low-conductivity samples, e.g., high-purity waters, because of the potential impact of ionic leachables from certain containers.

Transfer the fluid to the measuring container, immerse the sensor into the fluid, and ensure acceptable clearance around the sensor's measurement area. Stir or agitate the sample to prevent bubbles from attaching to the electrodes and disturbing the measurement. If a temperature-compensated measurement is used, then select the appropriate temperature-compensation algorithm in the transmitter, and adjust the sample temperature to the recommended range, if necessary, using an appropriate temperature bath. Otherwise, disable the temperature compensation. Verify that the temperature is sufficiently stable (<0.25° change per min), and record the conductivity reading and the temperature, if necessary.

## In-line Measurement

For in-line testing, the sensor is installed into the process piping or vessel. The orientation of the sensor relative to the flow of the fluid is critical to ensure that (1) particles and sediment do not collect between the measuring electrodes, and (2) no air pockets are trapped between the measuring electrodes. Both factors can adversely affect the measurement accuracy. Depending on the electrode design, manufacturers usually provide recommendations. Ensure the sensor is clean before installation.

After the sensor is immersed in the closed process, such as a piping system or tank, the sensor does not require removal and cleaning before a measurement. If a temperature-compensated measurement is used, then select the appropriate temperature-compensation algorithm. Otherwise, disable the temperature compensation. Although temperature stability is desirable, it may not be possible depending on the temperature control of the process. Record the conductivity reading and the temperature, if necessary.

## At-line Measurement

For at-line testing, a piece of tubing is used to connect the process vessel/piping to the sensor and its housing. The tubing should be cleaned or flushed with an appropriate cleaning agent to remove any impurities that could alter the conductivity measurement. The tubing can be made of metal or plastic depending on the application and chemical compatibility. Installation of the sensor into a housing permits fluid to be directed into the sensor and then to drain. Installation considerations are similar to those for in-line installations. Ensure the sensor and housing are clean before installation.

After the sensor and housing are connected to the sidestream, the sensor does not require removal and cleaning before a measurement. If a temperature-compensated measurement is used, then select the appropriate temperature-compensation algorithm. Otherwise, disable the temperature compensation. Although temperature stability is desirable, it may not be possible depending on the temperature control of the process. Record the conductivity reading and the temperature, if necessary.

## Other Considerations

In all cases mentioned above, the use of abrasive materials to clean the sensor typically is discouraged. Two reasons to avoid abrasive cleaning materials are that (1) the passive layer of stainless steel sensors (when used) can be destroyed, and (2) the surface of the measurement area can affect the measurement accuracy. For these reasons, the use of appropriate chemically compatible fluids is preferred instead of mechanical methods for cleaning.

Unlike the requirements for many electrochemical measurements, the need for flowing, circulating, or agitating fluid is not a fundamental requirement for a conductivity measurement. In general, there is no difference in the conductivity measurement of a static or a flowing sample, but two conditions must be met for static samples: First, bubbles cannot be allowed to collect on the measuring area of the electrodes because they can interfere with the flow of current conductivity measurement. Second, if sample homogeneity is affected by the lack of agitation or circulation, then the conductivity measurement may not represent the conductivity of the bulk fluid.

In all cases, the installation of the sensor should take into consideration wall effects from the vessel, piping, or laboratory container. If the proximity of the wall interferes with the electromagnetic field for the conductivity measurement, then the measurement could be positively or negatively altered. Some 2-electrode sensor designs, such as coaxial concentric electrodes, are not affected by nearby objects. The sensor's installation instructions may indicate if this must be considered.

Official

https://pharmacopeia.cn/v-download/

If unstable conductivity readings are observed, some common causes could be inadequate grounding of the water system, electronic noise from pumps and other high-frequency generators, or internal leakage of the sensor. Various diagnostic approaches are available and can help identify the cause.

# ⟨1660⟩ EVALUATION OF THE INNER SURFACE DURABILITY OF GLASS CONTAINERS

## PURPOSE

This general information chapter provides information about factors that affect the durability of the inner surface of glass containers. Recommended approaches are provided to evaluate the potential of a drug product to cause formation of glass particles and delamination of the inner surface. Screening methods are provided to detect glass particles and delamination, allowing a comparison to be made of glass durability on a lot-to-lot basis or between different glass manufacturers.

## SCOPE

This chapter addresses bottles and vials manufactured by molding and ampuls, cartridges, vials, and prefillable syringes manufactured from tubing glass. Glass for pharmaceutical packaging is classified as Type I borosilicate glass, Type II treated soda-lime-silica glass, or Type III soda-lime-silica glass on the basis of the hydrolytic resistance of the glass, as defined in *Containers—Glass* ⟨660⟩. Type I glass containers are suitable for most products for parenteral and nonparenteral use. Type II glass containers are suitable for most acidic and neutral aqueous products for parenteral and nonparenteral uses, and can be used for alkaline parenteral products when stability data demonstrate their suitability. Type III glass containers usually are not used for parenteral products or for powders for parenteral use, except when suitable stability test data indicate that Type III glass is satisfactory. This chapter focuses primarily on Type I glass, because it is the most widely used in the pharmaceutical and biopharmaceutical industry for parenteral products although the guidance can be equally applied to Type II and Type III glass used for parenteral products.

The chapter should be useful for the following:

- Molded and tubular glass container manufacturers and converters
- Pharmaceutical and biopharmaceutical companies
- Contract manufacturing and filling organizations

Glass delamination may be described as the appearance of thin flexible flakes of glass (or lamellae) that can range in size from <50 µm to 200 µm in a drug product solution. This is a serious quality issue and can result in a product recall. The appearance of glass lamellae is a lagging indicator of a strong interaction between the drug product and the inner surface of the glass. Although delamination is the most obvious visual indicator, it represents the final stage of a complex glass corrosion reaction, and can be observed only at a point where prevention is no longer an option. Adding further complexity to detection, mechanical energy from shaking or vial-to-vial contact during transportation may be required to dislodge the lamellae from the internal surface of a filled vial and facilitate observation.

Tests for delamination combine the visual examination of the solution, an examination of the vial's internal surface and analysis of an aggressive test solution to assess the propensity of the internal glass surface of vials to delaminate. These examinations and the use of an aggressive test solution are intended to be conducted by the pharmaceutical manufacturer, not the glass manufacturer or converter.

## GLASS TYPES

Glass in its pure form consists of silicon dioxide with a melting point in excess of 1700°. However, this is rarely used commercially because of the cost of working at these elevated temperatures. Added network modifiers, such as sodium, potassium, or boron oxide, lower the melting point and lower the chemical durability, whereas added network stabilizers, such as calcium and aluminum oxides, improve the durability of the glass. Colored glass (e.g., amber glass) is produced by transition metal oxides such as iron oxides. All additives to pure silicon dioxide, as well as silicon itself, can be viewed as potential extractables from glass containers.

Glass compositions do not exist as stoichiometric chemical compounds but rather are expressed by a range of compositions. Thus, there is allowable variation within a glass type, and glass types may vary slightly among glass producers. Soda-lime-silica glass consists of silicon dioxide (60–75 wt%), sodium and potassium oxides (12–18 wt%), and smaller amounts of calcium, magnesium, and aluminum oxides (5–12 wt%). This glass has a relatively high coefficient expansion (COE) of 80–90 × $10^{-7}$ per degree and is susceptible to breakage by thermic shock. Borosilicate glass consists of silica (65–80 wt%), boric oxide (7–13 wt %), and smaller amounts of sodium, potassium, and aluminum oxides. The presence of boron provides greater resistance to thermal shock through a reduction in COE and to hydrolytic attack by increasing the connectivity of the glass network. Type I glass is available in multiple formulations: tubular glass is available with a low COE, described as 32–33 expansion glass and with a relatively low COE (range, 48–56 expansion), for example 51 expansion glass, in reference to their individual COEs of 32.5 × $10^{-7}$ per degree and 51.0 × $10^{-7}$ per degree, respectively. Molded glass has a higher COE in the region of 60–63 expansion.

## FORMATION OF MOLDED AND TUBULAR GLASS CONTAINERS

Formation of molded and tubular glass containers requires a number of steps. The quality of the container used in packaging depends on the conditions and the quality control of each step. Both molded and tubular containers originate from a glass furnace, and different furnaces are dedicated to borosilicate or soda-lime-silica glass. The refractory bricks lining the furnace

DOI: https://doi.org/10.31003/USPNF_M7125_02_01

deteriorate with time and must be replaced. Worn bricks can contribute to cosmetic defects such as stones (inclusions in the glass) that become incorporated into the molded glass containers or glass tubing.

Molded glass vials and bottles are manufactured in a one-step process whereby a stream of molten glass is cut into a gob, which then enters a mold where air or tooling is used to shape the container to the mold. Formation of containers from tubing glass is a two-step process. Glass tubes of a specific diameter are formed from a stream of molten glass that exits the furnace, is cooled, and is sectioned into standard lengths. These tubes are subsequently converted into glass containers (ampuls, cartridges, syringes, or vials) by either the tubing glass manufacturer or by independent converters. It is technically difficult to form glass tubing with a diameter sufficient to make bottles containing 100 mL or more, so these containers are produced by molding.

Gas flames are used to soften tubing glass to form the neck, to melt the glass to form the base of ampuls or vials, and to separate the container from the glass tube. In the case of cartridges and prefillable syringes, the glass tube is cut to length, and the ends are softened to form the nozzle and flange of the syringe and the neck and rear of the cartridge. Heating rate, maximum glass temperature, and production speed are critical parameters that can be adjusted for individual forming machines. After formation, both tubular and molded containers pass through an annealing oven (lehr) that heats the containers to 20° to 30° above the transformation temperature ($T_g$) of the individual glass formulation ($T_g$ for borosilicate glass is approximately 570°) and then gradually cools them in order to remove stresses in the container due to the manufacturing process. This too is a critical process because poorly annealed containers show reduced chemical and mechanical durability.

The process of forming tubular vials and ampuls has an effect on the local surface composition of the glass. During formation of the neck and particularly the base, the temperature of the inner surface of the containers can exceed the evaporation point of some of the glass components such as alkali borates. Under certain time–temperature conditions, the glass can phase separate during forming, creating nonhomogenous surface chemistry on the interior of the container. Both scenarios are undesirable for the storage of aggressive liquids from a surface chemical durability perspective. Evidence of this can be obtained by appropriately etching the glass with acid, after which an opaque ring will appear above the heel of the container, indicating a negative change in the inner surface chemistry. The same phenomenon can be observed at the shoulder of the container as well, but in many instances this area does not experience prolonged contact with a liquid.

## PROCESSING OF MOLDED AND TUBULAR GLASS CONTAINERS

At times, the inner surfaces of glass ampuls, vials, and bottles undergo additional treatments. As an example, heating glass propagates sodium oxide toward the inner surface of the container, but washing with water does not remove sodium oxide because of the latter's limited solubility. When glass is exposed to an aqueous solution, sodium ions diffuse into the solution from the glass surface to produce hydroxide ions, resulting in an elevated pH in unbuffered solutions. One common treatment is the use of ammonium sulfate which converts the sodium oxide on the inner surface to a depth of approximately 10–100 nm into highly soluble sodium sulfate that then can be removed by washing. Although removal of sodium ions from the surface does reduce the propensity for pH shift, the treatment does remove structural elements, leaving a thin silica-rich inner surface layer. The process originally was designed to raise the surface hydrolytic resistance of Type III soda-lime-silica glass to that of Type II glass in order to mimic the hydrolytic resistance of Type I glass. This process also can be applied to Type I glass.

In summary, the key factors that influence glass surface durability of containers manufactured from Type I glass are primarily the manufacturing conditions, such as the forming temperature, the time of exposure to heat, and the annealing conditions. The temperatures used for subsequent steps are lower than those used for forming and annealing (see *Table 1*), and do not pose an additional risk to the chemical durability of the glass from phase separation or volatilization. Post-manufacturing operations such as storage in humid conditions and processing, such as depyrogenation in the presence of water vapor and terminal sterilization via autoclaving, can also impact glass surface chemical durability.

**Table 1. Temperatures Encountered During Formation and Processing of Type I Tubular Glass Containers**

| Key Operations | Typical Temperatures (°) |
|---|---|
| Furnace | 1500–1650 |
| Sectioning of tube and base formation | 1300–1500 |
| Working range | 1000–1250 |
| Softening | 750–850 |
| Annealing | 550–600 |
| Depyrogenation range | 250–350 |
| Terminal sterilization | 110–130 |

## GLASS CONTAINER SOURCING

A pharmaceutical manufacturer has a range of choices when selecting a glass container for a drug product. These include the type of glass (I, II, or III), the production method (tubular or molded), surface treatments, as well as the size and neck finish of the container. It is important that the pharmaceutical manufacturers provide sufficient information on their requirements, such as the drug product formulation and the manufacturing and filling process, to allow the glass vendors to make informed judgments as to what containers to recommend.

@2024 USPC

Pharmaceutical manufacturers should consider the upstream provenance of the containers they purchase in that they should have sufficient knowledge of the glass manufacturing process and glass composition. This is essential to qualify a particular glass container type from a glass manufacturer for a particular drug product. The following knowledge is useful in this regard:

- Glass formulation
- COE for Type I tubular glass (32–33 or 48–56 expansion)
- Whether the glass converter makes its own glass feedstock or sources the glass feedstock from a third party
- The manufacturing site for the glass containers. If multiple sites manufacture glass containers for a given product, information to determine if the glass containers made at the different sites will perform comparably
- Whether the glass surface has been modified through chemical treatment such as ammonium sulfate by the glass manufacturer or converter.

The maker and user of a glass container should collaborate to assure that glass quality is monitored and maintained throughout the extent of the glass supply relationship. Glass quality should also be monitored and inferred by the user through observations made during storage throughout the product's use-by-date. The glass manufacturer and glass user quality management programs should include the following:

- Quality audits of glass supplier (glass manufacturer and/or converter) by the glass user
- Establishing mutually agreed upon acceptable quality levels for lots of glass containers
- Monitoring and trending of the quality of glass batches, including but not necessarily limited to, monitoring the values obtained by the *Surface Glass Test* in ⟨660⟩
- Monitoring and trending of glass quality and glass manufacturing process performance by the glass container manufacturer, including the effectiveness of methods used during the manufacturing process of the glass container to measure geometric tolerances and identify cosmetic defects
- Assurance that differences among different glass manufacturing sites do not significantly affect quality of a specified glass container sourced from multiple sites
- Presence of a system to monitor and qualify changes made to the glass manufacturing process and to inform customers of such changes.

## GLASS SURFACE CHEMISTRY

After manufacturers are assured of the quality and consistency of the glass containers they purchase, they can use the complex aqueous chemistry of surface glass to decide on potential drug product formulation and treatment steps that could increase glass stability. The first reaction between the glass surface and an aqueous phase (water or water vapor) involves ion exchange between hydrogen ions (or hydronium ions $H_3O^+$) from the aqueous phase and alkaline ions in the glass (*Equation 1*). This ion-exchange occurs in a short reaction time in acidic or neutral solutions. In basic solutions, the reaction occurs at the glass/water interface and dissolves the silica network. Further reaction of the silica releases silicic acid into the solution, thereby lowering the pH (*Equation 2*). These reactions result in hydration of the glass surface and an alkali-depleted, silica-rich layer.

$$H^+ + Na^+SiO^-(glass) \Rightarrow SiOH + Na^+ [1]$$

$$H_2O + Na^+SiO^-(glass) \Rightarrow SiOH + Na^+ + OH^- [2]$$

The presence of water in the leachate promotes hydrolysis of the Si–O bond forming a silica-gel layer (*Equation 3*).

$$H_2O + Si–O–Si \Leftrightarrow 2\ SiOH\ [3]$$

The mechanical properties of the surface gel that forms are different from those of bulk glass. Repeated hydration and dehydration of the layer leads to the cracking of the gel layer and eventual generation of particles. This process is worsened as the gel layer increases in thickness. This phenomenon is well known in glass exposed to ambient moisture (known as weathering). At higher pH values, the mechanism of glass degradation changes from the leaching of alkali elements to the dissolution of the silicate network as shown in *Equations 4* and *5*.

$$SiO_2 + 2H_2O \Leftrightarrow H_4SiO_4 [4]$$

$$H_4SiO_4 + OH^- \Leftrightarrow H_3SiO_4^- + H_2O\ [5]$$

Reaction (*Equation 5*) increases the solubility of the silicic acid in solution, driving the reaction forward. At some point the limit of solubility is exceeded, and particles are formed via precipitation. If the solution is not buffered, a decrease in the solution pH will take place. These reactions and scenarios apply only to the reactions of glass with water; the presence of drug product formulations can complicate the situation considerably.

## FACTORS THAT INFLUENCE INNER SURFACE DURABILITY

A number of factors have the potential to negatively influence the chemical durability of the inner surface of glass containers. These factors include glass composition, the conditions under which the containers were formed, subsequent handling and

Official

https://pharmacopeia.com/
Printed on: Fri Jan 05 2024 06:33:58 AM(EST)
Printed by: USP NF
Do Not Distribute

treatments, and the drug product in the container (*Table 2*). Not only can an aggressive drug substance corrode the inner surface, but excipients such as buffers, chelating agents and organic acids and high pH can also have a deleterious effect. For example, neutral solutions of sodium citrate attack glass with a severity similar to that of substantially alkaline solutions. Organic acids, such as gluconic and malonic acids, also corrode glass through a proposed mechanism of an ion exchange reaction in which metal ions on the glass surface are replaced by hydrogen ions from the acid. Not all listed factors negatively influence surface durability to the same degree, and can contribute to delamination either acting alone or in combination. Because of the range of variables, end users should examine all relevant variables for an individual drug product and assess the degree of risk for delamination and formation of subvisible and visible glass particles. In some situations, the accumulation of risk factors may indicate that the selection of a glass container for a particular formulation should be done following a predictive screening study to establish more stringent glass quality requirements or may indicate that a glass container should not be used for a formulation.

**Table 2. Factors That Influence the Inner Surface Durability of Glass**

| Container Manufacture | Container Processing and Storage | Drug Product: Formulation, Processing, and Storage |
|---|---|---|
| • Glass composition<br>• Molded or tubular container<br>• Tubular manufacturing process:<br>— Converting speed<br>— Converting temperature | • Post-formation treatments:<br>— Ammonium sulfate<br>—Washing<br>—Depyrogenation<br>• Storage conditions:<br>— High humidity | • Drug substance<br>• Formulation:<br>— Acetate, citrate, phosphate buffers<br>— Sodium salts of organic acids, e.g., gluconate, malate, succinate, tartrate<br>— High ionic strength, e.g., >0.1 M of alkaline salts<br>— Complexing agents, e.g., EDTA<br>— High pH, e.g., >8.0<br>• Terminal sterilization<br>• Labeled storage conditions (refrigerated or controlled room temperature)<br>• Shelf life |

## EVALUATION OF THE INNER SURFACE DURABILITY

Each lot of Type I, II, or III glass containers received by a pharmaceutical manufacturer must comply with the *Surface Glass Test* in chapter ⟨660⟩. This test provides an indication of inner surface chemical durability but does not appear to provide a clear direct correlation with the propensity to form glass particles or to delaminate. The alkalinity value represents the sum of all the internal surfaces of the container, and although this is representative for molded containers, tubular glass vials can have different degrees of surface chemical durability, depending on the location (e.g., just above the heel versus the side wall). A low surface alkalinity value can be obtained from containers treated with ammonium sulfate but the treatment itself may reduce the inner surface chemical durability, dependent upon the drug product formulation used to fill the vial. The most important variable that affects the surface durability is the drug product itself, and because it uses water as the extracting medium, the *Surface Glass Test* does not take this into consideration. Therefore, the *Surface Glass Test* represents only a first step in quality control of surface chemical durability, and additional screening methods should be used to demonstrate the suitability of vials for a formulation from a particular source before formal stability studies begin.

### Predictive Screening Methods

Screening methods help evaluate glass containers from different vendors (molded or tubular), glass formulations (e.g., 32–33 or 48–56 expansion for tubular glass), and post-formation treatments. Screening also establishes lot-to-lot variation from individual vendors during the drug development process, as well as lot-to-lot variations for products that have been shown to have a particular propensity to form glass particles or to delaminate. Screening methods can use a number of different technologies to examine three key parameters: visual examination and chemical profile of the inner surface layer, the amount and identity of extracted elements in solution, and the number of subvisible and visible particles in solution. Taken together, these elements are assessed by predictive tests for formation of glass particles and delamination, processes that reflect reduced durability. Predictive tests should look for precursors that lead to delamination rather than looking only for glass lamellae, and should be able to quickly provide predictive indication of surface durability. This makes the tests useful not just for vendor selection but also for evaluation of individual lots if necessary. Some of the more commonly used analytical techniques for evaluating the three key parameters are shown in *Table 3*.

**Table 3. Analytical Techniques for Screening Studies**

| Parameter | Test Parameter | Instrumentation |
|---|---|---|
| Glass inner surface | • Degree of surface pitting<br>• Chemical composition as a function of depth | • DIC Microscopy[a] or EM[b]<br>• SIMS[c] |
| Extracted elements in solution | • Conductivity/pH<br>• $SiO_2$ concentration | • Conductivity/pH meter<br>• IC–MS[d] or ICP–OES[e] |
| Lamellae and visible and subvisible glass particles | • Presence of lamellae and visible particles<br>• Lamellae or particle number and size<br>• Lamellae or particle morphology and composition | • Visual inspection<br>• Particle size analyzer<br>• SEM–EDX[f] |

[f] Scanning electron microscopy–energy-dispersive X-ray spectroscopy.

## Aggressive Screening Conditions

In selecting an appropriate primary glass container for pharmaceutical liquids, analysts should consider two approaches. The first is a series of accelerated temperature exposures using aggressive conditions that establish, in rank order, the chemical durability of the container without any specific reference to a given compound. Such testing can be helpful when selecting a packaging system for which the most chemically durable glass is desired. This testing also can be helpful in determining if changes in glass quality have occurred or in assessing processing changes that have been made by the primary container manufacturer. *Table 4* provides three examples of model systems that could be used for this assessment. Other model systems may be developed by the end users.

**Table 4. Formulations and Conditions Used to Accelerate Delamination**

| Formulation | 0.9% KCl<br>pH 8.0 | 3% Sodium Citrate<br>pH 8.0 | 20 mM<br>Glycine<br>pH 10.0 |
|---|---|---|---|
| Conditions | 1 h at 121°<br>1 or 2 cycles | 24 h at 80° | 24 h at 50° |

## Screening Strategy for Drug Products

Indicators include the appearance of a pitted, fractured inner surface particularly around the heel of the vial instead of a smooth surface, as well as a number of changes in the test solution, especially increases in $SiO_2$ concentration, the number of subvisible particulates in the solution, and a change in pH.

If the purpose of the glass screening is to determine the suitability of a given glass container for a specific product, the testing proposed in *Table 4* is insufficient. The exposure conditions are too harsh and do not provide a direct link to the product itself. In these instances, accelerated conditions are still relevant, but they must link to the relevant conditions for the given product. For example, if a product will be stored at 5° and the appropriate accelerated conditions are 30°, then testing should occur at 30°. Many products or formulations cannot withstand the elevated temperatures or high pH shown in *Table 4*. In addition, false positive testing results could be obtained because the unusually high temperatures shown in *Table 4* could cause signs of delamination, but moderate exposure at 30° would produce no evidence of glass incompatibility.

Because lower temperatures are required for actual product testing, the duration of testing must be longer, ranging from weeks to months. A larger number of vials also is appropriate for this scenario because the goal of the testing is to ensure the results are representative of the quality of the glass that will be used for the drug product. *Table 5* shows some of the conditions that could be used for testing with a specific product.

**Table 5. Screening Strategy for Glass Vials**

| Stress Test | Water Control | Drug Product Control |
|---|---|---|
| • Vials: washed, depyrogenated<br>• Filled with Stress Test solution<br>• Accelerated time and temperature treatment conditions | • Vials: washed, depyrogenated<br>• Filled with Water for Injection<br>• Autoclave if applicable to Drug Product<br>• Accelerated Drug Product stability storage conditions | • Vials: washed, depyrogenated<br>• Filled with Drug Product<br>• Autoclave if applicable<br>• Accelerated Drug Product stability storage conditions |

# CONCLUSIONS

Evaluation of the internal surface of glass containers begins with the *Surface Glass Test*, which uses water as the extracting medium. A low value is not always an indicator of a durable inner surface if the results are obtained using surface treatments (e.g., ammonium sulfate). Such treatments can lead to a silica-rich inner surface layer that represents a weakened glass structure, and risk of delamination increases when the vial is filled with formulations that contain aggressive agents such as organic acids, EDTA, or solutions that have high ionic strength or high pH. The screening methods and strategies described in this chapter can assist in the evaluation of glass containers from different suppliers or on a lot-to-lot basis and can provide an indication of the propensity of the selected formulation to cause delamination over time. Selection of glass vials intended to contain a drug product with one or more of the formulation risk factors identified in *Table 2* should undergo particular scrutiny.

    7.1 Applicability
    7.2 Application

## 1. INTRODUCTION

Drug products can chemically interact with their associated packaging systems and/or the system's plastic materials of construction while the drug product is being manufactured, shipped, stored, and administered. The magnitude of these interactions should not adversely affect the suitability of the packaged drug product, which includes both quality aspects and performance aspects such as efficacy, stability, purity, and compendial compliance.

Suitability for use, as determined by the impact of the interaction between a drug product and its packaging system, is assessed and established via the appropriate testing of the materials of construction, components, and packaging systems. *Plastic Packaging Systems and Their Materials of Construction* ⟨661⟩ establishes the tests and acceptance criteria that are necessary and appropriate for ensuring that such systems are suitable.

## 2. SCOPE

The purpose of this chapter is to communicate the key concepts behind ⟨661⟩ and its related sub-chapters, *Plastic Materials of Construction* ⟨661.1⟩ and *Plastic Packaging Systems for Pharmaceutical Use* ⟨661.2⟩, and to provide additional information and guidance regarding the application and applicability of these chapters.

## 3. GENERAL PRINCIPLES—THE OVERALL ASSESSMENT PROCESS

The objective of *USP* plastic packaging standards is to establish the tests and acceptance criteria to ensure packaging systems do not materially impact the effectiveness of the drug product. Given the complex nature of packaging systems and their development and manufacturing processes, multiple testing procedures are needed to establish their suitability with a specific drug product. The logical development and manufacturing process for packaged drug products, starts with the packaging system's materials of construction, continues with the packaging system itself, and ends with the packaged drug product. This progression forms the basis of a three-stage approach to packaging systems qualification, as illustrated in *Figure 1*.

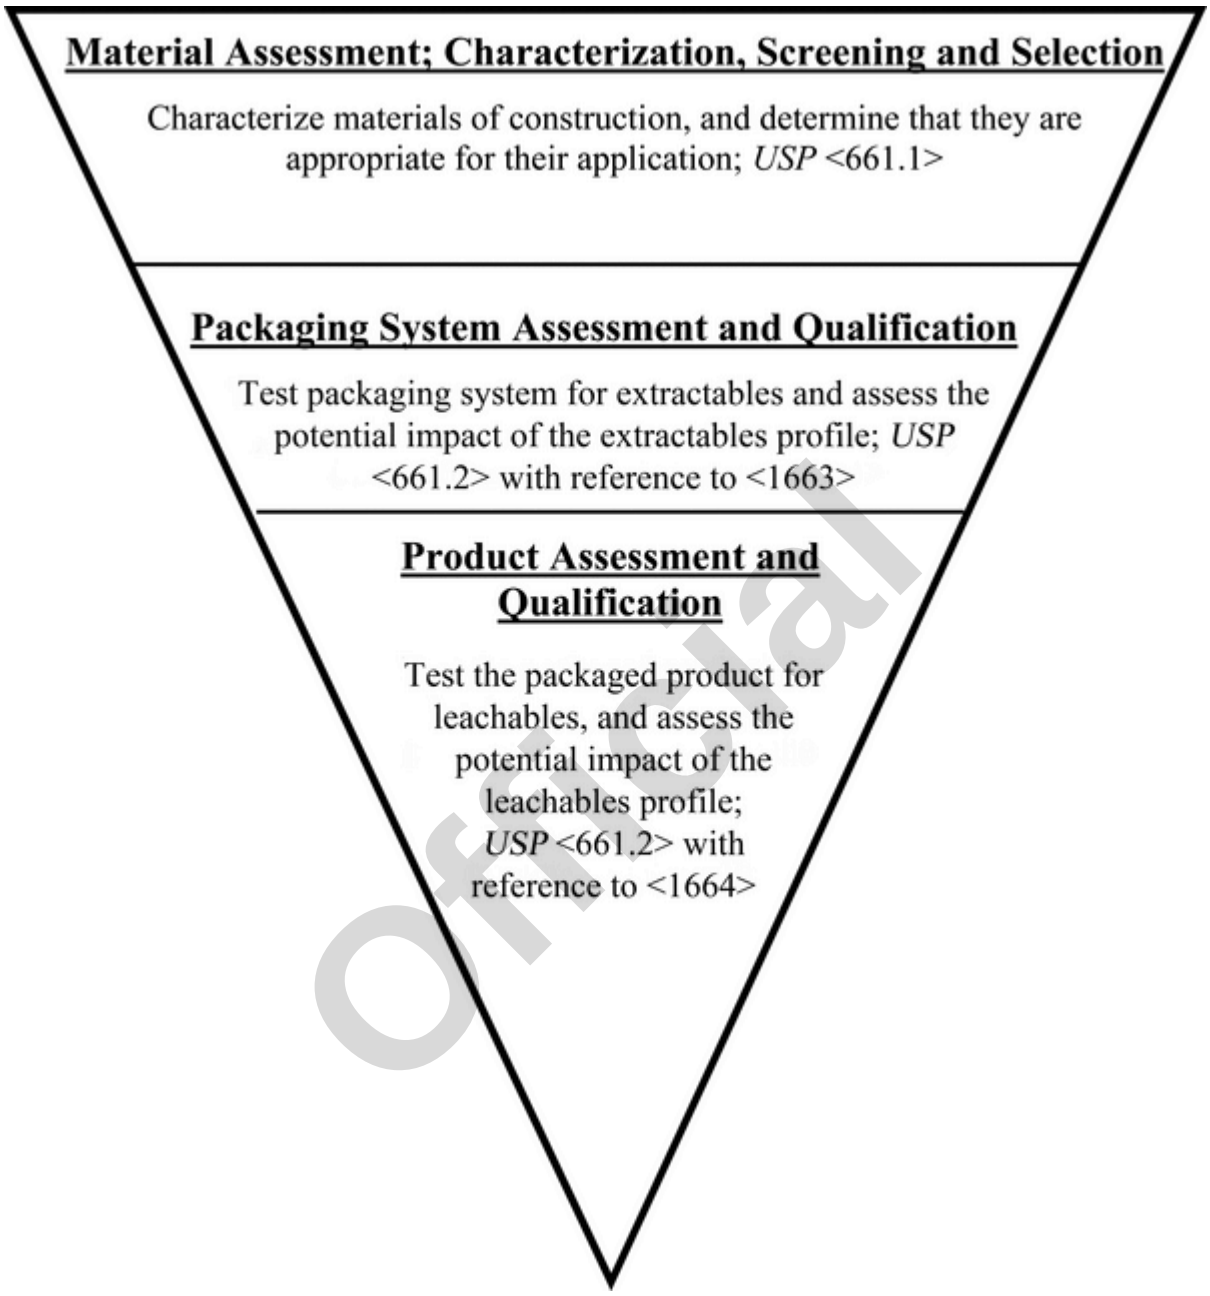

Figure 1. The three-stage process for the characterization and qualification of packaging systems and their materials of construction.

The process for establishing a packaging system's suitability includes: characterization of its materials of construction (ingredients); testing and assessment of the system itself (extractables); and testing and assessment of the packaged drug product (leachables). The initial step of this process involves chemically characterizing candidate materials of construction so the selection of materials can be rationally made and scientifically justified. The intermediate step of system assessment is useful and necessary because it bridges the risk assessment gap between testing starting materials and testing the finished drug product, while providing a means for optimizing drug product testing. This intermediate test is necessary because materials of construction undergo considerable stress, such as exposure to high temperatures, as they are being converted into either components of the packaging system or the packaging system itself. Processing aids and additional additives may be introduced during the manufacturing process for a packaging system, so the extractables profile is likely to be different from, and potentially more complex than, the extractables profiles of its materials of construction. Therefore, the initial hazard identification performed during material selection is appropriately revisited by testing and qualification of the overall packaging system.

Ultimately, the effect the packaging system may have on the drug product end-user is mediated by packaging system-derived substances that are present in the drug product. The third stage of the process includes product assessment, specifically leachables testing of the packaged product and impact assessment, which considers the user's exposure to the leachables.

## 4. MATERIALS ASSESSMENT: CHARACTERIZATION, SCREENING, AND SELECTION, *USP* ⟨661.1⟩

Testing and characterizing materials of construction for attributes relevant to their suitability provides a rational basis for material selection in designing a packaging system and minimizes the risk that a system made from those materials will be unsuitable. Therefore, the characterization of materials of construction is the first step in the process of developing and qualifying suitable packaging materials. Additionally, chemical characterization data may also provide the basis for effective and appropriate change control.

The intent of ⟨661.1⟩ is to establish whether potential material candidates could adversely affect the quality of packaged drug products. The basic tenet of materials assessment is that knowing the general composition and certain general characteristics of a material of construction allows one to:

- Rationally assess the potential suitability of materials with a degree of certainty that is appropriate for early product development and/or manufacturing.
- Forecast with some degree of accuracy the identity of extractables from that material of construction and from systems that use that material of construction.
- Use the assessment and forecast to establish and justify the use (or rejection) of a particular material in a particular packaging system.

To this end, ⟨661.1⟩ defines a well-characterized plastic material of construction as one whose:

- Identity has been definitively established.
- Biological reactivity has been established.
- General physicochemical properties have been established.
- Extractable elements (when necessary).
- Additives have been quantified.

Chapter ⟨661.1⟩ testing is not a guarantee that packaging systems constructed from plastic materials meeting ⟨661.1⟩ requirements will be suitable for their intended use. Characterization of a material using ⟨661.1⟩ establishes the composition or characteristics of the material, which can be used to determine if the material is an appropriate candidate for use in a packaging system. Nevertheless, ⟨661.1⟩ testing leverages the logical connection between material additives, material extractables, and system extractables, and thus provides a useful indication of the probable suitability issues for materials and systems. The actual qualification of the material occurs when the entire system is qualified for use in a particular application via ⟨661.2⟩ testing.

## 5. PACKAGING SYSTEM ASSESSMENT AND QUALIFICATION, *USP* ⟨661.2⟩

The impact of packaging systems on the chemical composition of packaged drug product can be established in two ways: 1) the packaging system itself can be characterized with respect to substances that can extract from it (extractables); or 2) the packaged drug product can be tested for packaging-derived substances that have leached into the drug product (leachables). In the case of extractables assessment, the impact is predicted based on a relationship that is established (or inferred) between extractables and leachables. In the case of leachables assessment, the impact is specifically measurable, assuming that all the relevant leachables can be discovered, identified, and quantified in the packaged drug product. In either case, ⟨661.2⟩ establishes the tests and acceptance criteria for the packaging system, while referring users to relevant informational chapters (e.g., *Assessment of Extractables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1663⟩ for extractables and *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩ for leachables) for insights on how to design and execute relevant studies.

Considering the packaging system as the test article, the intent of ⟨661.2⟩ is to define and delineate the testing needed to produce the data required for establishing the packaging system's suitability. Chapter ⟨661.2⟩ refers to this process of establishing the suitability of packaging systems as chemical suitability for use assessment and notes that a packaging system is suited for its intended use if:

- The packaging system is constructed from well-characterized materials, as established by testing according to ⟨661.1⟩.
- The packaging system's general physicochemical properties have been established.
- The packaging system's biological reactivity has been established.
- The packaging system has been established to be suitable by means of the appropriate chemical suitability for use assessment.
- The packaging system is chemically compatible with the packaged product, as established by appropriate compatibility assessments (e.g., stability studies).

### 5.1 Extractables and Leachables

For high risk dosage forms, in addition to being the basis for toxicological assessments, information about a packaging system's extractables can be used in several ways to optimize finished product testing for leachables. The potential quality or impact of extractables may facilitate identification of leachables that might adversely affect product quality. Such leachables of potential concern would necessarily be among the targeted analytes in testing of a final drug product within its packaging system. The targeting of specific leachables, as opposed to the screening of drug products for unspecified leachables, has significant analytical benefits, including the ability to develop, validate, and utilize test procedures that are appropriately sensitive, specific, and accurate. Extractables (and their accumulation levels in extracts) can be used to forecast the levels of leachables in the finished product, depending on how well the extraction conditions mimic the drug product's composition and actual conditions of clinical use. If the extraction conditions are such that they accelerate and modestly exaggerate the product's clinical use conditions, then the extractables and their levels in the extracts can be extrapolated to estimate the

Official

https://pharmacopeia.cn/

maximum levels of leachables in the finished product. If such extractables are assessed for their quality impact, the results of that assessment can also be extrapolated to, and considered to be relevant for, the drug product. Finally, if no adverse impact is found based on the extractables data, then no adverse impact can be inferred for the leachables in the packaged drug product.

***Change to read:***

## 6. APPLICABILITY AND APPLICATION OF ⟨661.1⟩

### 6.1 Applicability

1. The holder of the drug product application and drug product manufacturer [in the case of many over-the-counter products (OTCs), where there is no application] bear primary responsibility and accountability for ensuring that the requirements of the chapters are met. The means by which the holder of the drug product application and drug product manufacturer obtain information to meet the requirement is at the discretion of the holder.
2. The testing required and acceptance criteria for materials of construction contained within ⟨661.1⟩ are relevant to and applicable for all dosage forms, because it is the universal expectation that packaging materials be constructed from well-characterized materials, regardless of the potential interaction between a dosage form. It has been established that the concepts and principles of risk management has a strategic role in designing, implementing, and interpreting effective and efficient material suitability testing and assessments. It is well-established that risk-management tools and principles can be used to define the nature and magnitude of assessment (including testing), where low-risk situations require reduced or alternate assessment (testing) versus high-risk situations noted in *Plastic Materials of Construction* ⟨661.1⟩, *Table 1*, which establishes biological reactivity and chemical tests that differ for low-risk dosage forms (such as oral and topical) versus high-risk dosage forms (such as inhalation and injections).
3. Application of ⟨661.1⟩ to materials of construction used for systems other than packaging systems for finished drug product is beyond the scope of this chapter at the present time, but the concepts and principles of the chapter may be applicable and relevant to other systems and their materials for construction (e.g., manufacturing systems for pharmaceutical products, and packaging/storage systems for drug substances).
4. The scope of ⟨661.1⟩ is materials of construction for packaging systems for finished drug products and ⟨661.2⟩ is packaging systems for finished drug products. A third type of test article is components and if component testing is considered to be necessary, the relevant testing and acceptance criteria for the component are contained within ⟨661.2⟩.

### 6.2 Application

1. There are two means of demonstrating that a plastic material of construction has met the requirements of ⟨661.1⟩. The first is to perform the testing contained within ⟨661.1⟩ and meet the acceptance criteria. The second is the use of the material in a packaging system that meets the requirements of ⟨661.2⟩.
2. The outcome of ⟨661.1⟩ testing is that the tested material of construction has been well-characterized. Characterization data generated during ⟨661.1⟩ testing can be used to support decisions on the proper use of the tested material. The characterization data do not specifically or universally qualify the material for use in packaging systems because the material's use can vary depending on the packaging applications.
3. It is the responsibility of the user of the tested material to decide if the material is appropriate for their intended application. It is the user's expert review of ⟨661.1⟩ test results, coupled with additional information as necessary and appropriate, that establishes whether a well-characterized material is suitable for a specific application.

#### 6.2.1 IDENTIFICATION TESTS

The identification tests required in ⟨661.1⟩ serve the purpose of categorizing a material so that it is properly tested and evaluated against the appropriate acceptance criteria. The acceptance criteria for identification are based on a comparison of the test result obtained for the test material versus the relevant Reference Standard. This comparison is based on the concept of substantial equivalence as opposed to an exact quantitative acceptance criteria.

Establishing substantial equivalence requires that the test results and test material versus Reference Standard be considered to be equivalent. For example, although the infrared (IR) identification acceptance criteria may include wavenumber targets, these targets are not acceptance criteria but rather serve the purpose of establishing the expected general characteristics of the IR spectra. An identification test is considered successfully completed if the analytical results obtained for the test article and the appropriate Reference Standard are substantially equivalent, and where all differences between the test results for the article and the Standard are explained by the nature, processing, and/or composition of the test article.

#### 6.2.2 CHEMICAL TESTING

The chemical testing prescribed in ⟨661.1⟩ is orthogonal: physicochemical tests provide a general overview of extracted substances whereas plastic additives tests address potential organic extractables. It is also the case that chemical testing alone may not demonstrate all potential impacting attributes. Thus, chemical testing is augmented by the orthogonal approach of establishing biological reactivity.

#### 6.2.3 EXTRACTABLE ELEMENTS

Knowledge of the potential extractable elements present in the materials of construction for plastic packaging components is important in establishing that the material is well-characterized. Knowledge of the elements that are likely to be present and

https://pharmacopeia.cn/

the concentrations at which they may be observed provides information to determine potential drug product quality. Materials of construction can vary widely in terms of their intentionally and unintentionally added elements, the levels of the elements, and the chemical form of the elements. Because of this variety in composition, it is challenging to provide universally effective and efficient test methodologies for extracted elements (including extraction conditions), lists of elements to target, and reporting requirements. Therefore, it is the material user's responsibility to evaluate the need for extractable elements testing and, if such testing is necessary, to establish and justify the means by which testing is accomplished, taking into account extraction conditions, target elements, extract analysis, and reporting requirements.

In general, however, the following points are relevant:

- Extraction conditions should be such that elements that could be leached into pharmaceutical drug products are fully extracted from the test material. Thus, the combination of extraction solvent(s), extraction temperature, extraction duration, extraction process, and extracted surface area to extraction solution volume should be carefully considered. It is important to remember that the objective is to perform an extraction, not to digest or dissolve the test material. Furthermore, the extraction process should produce an extract that is analytically expedient, meaning that the extract is amenable to analysis by the chosen test methodology with the necessary levels of sensitivity, accuracy, and precision.
- Target elements should minimally reflect those elements that have been intentionally added (e.g., catalyst and processing aids) to the material, those elements that could be unintentionally added to the material (e.g., processing contaminants, ingredient impurities), and those elements of potential toxicological concern, whether they are intentionally or unintentionally added.
- Analytical test methods should be compatible with the extract and should have the specified sensitivity, accuracy, and precision.
- Reporting requirements must reflect the analytical capabilities of the method and the levels at which an extracted element could have an adverse effect on drug product quality. The desired situation is that the test method is capable of producing reliable information at levels near those at which an element could have such an adverse effect. In this case, the reporting requirement is established considering the juxtaposition of analytical capability and potential effect.

### 6.2.4 PLASTIC ADDITIVES

The sole purpose of the tests for plastic additives is to establish which additives are present and to ensure that the levels of these additives are known. This information is relevant because additives are typically a source of extractables and leachables.

In ⟨661.1⟩, the chapter requires that materials be tested for all relevant analytes. Clearly, an analyte will be present in a material if it is intentionally or knowingly added to the material during its production or if testing of the material has revealed the presence of the analyte. Although test methods included in ⟨661.1⟩ may be of sufficiently broad scope to detect all relevant additives, this is not always the case and one cannot rely on these methods to reveal all relevant analytes. It may be the case that the material's vendor has knowledge that may be unavailable to the material's user, which is germane to establishing relevant analytes. It is reasonable to expect that material vendors and users work together to produce a complete and robust list of relevant analytes.

It is reasonable to anticipate that there may be some information that the vendor is not in a position to share with a material's user. Nevertheless, it is in the interest of both the vendor and the user that a material be well characterized and that the characterization include all relevant analytes. Thus, it is strongly recommended that the vendor and the user find a means of establishing all relevant analytes.

### 6.2.5 UNADDRESSED MATERIALS

For the materials that are not currently listed in ⟨661.1⟩ (unaddressed plastics), it is the responsibility of the user to: 1) develop those test methods (e.g., ▲physicochemical▲ (ERR 1-Nov-2020), biological reactivity, and plastic additives) and acceptance criteria; 2) justify those test methods and acceptance criteria, specifically considering their consistency with test methods and acceptance criteria that exist for materials that are listed in ⟨661.1⟩; and 3) possess the test results obtained when the material is tested.

### 6.2.6 CONCEPT OF NON-INTERACTION OF MATERIALS

Testing of materials of construction via ⟨661.1⟩ is predicated on the circumstance that the material will most likely interact with the packaged drug product when the material is used in a packaging system. It is not necessary for a material used in a packaging system to be well-characterized if there is little or no chance of the material and the packaged drug product interacting. Under these conditions the materials of construction would be considered non-interacting and would be exempt from ⟨661.1⟩ and ⟨661.2⟩ testing.

It is relevant to differentiate between "no direct contact" and "non-interacting", where the term "no direct contact" means that the material and the packaged drug product do not come into direct physical contact under the clinical conditions of use.

In certain applications a "no direct contact" material of construction is also a "non-interacting" material of construction, this does not ensure no interaction, especially when the conditions of contact include long durations and/or substantially elevated temperatures. To explain the concepts of "no direct contact" and "non-interacting", consider the following example. An aqueous drug product is packaged in a flexible plastic container, which is placed in a foil overpouch and the combination is terminally sterilized. An adhesive label is then applied to the outside of the foil overpouch.

Here, both the foil overpouch and the label are examples of "no direct contact", because there is at least one physical barrier (the primary container) between the packaged drug product and these two items. However, if the flexible plastic primary container is permeable, the foil overpouch can be considered a "potentially interacting" component, as substances from the overpouch could migrate through the primary packaging, especially under the high-temperature conditions of terminal sterilization. The label is a "non-interacting" component because 1) the foil overpouch is impermeable and 2) the label is applied after the thermal stress associated with terminal sterilization.

Official

https://pharmacopeia.cn/

The difference between a “potentially interacting” and “non-interacting” “no direct contact” component is the permeability of the barrier that separates the “no direct contact” components from the drug product. If the barrier is incomplete, then the component (and its materials of construction) is “potentially interacting” and the materials should be tested per ⟨661.1⟩. If the barrier is complete, then the component (and its materials of construction) is “non-interacting” and the materials need not be tested per ⟨661.1⟩.

## 6.3 Description of Plastics Contained in ⟨661.1⟩

### 6.3.1 CYCLIC OLEFINS

Cyclic olefin copolymers are manufactured by the copolymerization of cyclic monomers, such as tetracyclododecene or norbornene, with an olefin such as ethylene or propylene; or by ring-opening metathesis polymerization (ROMP) of cyclic monomers, followed by hydrogenation facilitated by Ziegler-Natta catalysts to produce cyclic olefin polymers. Cyclic olefins are commonly supplied in pellet form and are suited for standard polymer processing techniques such as extrusion, injection molding, injection blow molding, compression molding, thermoforming, and others. As they are amorphous, and given their high purity, moisture barrier, clarity, and sterilization compatibility, cyclic olefins are an excellent alternative to glass in a wide range of medical products, including packaging. Cyclic olefins exhibit good chemical resistance and are generally considered to be of high purity with low levels of extractables. Nevertheless, cyclic olefins may contain residual processing aids, colorants, and antioxidants.

### 6.3.2 POLYAMIDE 6

Polyamide 6 is synthesized by ring-opening polymerization of caprolactam. Hydrolytic or catalytic ring-opening polymerization of caprolactam produces epsilon-aminocaproic acid, which readily condenses to polyamide 6 at high temperatures and under a vacuum. The high strength, flexibility, and chemical resistance of crystalline polyamide 6 make it well suited for pharmaceutical applications ranging from soft and flexible tubing to catheters and containers to stiff components for surgical and dental instruments. Entities present in commercial polyamide 6 include residual monomers, residual reaction intermediates, residual catalysts (copper and chromium oxides) and activators (acetyl lactams, oxazolines, ethylenebisamides, and isocyanates) and certain additives including stabilizers (mixtures of metal and alkali metal halides), processing aids (nucleating agents and lubricants), and modifiers (chain extenders, plasticizers, and impact modifiers).

### 6.3.3 POLYCARBONATES

Polycarbonates are a group of thermoplastic polymers containing carbonate groups in their chemical structures. In interfacial polymerization, the polycarbonate material is produced by the reaction of bisphenol A (BPA) and phosgene. This process is being replaced by an alternative, termed “melt polymerization”, which entails transesterification from BPA and diphenyl carbonate, thus avoiding the use of phosgene. Entities present in commercial polycarbonates include residual monomers, solvents or catalysts (triethylamine or lithium halides, and hydroxides or aluminum hydrides), processing aids (e.g., mold release agents), UV stabilizers, impact modifiers, flame retardants, colorants, and sterilization stabilizers (free radical scavengers including propylene glycol, aromatic bromate, or disulfide compounds).

### 6.3.4 POLYETHYLENES

High- and low-density polyethylenes are long-chain ethylene-based polymers synthesized under controlled conditions of heat and pressure with the aid of catalysts from NLT 85.0% ethylene and NLT 95.0% total olefins. Other olefin ingredients that are most frequently used are butene, hexene, and propylene. Low-density polyethylene (LDPE) contains many long-chain branches along the polymer backbone, preventing the alignment and packing of the chains, thus forming a low-density material. Linear low-density polyethylene (LLDPE) contains several short chains along the polymer backbone that prevent the alignment and packing of the polymer chains, thus creating a poor crystalline material. High-density polyethylene (HDPE) contains relatively few side chains, allowing the polymer backbone to align and pack together, thus forming a crystalline, high-density plastic. High-, low-, and linear low-density polyethylene all have an IR absorption spectrum that is distinctive for polyethylene, and each possesses characteristic thermal properties. High-density polyethylene has a density between 0.941 and 0.965 g/cm$^3$. Low-density polyethylene has a density between 0.850 and 0.940 g/cm$^3$. Additives are added to the polymer in order to optimize its chemical, physical, and mechanical properties, thereby rendering it suitable for its intended use. These additives may include nucleating agents, clarifying agents, antioxidants, colorants, lubricants, antiblocking agents, and others. These additives typically are present individually in the polyethylene at levels of 0.01–0.3 weight %, and the total levels of the antioxidants typically are < 0.3%. Other additives, specifically amides and stearates, typically are present in polyethylenes individually at levels of NMT 0.5 weight %. Polyethylene materials that provide light protection can contain as much as 4% by weight titanium oxide.

### 6.3.5 POLYETHYLENE TEREPHTHALATE AND POLYETHYLENE TEREPHTHALATE G

Polyethylene terephthalate (PET) polymers are long-chain crystalline [e.g., polyethylene terephthalate glycol-modified (PETG)] polymers prepared by the condensation of ethylene glycol with dimethyl terephthalate or terephthalic acid. PET copolymer resins are prepared in a similar way except that they may also contain a small amount of either isophthalic acid (NMT 3 mole %) or 1,4-cyclohexanedimethanol (NMT 5 mole %). Polymerization is conducted with the aid of catalysts and stabilizers. PET polymers may contain silica or silicates (NMT 0.5% by weight) and may contain colorants.

Official

https://mhathaway.github.io/

#### 6.3.6 POLY(ETHYLENE-VINYL ACETATE)

Poly(ethylene-vinyl acetate) polymers are typically obtained by copolymerization of mixtures of ethylene and vinyl acetate. Poly(ethylene-vinyl acetate) used in containers has a defined quantity of vinyl acetate of NMT 25%. Poly(ethylene-vinyl acetate) used in tubing has a defined quantity of vinyl acetate of NMT 30%. A certain number of additives are present in the polymer to optimize its chemical, physical, and mechanical properties, thereby rendering it suitable for its intended use. These additives may include antioxidants, amides, stearic acid salts, a source of base (calcium carbonate or potassium hydroxide), and inorganic fillers. Poly(ethylene-vinyl acetate) can contain NMT 3 antioxidants with individual levels of NMT 0.2 weight %. This material may also contain: 1) oleamide and/or erucamide at individual levels of 0.5 weight %; 2) calcium stearate, zinc stearate, or both at levels NMT 0.5 weight %; 3) sources of base at levels NMT 0.5 weight %; and 4) colloidal silica at 0.2 weight %.

#### 6.3.7 POLYPROPYLENE

Propylene polymers are long-chain polymers synthesized from propylene or other olefins, for example, ethylene or butene, under controlled conditions of heat and pressure with the aid of catalysts. A certain number of additives are added to the polymer in order to optimize its chemical, physical, and mechanical properties, thereby rendering it suitable for its intended use. These additives may include nucleating agents, clarifying agents, antioxidants, colorants, lubricants, antiblocking agents, and others. These additives typically are present individually in the polypropylene at levels of 0.01–0.3 weight %, and the total levels of the antioxidants typically are less than 0.3%. Polypropylene that provides light protection can contain as much as 4% by weight titanium dioxide.

#### 6.3.8 POLYVINYL CHLORIDE

Polyvinyl chloride (PVC) is produced by polymerization of the vinyl chloride monomer in a process that uses initiators that break down to start the radical chain reaction. The polymerization reactions used to produce PVC are designed to produce levels of residual vinyl chloride monomer of <1 ppm on a weight basis. Polyvinyl chloride may contain NMT 15% by weight of: 1) copolymers based on acrylic and/or methacrylic acids and/or their esters, 2) styrene, and/or 3) butadiene.

To obtain the required mechanical and stability characteristics, materials based on PVC may contain: 1) epoxidized oils at levels up to 8 weight %; 2) calcium and/or zinc salts of long chain fatty acids at levels NMT 1.5 weight %; 3) liquid paraffin, waxes, and/or hydrogenated oils at individual levels NMT 2 weight %; 4) nonylphenyl phosphite-type compounds at levels NMT 1 weight %; 5) sorbitol and macrogel esters, NMT 1.5 weight % each; 6) stabilizers at levels of either 0.25 weight % (for tin-based stabilizers) or 1 weight % (for other stabilizers); and 7) colorants, pigments, or opacifiers. The additives used and their allowed levels are dictated by the application of the polyvinyl chloride.

#### 6.3.9 POLYVINYL CHLORIDE, PLASTICIZED

PVC polymers are long-chain vinyl chloride polymers synthesized from vinyl chloride monomers via free radical polymerization. Various additives are compounded into PVC to provide the materials with properties that render it suitable for its intended use. These additives may include heat stabilizers, primary and secondary plasticizers, stabilizers, impact modifiers, lubricants, pigments, and others. These additives typically are present individually in the PVC at levels ranging from 0.1 to 45 weight %. The additives used and their allowed levels are dictated by the application of the plasticized PVC.

## 7. APPLICABILITY AND APPLICATION OF ⟨661.2⟩

### 7.1 Applicability

1. The holder of the drug product application and drug product manufacturer [in the case of many OTCs, where there is no application] bear primary responsibility and accountability for ensuring the requirements of the chapter are met. The means by which the holder of the drug product application and drug product manufacturer obtain information to meet the requirement are at the discretion of the holder.
2. The scope of ⟨661.2⟩ is packaging systems for finished drug products. If component testing is considered to be necessary, the relevant testing and acceptance criteria for components are contained within ⟨661.2⟩.
3. Application of ⟨661.2⟩ to systems other than packaging systems for finished drug products is beyond the scope of these chapters at the present time, but the concepts and principles of these chapters may be applicable and relevant to other systems.

### 7.2 Application

1. Chapter ⟨661.2⟩ requires that all packaging systems be demonstrated to be suitable by performing a chemical suitability for use assessment but does not specify the details of the chemical suitability for use assessment process acceptance criteria. Rather, for the chemical suitability for use assessment, ⟨661.2⟩ discusses the use of a risk-based approach in determining the level of testing that is deemed necessary for a packaging system. It is currently a regulatory expectation that extractables and leachables testing be performed for high risk dosage forms. Thus, ⟨661.2⟩ references chapters ⟨1663⟩ for extractables and ⟨1664⟩ for leachables, thereby providing users with a means for designing and implementing an effective, efficient, risk-based, and more or less customized extractables or leachables assessments that comply with regulatory requirements.

Official

https://pharmacopeia.cn/v29240/

2. Chapter ⟨661.2⟩ provides holders of packaging system or drug product applications and/or packaged drug products manufacturers with the flexibility to operate within the context of their own specific situation and their own specific risk-management philosophy. The trade-off for having such flexibility is that it is the responsibility of the holders and manufacturers to justify their test methods and acceptance criteria. It is proper and appropriate that the justification exists and that it be judged (and approved) on the basis of its individual scientific and risk-management merits.

# ⟨1663⟩ ASSESSMENT OF EXTRACTABLES ASSOCIATED WITH PHARMACEUTICAL PACKAGING/DELIVERY SYSTEMS

## PURPOSE

This general information chapter presents a framework for the design, justification, and execution of an extractables assessment for pharmaceutical packaging and delivery systems. The chapter establishes critical dimensions of an extractables assessment and discusses practical and technical aspects of each dimension. Although intended to be helpful and generally applicable, the chapter is for informational purposes and does not establish specific extraction conditions, analytical procedures, or mandatory extractables specifications and acceptance criteria for particular packaging and delivery systems or dosage forms; nor does it delineate every situation in which an extractables assessment is required. It is not possible for a general discussion of extractables to anticipate and cover all situations where an extractables assessment might be required. Designing an individual extractables assessment is a process that balances sound science, prudent resource allocation, and effective risk management. Achieving this balance is the responsibility and obligation of the drug product manufacturer and assumes due consideration of all applicable legal and regulatory requirements. The principles and best demonstrated practices outlined in this general chapter represent a consensus interpretation of sound science and can therefore be applied to any situation in which an extractables assessment is required for pharmaceutical application.

## KEY TERMS

This general chapter uses the following key terms listed below (*1*, *2*; also see *Packaging and Storage Requirements* ⟨659⟩). Note that the terms *Packaging System*, *Packaging Component*, *Primary Packaging Component*, *Secondary Packaging Component*, and *Materials of Construction* are also defined in ⟨659⟩, and the definitions below are intended for clarification purposes within the context of this chapter and are not intended to supersede those provided in ⟨659⟩.

*Packaging System (also referred to as a container–closure system):* The sum of packaging components and materials that together contain and protect the product. This includes primary, secondary, and tertiary packaging components.

*Delivery System:* The sum of components and materials that are used to transport a drug product from its packaging to the point of administration into the patient. For example, an administration set is a delivery system that is used to transfer liquid drug products from their plastic packaging system to the site of administration to the patient. It is noted that in some cases, the packaging system itself may perform the delivery function.

*Container:* A receptacle that holds an intermediate compound, active pharmaceutical ingredient, excipient, or dosage form and is in direct contact with the product.

*Closure:* A material that seals an otherwise open space on a container and provides protection for the contents. It also provides access to the contents of the container.

*Packaging Component* is any single part of the package or container–closure system including the container (e.g., ampuls, prefilled syringes, vials, bottles); closures (e.g., screw caps, stoppers); ferrules and overseals; closure liners; inner seals; administration ports; overwraps; administration accessories; labels; cardboard boxes; and shrink wrap.

*Primary Packaging Component* is a packaging component that is in direct contact or may become in direct contact with the product (e.g., IV bag).

*Secondary Packaging Component* is a packaging component that is in direct contact with a primary packaging component and may provide additional protection for the product (e.g., overpouch or dustcover for an IV bag).

*Tertiary Packaging* is a packaging component that is in direct contact with a secondary packaging component and may provide additional protection of the product during transportation and/or storage (e.g., shipping carton for an overpouched IV bag).

*Ancillary Component* is a component or entity that may come into contact with a tertiary packaging component during the distribution, storage, and transportation of the packaged product (e.g., pallets, skids, shrink wrap).

*Packaging Materials of Construction* are substances used to manufacture packaging components. These are also referred to as *Raw Materials*.

*Extractables* are organic and inorganic chemical entities that are released from a pharmaceutical packaging/delivery system, packaging component, or packaging material of construction and into an extraction solvent under laboratory conditions. Depending on the specific purpose of the extraction study (discussed below), these laboratory conditions (e.g., solvent, temperature, stoichiometry, etc.) may accelerate or exaggerate the normal conditions of storage and use for a packaged dosage form. Extractables themselves, or substances derived from extractables, have the potential to leach into a drug product under normal conditions of storage and use and thus become leachables.

*Leachables* are foreign organic and inorganic chemical entities that are present in a packaged drug product because they have leached into the packaged drug product from a packaging/delivery system, packaging component, or packaging material of construction under normal conditions of storage and use or during accelerated drug product stability studies. Because leachables are derived from the packaging or delivery system, they are not related to either the drug product itself or its vehicle and ingredients. Leachables are present in a packaged drug product because of the direct action of the drug product on the source of the leachable. Thus leachables are typically derived from primary and secondary packaging, as the primary and secondary packaging can serve as a barrier between the packaged drug product and other potential sources of foreign chemical entities (such as tertiary packaging and ancillary components). In certain circumstances, packaging may directly contact the patient under typical clinical conditions of use (for example, the mouthpiece of a metered dose inhaler). As a result of this contact, patients may be exposed to leachables from the packaging without the action of the drug product. Leachables are typically a subset of extractables or are derived from extractables.

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M7126_03_01
@2024 USPC

*Migrants* are also foreign organic and inorganic chemical entities that are present in a packaged drug product because they have leached into the packaged drug product from a packaging/delivery system, packaging component, or packaging material of construction under normal conditions of storage and use or during accelerated drug product stability studies. However, migrants are differentiated from leachables by the circumstance that migrants accumulate in the packaged drug product after the migrant has crossed a physical barrier, such as that provided by primary and secondary packaging. Because migrants cross a physical barrier, they are not present in the packaged drug product due to direct action of the drug product on the source of the migrant because the barrier prevents such direct action. Thus migrants are derived from secondary and tertiary packaging and ancillary components. Regardless of whether a substance is a leachable or a migrant, it is still a foreign substance in the packaged drug product and thus it must be impact assessed in the same manner. However, as the means by which a leachable and a migrant become entrained in a packaged drug product may be different, extractables studies meant to address leachables may be designed and implemented differently than extractables studies meant to address migrants.

*Extraction Studies* are the overall laboratory processes required in order to create extractables profile(s) of particular pharmaceutical packaging/delivery systems, packaging components, or materials of construction. Extraction studies are also referred to as *Controlled Extraction Studies*.

*Characterization* is the discovery, identification, and quantitation of each individual organic and inorganic chemical entity present in an extract above a specified level or threshold. Such thresholds can be based on patient safety considerations, materials considerations, the capabilities of analytical technology, etc.

*Scouting* is the process of acquiring general chemical information that provides insight into the nature and magnitude of extractables.

*Discovery* is the process of searching for, and ultimately finding, individual organic and inorganic chemical entities present in an extract.

*Identification* is the process of assigning a molecular structure to an organic extractable, or assigning constituent elements in the case of an inorganic extractable.

*Quantitation* is the process of measuring the level, or concentration, of an individual organic or inorganic chemical entity contained in an extract.

*Extractables Profiles* are qualitative and/or quantitative analytical representations of the extractables content of a particular extracting medium and set of laboratory extraction conditions.

*Leachables–Extractables Correlations* are established when observed drug product leachables are linked both *qualitatively* and *quantitatively* to extractables from associated packaging/delivery systems, packaging components, or materials of construction.

*Safety Concern Threshold (SCT)* is the threshold below which a leachable has a dose so low that it presents negligible safety concerns from carcinogenic and noncarcinogenic toxic effects.

*Analytical Evaluation Threshold (AET)* is the threshold at or above which a leachable should be characterized and reported for toxicological assessment. The AET can be mathematically derived from the SCT (or other threshold concepts) based on factors that include the dosing parameters of the drug product. When an extraction study is performed for the purpose of estimating the accumulation levels of leachables, the AET may be applicable to extractables as well as leachables. The concept of the AET is discussed in greater detail in *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩.

As noted, additional terminology and associated definitions are available (*1*, *2*, and ⟨659⟩).

## SCOPE

The scientific principles and best-practices described in this general chapter are intended to apply to any extractables assessment or extraction study of pharmaceutical packaging/delivery systems, packaging components, or materials of construction; the results of which are intended for establishing extractables profiles. Extractables profiles can be used in a variety of pharmaceutical development and manufacturing applications, including the characterization, selection, and qualification of materials of construction, packaging components or packaging/delivery systems; establishing leachables–extractables correlations; and/or simulating worst-case drug product leachables profiles. When appropriate, extractables profiles can also be used in establishing leachables–extractables correlations as described in *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩. These scientific principles and best practices can also be applied to materials of construction and functional components of equipment used to manufacture drug substances and drug products; e.g., filters, tubing, and tanks. In addition, these principles and best practices can be applied to materials of construction for the medical device component of a combination product (*2*), with appropriate consideration of the guidances and regulations that apply specifically to medical devices. These scientific principles and best practices apply to all organizations and individuals involved in the manufacture of drug substances, drug products, and in their stability studies, including but not limited to:

- Manufacturers of drug substances and drug products for human and veterinary use where manufacturing may involve operations at the applicant holder's facilities (i.e., facilities that belong to the holder of an approved New Drug Application or Abbreviated New Drug Application) or at those of a contractor for the applicant holder
- Manufacturers of combination products
- Packaging operations by the manufacturer or a designated contractor for the application holder
- Repackaging operations in which the drug product may be owned by an organization other than the primary manufacturer

Manufacturers and fabricators of pharmaceutical packaging/delivery systems, packaging components, and materials of construction may also apply these scientific principles and best-practices as appropriate.

## BACKGROUND INFORMATION

During the course of manufacturing, packaging, storage, distribution, and administration; dosage forms and their constituents can contact components and materials of construction of manufacturing and packaging equipment, and primary

@2024 USPC

and secondary packaging components and systems. Such contact may result in interactions between the dosage form and these components and materials. One such interaction is the migration or leaching of substances from any of these components and materials into the dosage form with subsequent delivery to the patient during drug administration. Patients also can be directly exposed to substances via direct contact with the packaging/delivery system during drug administration. Leachables, which can include both organic and inorganic chemical entities with wide chemical diversity, are of concern due to their potential safety risk to patients and potential compatibility risks for the drug product (e.g., drug substance interaction/degradation, pH change, appearance change, particle formation, protein aggregation/structure change, etc.). In order to assess these risks and manage the potential issues posed by leachables, it is necessary to know the identities and the levels to which leachables will accumulate in the finished drug product over its shelf-life. These two pieces of information can be used to establish the magnitude of patient exposure (dose) and therefore the safety risk posed by an individual leachable, as well as the likelihood of any compatibility issues involving the drug product.

Regulatory guidelines and various best-practice recommendations state that assessment of the potential impact of contact between a component or material and a final dosage form involves evaluating the final dosage form with respect to leachables. This assessment can include a migration or leachables study whose purpose is to discover, identify, and quantitate leachables that have migrated from the contacted system, components, or materials and accumulated in the dosage form. Alternatively, this assessment may involve performing a simulation extraction study, when use of such a study in lieu of a migration study can be justified. There are many science-based and practical reasons why such a leachables assessment typically does not stand alone as the single means of assessment. Since the pharmaceutical packaging/delivery system is the primary source of potential leachables, it is generally appropriate that any leachables assessment be preceded by an extractables assessment performed on the packaging/delivery system, its primary and certain critical secondary packaging components that are noncontacting but potentially interacting, and/or packaging and delivery system materials of construction; consistent with regulatory guidelines and best-practice recommendations. Such an extractables assessment can also be performed on particular components and/or materials of construction of manufacturing and packaging equipment, as well as certain tertiary packaging components, that are deemed of high leaching potential or have been implicated in an identified leachables problem with a particular drug product.

Extractables assessments can be used to:

- Characterize packaging/delivery systems, packaging components, combination product medical device components, manufacturing components, and their various materials of construction
- Facilitate the timely development of safe and effective dosage form packaging/delivery systems, manufacturing systems and processes by assisting in the selection of components and materials of construction
- Understand the effects of various manufacturing processes (e.g., sterilization) on packaging components and their potential leachables
- Establish the worst-case potential leachables profile in a manner which facilitates leachables studies, the development of leachables specifications and acceptance criteria (should these be required), and the safety evaluation/qualification of potential and actual leachables
- Establish the worst-case potential leachables profile in a manner which facilitates the safety evaluation/qualification of probable leachables when it is not scientifically possible to determine actual leachables
- Facilitate the assessment of patient exposure to chemical entities resulting from direct contact between a patient's body tissue(s) (e.g., mouth, nasal mucosa) and a packaging or combination product medical device component (e.g., a metered dose inhaler's plastic actuator/mouthpiece)
- Facilitate the establishment of qualitative and quantitative leachables–extractables correlations
- Facilitate the development of extractables specifications and acceptance criteria (if these are required) for packaging components, combination product medical device components, and materials of construction
- Facilitate investigations into the origin(s) of identified leachables whose presence causes quality and/or safety issues (such as out-of-specification results) for a marketed product

In these ways, extractables assessments can support Quality by Design (QbD) principles for the development and manufacture of pharmaceutical packaging/delivery systems and drug products. Note that although characterization of packaging/delivery systems and materials is a goal of many extractables assessments, regulatory guidances and best-practice recommendations clearly stress that extractables assessments also serve as investigations into potential leachables (*1*–*5*).

As stated previously, it is not a goal of this chapter to identify each case in which an extractables assessment is required for packaging/delivery systems, individual packaging components, or materials of construction for any particular type of dosage form. This is the responsibility of the Holder of the NDA (applicant holder), and assumes appropriate consideration of applicable regulatory guidance documents. Rather, this chapter addresses the question "If an extractables assessment is required, what are the scientific principles and best demonstrated practices under which it should be accomplished?"

As performing an extractables assessment involves the processes of discovery and identification, an extractables assessment can be facilitated by knowledge about the test article, especially its composition. Thus it is strongly recommended that the test article assessor and the test article vendor collaborate in such a way that the test article assessor has access to critical information which will aid in the design and implementation of an effective and efficient extraction study. Additionally, it is noted that characterization of the test article per *Plastic Materials of Construction* ⟨661.1⟩ will provide information that is useful in the design and implementation of extraction studies.

Achieving the objectives of an extractables assessment requires performance of an extraction study in order to create extractables profiles. An extraction study has two critical dimensions: laboratory generation of the extract (extraction) and testing the extract (characterization).

# GENERATING THE EXTRACT

## General Concepts and Critical Experimental Design Parameters

Extractables are derived from a variety of sources and exhibit extensive chemical diversity. Primary sources of extractables include:

- Chemical additives in individual elastomeric/polymeric packaging components and raw materials, including impurities in these additives
- Chemical entities and additives that are present in packaging components composed of glass and metals
- Entities related to the dissolution of the packaging component itself (e.g., iron extracted from a stainless steel material, silicon extracted from glass)
- Monomers and higher molecular weight oligomers derived from incomplete polymerization
- Migrants from secondary and tertiary packaging components, such as inks, label adhesives, and volatiles from cardboard shipping containers, plastic storage bags, and other shipping aids such as wooden pallets
- Surface residues, such as heavy oils and degreasing agents on metal canisters and containers
- Chemical substances on the surfaces of component fabrication machinery or other drug product manufacturing systems, such as mold release agents, and antistatic and antislip agents
- Chemical additives, monomers/oligomers, impurities, etc., in various parts of component fabrication machinery or other drug product manufacturing systems

As noted above, the chemical diversity of extractables is significant. For example, the chemical additive category *antioxidants* includes hindered phenols, secondary aromatic amines, hindered amines, organosulfur compounds, organophosphorus compounds, and other chemical classes.

Extraction is a process of treating a material with a solvent to remove soluble substances. Extraction is a complex process influenced by time, temperature, surface area to volume ratio (i.e., stoichiometry), extraction medium, and the phase equilibrium of the material (*3*). There are two reasons why an extraction study is the necessary and appropriate means of accomplishing the various objectives of an extractables assessment. First, there is no other viable analytical alternative. Characterizing a material for potential leachables in its natural solid state is a goal of modern analytical chemistry rather than an accomplishment. Second, even if a direct characterization could be accomplished, it would at best only establish the identities and levels of chemical entities present in the material, and not assess the leaching characteristics of these chemical entities. A compositional assessment does not take into account any chemical reactions that can alter the molecular structures of potential leachables over the dosage form's lifecycle. For example, in the case of phenolic antioxidants that are leached by an aqueous drug product, hydrolysis and oxidation products can accumulate in the drug product. The only viable means for producing data related to leaching is to use a process such as laboratory extraction that is mechanistically similar to leaching.

The design of an extraction study is dictated by the purpose of the extractables assessment and the question(s) being asked, as well as the available information regarding the chemical composition of the test article(s) to be extracted. Extraction studies can be designed to answer questions such as:

- What are the chemical additives in a particular packaging component or material of construction?
- What are the maximum accumulations of chemical additives from a particular packaging component into the dosage form?
- What are the likely contents of an end-of-shelf-life drug product leachables profile?

Addressing each of these questions requires a particular set of parameters, such as extraction time, extraction temperature, extracting solvent, extraction technique, sample surface area to extracting solvent volume ratio, etc. Clearly, the intent of the extractables assessment must be established before the study design is finalized. For example, if the purpose of the extraction study is to simulate a worst-case leachables profile, then the study can be termed a simulation study that should produce an extract that:

- Contains all the substances (extractables) that could leach into the final product at levels considered potentially significant
- Contains these extractables at concentrations that are greater than or equal to the maximum concentration that these chemical entities will accumulate in the drug product as leachables at any time during the shelf-life
- Is generated more efficiently and in less time than that required for a drug product leachables study
- Is amenable to chemical analysis

The concept of a simulation study is addressed in greater detail in *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩. The means by which an extraction process is accomplished are reflected in the juxtaposition of several experimental parameters including:

- The chemical nature of the extracting media
- The time duration of the extraction process
- The temperature and pressure at which the extraction is performed
- The stoichiometry of the extraction process (extracted surface area per unit volume of extracting solution)
- The mechanism or process by which the extraction is accomplished

Extraction processes have been described as "accelerated", "aggressive", "exhaustive", "vigorous", "harsh", and so on, and for medical device studies certain of these terms have been defined. In general, extraction processes should allow completion in a reasonable time frame but should not be so aggressive that they alter the qualitative and/or quantitative nature of the resulting extractables profile. The most aggressive extraction conditions are reserved for the quantitative determination of chemical additive contents in components and materials. Because such studies are intended to quantitate specific known chemical additives and not to simulate a drug product leachables profile, it is acceptable to use extraction conditions which

disrupt or dissolve the component or material being extracted, and thus to alter the resulting extractables profile, while recovering the target additive(s) without loss or chemical decomposition.

## Chemical Nature of the Extracting Medium

Of all the parameters involved in generating the extract, the extracting medium is the most critical because it is the extracting medium that accomplishes the extraction, and all other parameters merely facilitate the extraction. Establishing and justifying the extracting medium (or media) is both straightforward *strategically* and complex *tactically*. *Strategically*, if the purpose of a particular extraction study is, for example, to simulate a worst-case leachables profile, then the ideal situation is for the extracting solvent to have a similar or greater propensity to extract substances as the formulation, thus obtaining a similar qualitative and quantitative extractables profile. This is clearly stated in regulatory guidances and best practice recommendations (*1*, *4*, *5*). Therefore, the most logical *tactic* for this simulation study is to use the formulation itself as the extracting medium and in the absence of complicating factors, such an approach is recommended. However, in certain cases the use of the formulation as an extracting medium complicates extract characterization to such an extent that it is impractical. The various guidances and recommendations suggest that if the use of the drug product as the extracting solvent is not feasible, then the drug product vehicle, or placebo, could be used as an effective extracting medium. This recommendation is derived from the fact that the drug substance itself does not typically create the "leaching power" of a drug product but rather that it is the formulation's ingredients (drug product vehicle) that establish the drug product's ability to leach substances from a contacted material.

When circumstances require that an extraction study must be accomplished with a simulating solvent(s), it is necessary to establish and justify the composition of these solvents. In order to accomplish this objective, one must consider all the physicochemical characteristics of a formulation and/or simulating solvent that influence its "extracting power". In certain circumstances, the formulation is sufficiently simple that the critical characteristics can be readily delineated and simulated. For example, the extracting power of polar aqueous drug products consisting of soluble ingredients (such as an injectable with a drug substance, buffers, and diluent) is, for organic extractables, driven primarily by drug product pH. In such a circumstance, simulating the drug product pH with an analytically viable buffer system for the extraction study may be appropriate and justifiable. For inorganic extractables, utilization of a simulating solvent having similar metal-chelating properties as the drug product vehicle may also be appropriate and justifiable. It may also be the case that largely non-polar drug products can be readily simulated with analytically expedient organic solvents. For example, chlorofluorocarbon and hydrofluoroalkane propellants used in metered dose inhalers (MDIs) can be simulated with dichloromethane as an extracting solvent and isopropanol can be used to simulate ethanol, a common co-solvent in MDI formulations.

Many drug products are compositionally intermediate between the polar and nonpolar examples just discussed. Examples of such products include "aqueous" drug products that contain stabilizers, solubilizing agents, chelating agents and buffers, lipid-containing products, and biotechnology products containing proteins, peptides, and blood-derived products. Such products have a characteristic polarity which establishes their "extracting power". Thus, an appropriate simulating solvent will have a polarity that matches that of the drug product. Binary mixtures of miscible solvents (such as alcohol/water) have been utilized as simulating solvents for these types of drugs product.

It may be that a single simulating solvent cannot be established and justified for a specific drug product, or that the focus of the extractables assessment is a material or system that will be characterized for use with multiple, compositionally diverse drug products. In such circumstances, the drug product's ability to leach chemical entities from a packaging system can be established based on the use of multiple extracting solvents, each of which addresses one (or more) of the extracting "mechanisms" that are relevant to the drug product (or drug products) under investigation. The use of multiple solvents is consistent with industry-driven best-practice recommendations for drug products that have a relatively high risk of dosage form interaction with the packaging system and a relatively high safety risk relative to the route of administration (e.g., inhalation aerosols and solutions, injectables and injectable suspensions) (*1*). Therefore, the use of multiple solvents (or extracting media) with different polarities, pH, ionic strength, or extracting powers, is recommended for high risk dosage form packaging system components and materials requiring extraction studies in order to simulate a drug product leachables profiles (see *Table 1*). If the goal of an extractables assessment is materials characterization, then simulating a drug product vehicle is both unnecessary and undesirable since this goal requires qualitatively and quantitatively efficient extractions. Such extractions generally are only achieved with relatively powerful organic solvent systems capable of softening, swelling, or dissolving the material's polymer matrix and releasing quantitative levels of additives and other chemical entities.

**Table 1. Possible Extracting Media Relative to Particular Packaging Components**

| Packaging Component | Possible Extracting Media[a] |
|---|---|
| MDI valve elastomer seal (MDI formulation contains 1,1,1,2-tetrafluoroethane and ethanol) | Nonaqueous solvents (e.g., Dichloromethane Isopropanol Hexane)[b] |
| Dry powder inhaler mouthpiece | Water (unbuffered)<br>Isopropanol[c] |
| Small-volume parenteral vial rubber stopper (aqueous formulation buffered at pH 6.5) | Water (pH 5.2)<br>Water (pH 9.5)<br>Isopropanol:water (50:50)[d] |
| Large-volume parenteral plastic bag (aqueous formulation buffered at pH 7.2) | Water (pH 5.2)<br>Water (pH 9.5)<br>Isopropanol:water (50:50)[d] |

[a] The possibilities listed in *Table 1* are provided for example only and should not be interpreted as standard practice recommendations.
[b] These extraction media reflect the varying polarities of the organic solvents used in MDI formulations.
[c] These extraction media reflect both the hydrophilic and lipophilic character of human saliva and allow materials characterization.

@2024 USPC

[d] These extraction media reflect the chemical nature of the formulation. Using media whose pH range encompasses, and slightly exceeds, the pH limits of the product addresses the potential effect of pH on the extractables profile. The use of an aqueous mixture containing an organic solvent takes into account the possible presence of formulation additives such as solubilizing agents that can influence the leaching power of the formulation. The specific organic solvent used and its proportion in the extracting medium depends on the specific chemical nature of the formulation and on practical issues associated with testing the extract.

If the goal of an extractables assessment is materials characterization, then simulating a drug product vehicle is both unnecessary and undesirable since these goals require qualitatively and quantitatively efficient extractions. Such extractions generally are only achieved with relatively powerful organic solvent systems capable of softening, swelling, or dissolving the material's polymer matrix and releasing quantitative levels of additives and other chemical entities.

## Extraction Time and Temperature

Extraction time and temperature are critical factors in the extraction process. Although the nature of the extraction solvent establishes the magnitude of the extraction (i.e., the amount of substances that can be extracted from a material at equilibrium), the combination of extraction time and temperature establishes the magnitude of the driving force and the degree to which equilibrium is actually achieved. In a simulating extraction study the purpose of elevated temperature is to increase the extraction rate, so that a short experimental time may simulate longer leaching times (*1*, *5*, and *6*).

Because extraction is a diffusion process, the relationship between the diffusion rate and temperature can be expressed empirically by the Arrhenius equation. The mathematics involved in a process that is driven by Arrhenius kinetics have been established in ASTM F1980-07 (2011) Standard Guide for Accelerated Aging of Sterile Barrier Systems for Medical Devices (*7*), which may be a useful guide for establishing accelerated contact conditions. As with all such models, the proper use of this model requires an understanding of the model's basis and essential principles, assumptions, and limitations (*2*).

Extractables profiles obtained with a given extracting medium and extraction technique can and should be monitored for equilibrium or the attainment of asymptotic levels of extractables (see *Figure 1*).

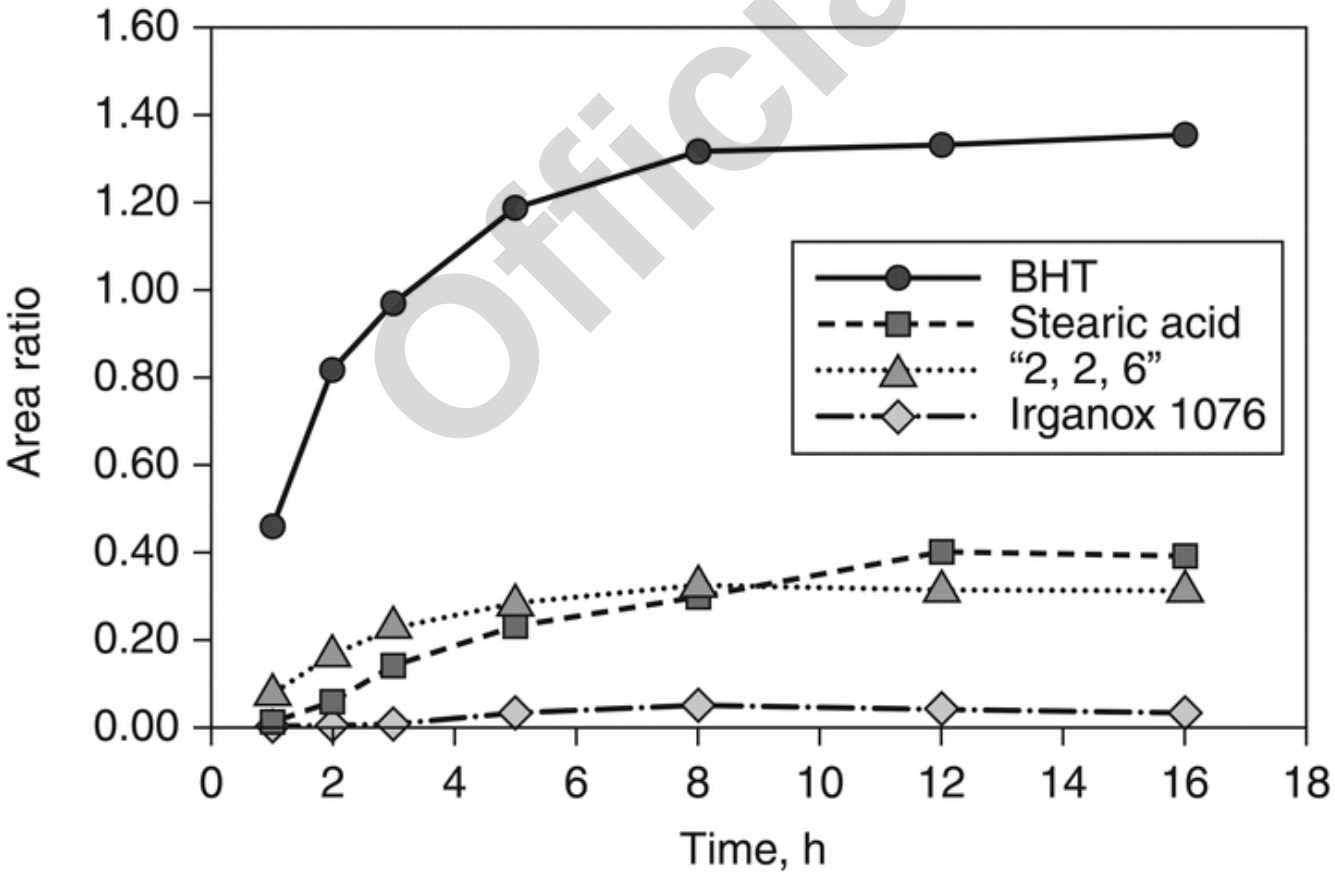

Figure 1. A graphical representation of an extraction that has attained equilibrium as indicated by the achievement of asymptotic levels of target individual extractables as a function of extraction time (i.e., GC/MS peak area ratios of target extractables relative to an internal standard plotted versus extraction time).

## Extraction Stoichiometry

Extraction stoichiometry considers the physical mass and/or surface area of the test article relative to the volume of the extracting medium, and the actual physical state of the material when it is extracted. Extraction stoichiometry can be manipulated to facilitate production of a more concentrated extract. For example, consider the case of a rubber stopper for a

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M7126_03_01

vial that contains 5 mL of a liquid drug product. A more concentrated extract than the drug product (i.e., an extract that contains higher levels of extractables than the leachables level in the drug product) could be produced by extracting 20 stoppers in 200 mL of extracting solvent. Another aspect of extraction stoichiometry is the physical state of the test article. It is not uncommon that components or materials are cut, opened, ground, or otherwise altered in size or configuration prior to being extracted. For inhomogeneous or layered materials such as film laminates, the process of cutting or grinding prior to extraction may alter the extractables profile as it may provide a means for the extracting solvent to come into contact with (and thus more effectively extract) materials (layers) that are shielded from contact with the solution under normal conditions of use. One can argue that the use of such sized material further facilitates the extraction process, however it is possible for sizing to reveal extractables that might not appear as leachables. Nevertheless, some sizing of components or materials before extraction can be useful in certain situations and for certain purposes, including: (a) reducing sample-to-sample variability by the consistent preparation of ground homogeneous polymeric material; (b) reducing the sizes of large packaging components to allow use of standard laboratory glassware for extraction studies; (c) increasing the surface area of a packaging component or material test article (e.g., via extruding, pressing, or grinding) in order to increase extraction efficiency. In any event, careful consideration should be given to the effect of physical sizing of test articles on the extractables profile before such sizing methods are employed in extraction studies.

For extractables assessments involving components or materials whose chemical ingredients are known based on information from the supplier or fabricator, analysts can manipulate extraction stoichiometry based on the known levels of chemical additives and the known sensitivity of the analytical technique(s) that will be used to characterize the extract. For example, consider the formulation for a peroxide-cured ethylene-propylene-diene-monomer (i.e., EPDM) gasket from an MDI valve shown in *Table 2*.

**Table 2. Ingredients in a Peroxide Cured Rubber Gasket Test Article that are Used in an MDI**

| Elastomer Ingredient | Amount (Nominal) |
|---|---|
| EPDM polymer | 64.0% |
| Mineral fillers (may include stearic acid) | 34.4% |
| Antioxidant 1: (butylated hydroxytoluene) | 0.3% |
| Antioxidant 2: (2,2′-methylene-bis-[6-(1,1-dimethylethyl)-4-methyl] phenol) | 0.3% |
| Peroxide curing agent | 1.0% |

Such information, when available from component and material suppliers, can be useful in designing an extraction study.

Analysts can also base the extraction stoichiometry on established safety thresholds for leachables. For example, an exposure of 0.15 µg/day total daily intake for an individual organic leachable has been proposed as an SCT for inhalation drug products, also termed orally inhaled and nasal drug products. Leachables present at or above the SCT, in an MDI for example, should be analytically and toxicologically evaluated, suggesting that extractables assessment also should be guided with the SCT in mind. The application of thresholds such as the SCT and AET to leachables assessments is discussed in greater detail in *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩.

In summary, extraction stoichiometry (and thus the "sensitivity" of an extraction study) can be based on:

- The known chemical ingredients in a component or material
- Safety-based thresholds for drug product leachables
- The known or determined sensitivities of analytical instrumentation used for extract characterization

## Mechanism of Extraction—Extraction Technique

An extraction can be accomplished in a variety of ways. It is necessary that the means of performing the extraction match the objectives of the extractables assessment. Common laboratory extraction techniques include:

- *Maceration (solvent soaking)*—in which the test article is allowed to soak for a period of time in an organic or aqueous extracting solvent at temperatures below the solvent's boiling point. Analysts can also fill packaging system units with extracting solvent and store them at relevant temperatures.
- *Reflux*—in which the test article is immersed in boiling solvent for a period of time.
- *Soxhlet*—in which the test article is placed in the "thimble" of a Soxhlet extraction apparatus that is slowly filled with redistilled solvent from a boiling flask/condenser system; and periodically, the extracting solvent (containing extractables) is siphoned back into the boiling flask and the process begins again (for as many times as required to attain equilibrium).
- *Sealed vessel*—in which the test article and extracting solvent are sealed inside a container capable of withstanding elevated temperatures and pressures, placed into a laboratory autoclave and heated with steam for a period of time.
- *Instrument-based solvent extraction*—in which the test article is placed inside a sealed apparatus and extracted in an automated cycle; examples include pressurized fluid extraction, microwave-assisted extraction, and supercritical fluid extraction.
- *Sonication*—in which the test article and extracting solvent are placed into a glass container and partly immersed in water inside an ultrasonic bath.

Each of these extraction mechanisms/techniques has its own unique advantages and limitations. For example, reflux extraction is very efficient, but may be too harsh for certain applications and can lead to thermal decomposition of certain organic extractables; the extracting power of sonication can be difficult to control; and because of its relatively high boiling point, water performs poorly in reflux and Soxhlet but well in a sealed vessel.

@2024 USPC

If the goal of the extractables assessment is identification and quantitation of the chemical additive content of a component or material, it is typical to use extraction techniques and processes that soften, swell, or dissolve (or in the case of inorganic extractables, *digest*) the component or material, thereby releasing quantitative amounts of chemical additives for analysis.

### Extractions That are Not Solvent Mediated

Not all drug product or material-contact situations are solution mediated and not all issues related to leaching of material-derived entities involve a solution phase. For example, doses of inhalation powder contained in a capsule or blister pack for use in a dry powder inhaler may have volatiles leached from the capsule or blister material, or by specialty surface additives such as mold-release agents; a solid oral dosage form could contain volatile leachables derived from the adhesive of a paper label affixed to the plastic bottle that contains the dosage form; and inhalation solutions packaged in low-density polyethylene containers could contain volatile migrants from tertiary packaging or auxiliary components such as wooden shipping pallets. In the latter two cases, chemical entities can migrate through the plastic containers and volatilize into the airspace, subsequently accumulating as migrants in the dosage forms.

Extraction techniques specifically designed for application to volatile organic compounds are usually directly coupled to analytical instruments. These extraction techniques include headspace analysis (as headspace gas chromatography; HD/GC), direct thermal desorption (usually coupled to gas chromatography; TD/GC), and thermogravimetric analysis (TGA/GC).

## CHARACTERIZING THE EXTRACT

### Objectives and Challenges

Once an extract has been generated, the next objective is to perform a thorough chemical characterization of the extract. Setting a threshold (as described above), which is a specified level of an individual extracted chemical entity which requires characterization, can be based on safety considerations such as the SCT; functional considerations including nominal levels of known chemical additives in the formulation of an extracted component or material; or technological considerations such as the known or determined sensitivity of an analytical technology, instrument, or method. The extract characterization phase of the extraction study must enable the realization of the overall goals of the extractables assessment.

The ultimate objective of thorough extract characterization as defined above cannot be realized in all cases, even when state-of-the-art analytical chemistry is practiced with best available skill and diligence. It is a reality that there is no analytical technique or combination of analytical techniques that is capable of the discovery, identification, and quantitation of any and all organic and inorganic extractable chemical entities known to science. In some cases, authentic reference compounds for organic extractables may not be available for confirmation of identifications, or for quantitative instrument calibration. Thus, the practical objective of extract characterization must therefore be an exercise of due diligence in the discovery, identification, and quantitation to a reasonable degree of scientific certainty of all individual extractable chemical entities present in an extract above a specified level or threshold.

### Processes Involved in Extract Characterization

#### 1. SCOUTING

The most useful analytical techniques in a scouting exercise are not compound specific, as they do not provide chemical information specific to the molecular structure of any particular extractable or chemical class of extractables. These analytical techniques provide information regarding bulk chemical properties of organic and/or inorganic chemical entities present in an extract, which can be used to guide extractables discovery, identification, and quantitation. Scouting analysis is not capable in and of itself of realizing the practical objective of extract characterization, regardless of which scouting technique or combination of techniques is applied.

Analytical techniques which can be employed for scouting are listed in *Table 3*, along with the particular bulk chemical property (and potential utility of this property) available from each technique. Some examples of the utility of scouting include the following:

- Significant levels of nonvolatile residue determined by gravimetric analysis could suggest the presence of significant levels of inorganic chemical entities in the extract. This suggestion would be reinforced if significant mass remained after ashing the extracted nonvolatile residue (residue on ignition).
- Significant UV absorbance of an extract suggests that organic chemical entities are present which contain UV chromophores within their molecular structure, such as phenolic antioxidants.
- Characteristic features in an infrared spectrum of this extract could provide more detailed insights into the chemical classes of organic extractables present. These insights could be used to develop and apply analytical methods for discovery and identification that would detect the chemical classes of extractables suggested by the scouting process.
- For aqueous extracts, total organic carbon provides a measure of the total amount of organic extractables present.

The scouting process and scouting analyses are optional for extract characterization. The utility of scouting is in the guidance it potentially provides for discovery, identification, and quantitation.

## 2. DISCOVERY

The process of discovery involves testing an extract and thereby producing one or more analytical results that are attributable to individual extractables. The process of discovery is accomplished by detecting instrumental responses from the individual organic and inorganic extractables that are proportional to the levels of these individual extractables within the extract. It is in the discovery process that analytical techniques typically associated with trace organic and inorganic analysis are first required for extract characterization. Trace organic analysis typically involves the use of chromatographic techniques, particularly gas chromatography (GC) and high-performance liquid chromatography (HPLC). GC has enormous separating capability for volatile and semi-volatile organic compounds while HPLC is most applicable to semi-volatile and relatively nonvolatile organic compounds, making the two separation techniques complementary and orthogonal for application to the significant chemical diversity of extractables. A discussion of the principles of both gas and liquid chromatography is available in *Chromatography* ⟨621⟩.

The chemical diversity of extractables with respect to polarity and volatility can require alternative sample introduction techniques or sample modification, particularly for GC. Relatively volatile extractables like methanol are most amenable to headspace sampling of aqueous-based extracts into a GC. Organic acids and bases can often be analyzed more effectively by GC after chemical derivatization, such as methylation or silylation for organic acids. Both GC and HPLC can employ detection systems with different specificities (*Table 3*) which take advantage of unique structural properties of various chemical classes of extractables.

The analytical techniques useful for organic extractables discovery can also be applied to identification as well as quantitation. Analytical techniques such as gas chromatography/mass spectrometry (GC/MS), that are most often applied to identification, can also be used for both discovery and quantitation (*Table 3*). Inorganic extractables such as trace elements and metals are typically discovered, identified, and quantitated by the same suite of analytical techniques, such as atomic emission spectroscopy. Analytical techniques designed to study inorganic speciation, particularly in aqueous extracts, are considered beyond the scope of this chapter.

It is important to state that the overall goals of an extraction study always require the identities and quantitative amounts of individual organic and inorganic extractables, and so the mere discovery of extractables does not achieve the ultimate objectives of an extraction study.

## 3. IDENTIFICATION

Identification of an extractable can be accomplished either by structural analysis or qualitative analysis. *Structural analysis* is the process by which the molecular structure of an unknown analyte is elucidated from compound-specific data, and therefore requires compound-specific detection of the unknown analyte. A compound-specific detector is one that provides information specific to the molecular structure of the individual unknown analyte (not just its chemical class). *Qualitative analysis* is the process by which an unknown analyte is matched with an authentic reference compound via one or more analytical techniques. The analytical techniques used for qualitative analysis can, but do not need to be, compound specific.

The analytical techniques most applicable to structural analysis, and to trace organic analysis problems in general, involve the combination of chromatography with mass spectrometry. These are the so-called “hyphenated” techniques of GC/MS and high-performance liquid chromatography/mass spectrometry (LC/MS). A discussion of the principles of mass spectrometry (including both GC/MS and LC/MS) is available in *Mass Spectrometry* ⟨736⟩.

Both GC/MS and LC/MS are capable of generating extractables profiles in the form of chromatograms. However, since LC/MS includes a relatively high chemical background of HPLC mobile phase ions, it is typical to include a non-destructive UV detector in series with the mass spectrometer to assist in locating peaks of individual extractables. The compound-specific data available from mass spectrometry include:

- The monoisotopic molecular weight of the extractable based on confirmation of the molecular ion from one or more ionization processes
- The molecular formula of the extractable based on accurate mass measurements, and/or accurate isotope ratio measurements, of the molecular ion
- The fragmentation behavior of the extractable based on in-source fragmentation or tandem mass spectrometry

GC/MS interfaced with electron ionization produces mass spectra which can be searched through computerized databases, or libraries, of mass spectra from known compounds. Note that searchable mass spectra are generally unavailable for LC/MS ionization processes because of the variable nature of such spectra over time and between various instruments and laboratories. Both GC/MS and LC/MS also include the retention time (or retention index) of the unknown extractable which can be compared with that of authentic reference compounds.

Given the number and chemical diversity of organic extractables, it is unreasonable to expect that authentic reference compounds will be available (or can be made available) to confirm every identification. It is therefore necessary that levels of identification confidence be established and appropriately utilized. Data typically available from GC/MS and LC/MS analyses (see items a through e below) are used to designate individual extractables identifications in the categories of *Confirmed*, *Confident*, or *Tentative* (*2* ):

- Mass spectrometric fragmentation behavior/expert mass spectrum interpretation
- Confirmation of molecular weight
- Confirmation of elemental composition
- Mass spectrum matches automated library or literature spectrum
- Mass spectrum and chromatographic retention index match authentic reference compound
- Supporting spectral information from an orthogonal method (e.g., NMR)

Official

- A *Tentative* identification means that data have been obtained that are consistent with a class of molecule only. This is typically the case when only information such as a or d is available.
- A *Confident* identification means that the tentative identification has been bolstered by additional and sufficient confirmatory information to preclude all but the most closely related structures. This would be the case, for example, if the tentative information (a and/or d) were augmented by b, c, or f. The more confirmatory information obtained, the greater the level of confidence.
- A *Confirmed* identification means that the preponderance of evidence confirms that the entity in question can only be the identification that is provided. Although it is possible that a highly confident identification may meet the standard implied by the preponderance of evidence (for example, having a, b, c, e, and f), the only means of providing a confirmed identification is via mass spectral and retention time match with an authentic reference compound (item e).

Although these identification categories are based on mass spectrometry, it is possible to use data from other analytical techniques to assist in extractables identification. Such techniques include GC/FTIR (Fourier Transform Infrared Spectroscopy) and LC/NMR (Nuclear Magnetic Resonance Spectroscopy). These and potentially other analytical techniques are capable of producing compound-specific data which are complementary to mass spectrometry.

The level of identification required for any individual extractable depends on the intended use of that identification. It is up to the organization responsible for the extraction study to determine this after appropriate consideration of applicable regulatory guidances.

Since the list of potential inorganic extractables, such as trace elements and metals, is finite compared with the population of organic extractables, identification and quantitative analysis for inorganic extractables are achieved simultaneously. While elemental analysis is relatively straightforward, it is not without its challenges. The issue of false positive responses and spectral or mass interference must be addressed in order for identifications based on atomic spectroscopy to be rigorous and accurate. It is also noted that elemental analysis provides element-specific identifications and quantitations, and not the chemical speciation of the extractable. Thus, interpretation of the impact of the elemental results may require further studies, such as detailed chemical speciation of elements deemed of significance. For example, while finding sulfur in an extract by atomic spectroscopy is an important outcome, the safety impact of this finding cannot be ascertained until the speciation of the sulfur is established. This is the case as the safety impact of sulfur as elemental sulfur may be different than that of sulfur as sulfate.

## 4. QUANTITATION

Quantitation is typically based on the instrumental response of an individual extractable relative to an authentic reference compound, and therefore requires that individual extractables be separated (either directly with chromatography or indirectly with selective detection) and produce detector responses that are directly proportional to the level (or concentration) of the extractable in a given extract. Calibration of an analytical system is accomplished by analysis of authentic reference compounds (external standards). One or more internal standards can also be included in both the extract and reference calibration solutions to increase accuracy and precision. The levels of extractables for which authentic reference compounds are not available can be estimated using their responses (or response factors) relative to internal standards, or other surrogate reference compounds of similar molecular structure. While such an analytical process can provide reliably accurate concentration estimates, diligence must be exercised in terms of establishing and justifying the choice and use of internal standards. Criteria for the selection of appropriate internal standards have been described (*2*).

## Preparation of Extracts for Analysis

Extracts can often be analyzed directly without significant preparation or concentration. Many organic solvent extracts (e.g., dichloromethane, ethyl acetate, hexane) can be directly injected into a gas chromatograph, while others (e.g., methanol, ethanol, isopropanol) are either too reactive in the heated GC injection port or too high boiling. Organic solvent extracts with inappropriate physical/chemical properties for direct analysis by GC can be switched to more appropriate solvents. Certain extractables, such as fatty acids (e.g., palmitic acid, stearic acid) perform better in gas chromatographic analysis when they are derivatized to either methyl esters or trimethylsilyl esters.

It is usually considered inappropriate to directly analyze aqueous extracts by gas chromatography, due to the reactivity and high boiling point of water. In addition, pH-buffered aqueous extracts contain nonvolatile salts which are not suitable for GC injection. Aqueous extracts are typically back extracted with an organic solvent to remove organic extractables from the water, with the resulting organic extract being injected into the GC. Unlike GC, liquid chromatography (HPLC, LC/MS) is perfectly suited to the direct analysis of aqueous extracts, since most HPLC methods include water and water-miscible mobile phases. Water-immiscible organic solvents (e.g., hexane) cannot be injected onto these reversed-phase HPLC systems, so these must be dried and the resulting extractable residue taken up in a solvent suitable for HPLC (e.g., acetonitrile, methanol, or mixtures of these with water).

Organic or aqueous extracts with insufficient levels of extractables for analysis can be concentrated by various techniques. Many organic solvents can be dried down under inert gas, a rotary evaporator, or a Kuderna-Danish concentrator. Aqueous extracts can be lyophilized, concentrated under vacuum, or back extracted into an organic solvent which is then further concentrated.

The final concentration at which an extract is analyzed depends on the goal(s) of the extractables assessment and the inherent sensitivities of the analytical techniques applied. A good “rule of thumb” is that in order to accomplish a complete structural analysis of an unknown extractable, a GC/MS requires approximately 5 ng injected into the instrument. This suggests a concentration in the injected extract of 5 ng/µL or 5 µg/mL. In a 200-mL dichloromethane extract, this converts to a total of 1 mg of this particular extractable recovered from the extracted test article. If this analyte concentration is insufficient to meet the goal of the extractables assessment, then the following parameters can be optimized:

- Extraction stoichiometry (i.e., extract more material or use more extracting solvent)

## SUMMARY

### Assessing the Completeness of an Extractables Assessment

The completeness of an extractables assessment can only be judged against the overall goals of the assessment. For example, an extractables assessment accomplished solely for materials characterization might include one extracting solvent, one extraction technique, and one set of extraction conditions; along with a materials-based threshold (e.g., 10 ppm w/w). Such an extractables assessment might be considered complete if all extractables above the defined threshold were identified to the confident level (defined above) and quantitated. For an extractables assessment designed to establish a rigorous leachables–extractables correlation for a high risk drug product, where a challenging safety threshold might apply (e.g., 0.15 µg/day), good scientific practice and due diligence requires the following:

- Generation of extracts should be accomplished with
  - Multiple solvents or extracting media with varying extracting power based on the known extracting power of the drug product vehicle;
  - Multiple and complementary extraction techniques, including those with the capability for volatiles analysis;
  - Extraction conditions that allow equilibrium to be achieved.
- Characterization of extracts should use
  - Multiple and complementary analytical techniques;
  - Careful sample preparation, keeping the analytical technique(s) in mind;
  - A systematic process for identification and quantitation of extractables.

In this case, the extractables assessment might be considered complete if all extractables above the defined threshold were identified to at least the confident level, quantitated, and correlated both qualitatively and quantitatively with drug product leachables data (if available) and the known ingredients in the packaging system, packaging component(s), or material(s) of construction.

It should be noted that limited extractables assessments with relatively narrow goals can be accomplished to required completeness with a relatively focused effort. For example, extraction studies designed to quantitate the levels of specific chemical additives in specific packaging components/materials can be done with specified extraction parameters and analytical methods (see *Plastic Packaging Systems and Their Materials of Construction* ⟨661⟩, *Plastic Materials of Construction* ⟨661.1⟩, and *Plastic Packaging Systems for Pharmaceutical Use* ⟨661.2⟩). The reader is also referred to various sources which describe extractables assessments and extraction studies for pharmaceutical applications (*2*, *5*), as well as other general sources which refer to extractables assessments for medical devices and food contact (*8*).

Reference is also made to compendial chapters in this Pharmacopeia which include extraction studies with specific goals and purposes:

### Example Extractables Profiles—Materials Characterization

As stated previously, extraction studies are usually designed to produce extractables profiles, which are qualitative and/or quantitative analytical representations of the extractables content of a particular extracting medium. To illustrate the concept of an extractables profile, the following is an example of an extractables study performed for the purpose of material characterization. Extractables profiles are commonly produced by analysis of laboratory extracts by instrumental chromatographic techniques. *Figure 2* and *Figure 3* show example extractables profiles (GC/MS and HPLC/UV, respectively) from a hexane Soxhlet extract of a cyclic olefin copolymer (COC) material of construction. COC materials are used in the fabrication of pre-filled syringes, vials for small-volume parenterals, and bags for large-volume parenterals. The extracts were generated by subjecting approximately 5 g of suitably sized material to 16 hours of Soxhlet extraction with 125 mL of hexane. The resulting extract was spiked with internal standards (details not relevant to this discussion) and was analyzed directly by GC/MS (see *Table 4*). For HPLC/UV analysis, an aliquot of the hexane extract was reduced in volume and diluted with methanol prior to analysis (see *Table 5*). Since the purpose of this extractables assessment was materials characterization, extraction study parameters were adjusted relative to an extractables identification threshold of 10 ppm (µg/g). It is clear from these chromatograms that the techniques used are both complementary and orthogonal, illustrating the concept that multiple analytical methods are required to typically elucidate the complete extractable profile.

Official

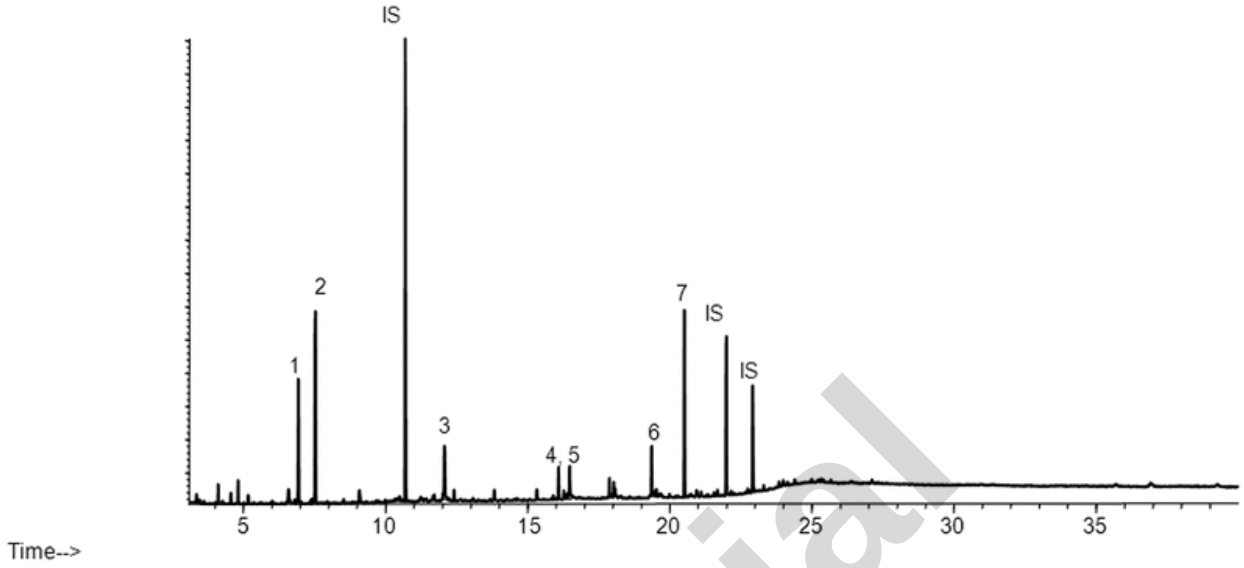

Figure 2. GC/MS chromatogram (extractables profile) for a hexane Soxhlet extract of a cyclic olefin copolymer. Internal standards (IS) producing peaks in this chromatogram include: 2-Fluorobiphenyl at 10.7 min, Irganox 415 at 22.0 min, and Bisphenol M at 23.0 min. Numbered peaks represent identified extractables above the materials-based threshold.

Official

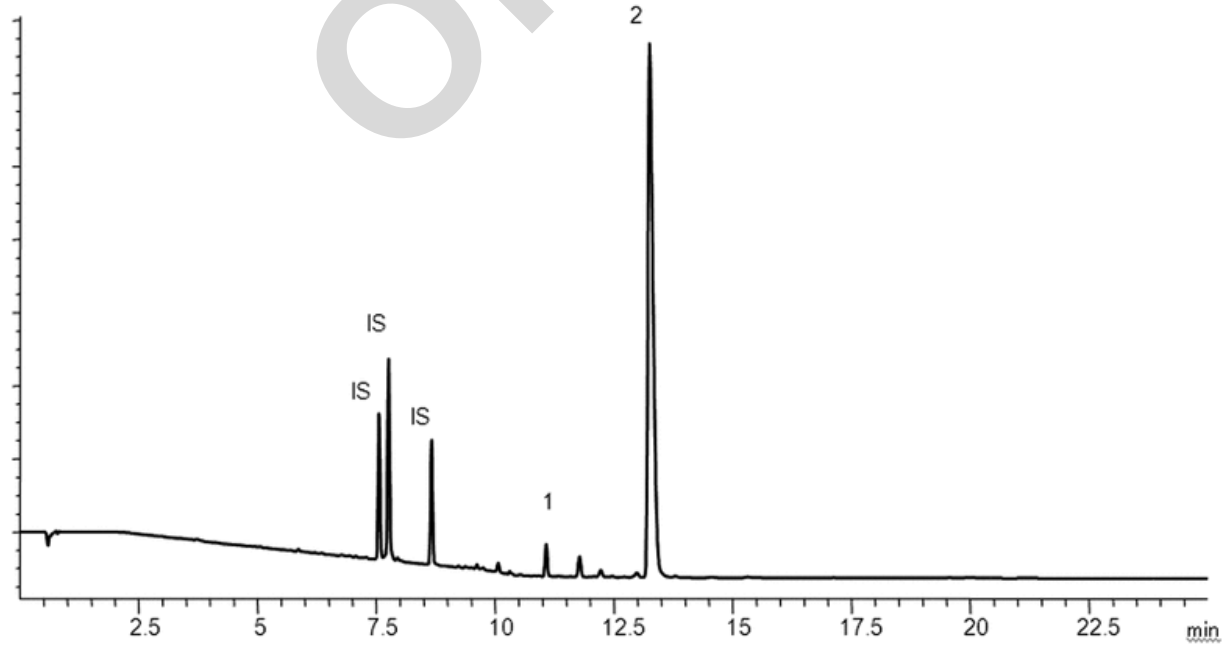

Figure 3. HPLC/UV Chromatograms (λ = 220 nm; extractables profile) for a hexane Soxhlet extract of a cyclic olefin copolymer. Internal standards (IS) producing peaks in this chromatogram include: Bisphenol M at 7.6 min, 2-Fluorobiphenyl at 7.8 min, and Irganox 415 at 8.7 min. The major peak in this extractables profile above the materials-based threshold is the known additive (antioxidant) Irganox 1010 (Peak 2).

# ⟨1664.1⟩ ORALLY INHALED AND NASAL DRUG PRODUCTS

## INTRODUCTION

This section addresses specific considerations for leachables in orally inhaled and nasal drug products (OINDP), including metered dose inhalers (MDIs); nasal sprays; inhalation solutions, suspensions, and sprays; and dry powder inhalers (DPIs). Although OINDP can be a combination of products that are comprised of drug and device constituent parts, the primary mode of action is typically through the drug. For this reason OINDP are treated as drugs from a regulatory perspective. Regulatory guidance documents and detailed best practice recommendations specific to OINDP are available (*1*–*4*). Note that the following discussion is primarily devoted to organic leachables. For consideration of inorganic (i.e., elemental) leachables, see *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩.

## KEY TERMS

In addition to the key terms listed in ⟨1664⟩, some additional key terms more specific to OINDP are the following:

- *Critical components* are packaging components that contact either the drug product formulation or the patient, or that affect the mechanics of the overall performance of the packaging and delivery system, including any necessary secondary packaging. The identification of critical components for a particular OINDP dosage form is the responsibility of the applicant in consultation with appropriate regulatory authorities.
- *Special case compounds* are individual (or classes of) compounds that have special safety or historical concerns as drug product leachables in OINDP, and therefore must be evaluated and controlled as leachables (and extractables) by specific analytical techniques and technology-defined thresholds.

Additional terminology and associated definitions specific to OINDP are available in the cited references (*1*–*4*).

## LEACHABLES ASSESSMENT RATIONALE FOR ORALLY INHALED AND NASAL DRUG PRODUCTS

OINDP are generally categorized as high-risk dosage forms due to safety considerations related to the route of administration and high probability of packaging component interaction with the formulation (see *Table 1* in ⟨1664⟩). The packaging systems used in these drug products incorporate components of various types, including components composed of polymeric (plastic or elastomeric) raw materials with complex chemical compositions and therefore a variety of potential leachables. Chemical entities may migrate (i.e., leach) into the formulation when there is direct contact with the primary packaging and delivery components for extended periods of time. In certain cases, there is also the potential for leaching from secondary and tertiary packaging. In addition, for OINDP, contact of the delivery device with mucosal tissue (mouth or nasal) is generally expected. Leachables studies for some OINDP may be considered separately for packaging components that are in continuous contact with the formulation (e.g., vials, bottles, blisters, metering valve components) versus those that are only in transient contact (e.g., DPI mouthpiece, MDI mouthpiece).

OINDP typically require:

- A leachables stability study for drug product registration that supports intended storage and use conditions throughout the proposed shelf-life (see *Table 1*), ideally on primary drug product stability batches manufactured with the same lots of packaging components used in extraction studies (in order to facilitate a leachables–extractables correlation)
- Sensitive, selective, and fully validated leachables analytical methods
- Leachables assessments based on safety thresholds [Safety Concern Threshold (SCT): 0.15 µg/day, and Qualification Threshold (QT): 5 µg/day total daily intake (TDI) for an individual organic leachable; however, for exceptions see *Special Case Compounds*]
- Complete qualitative and quantitative leachables–extractables correlations (which require that extractables assessments be accomplished on all critical packaging components; see *Assessment of Extractables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1663⟩)
- Leachables specifications including acceptance criteria (assumes a complete extractables assessment for each critical packaging component). (Note that in many cases routine extractables testing for release of critical components can be used to control drug product leachables in lieu of routine drug product leachables testing, providing that a comprehensive leachables–extractables correlation is established.)

For OINDP dosage forms based on formulations with relatively lower leaching potential for organic compounds (e.g., aqueous formulations, dry powder formulations), the above requirements should be considered and evaluated on a case-by-case basis, including consultations with the appropriate regulatory authorities.

**Table 1. Example Stability Storage Conditions and Testing Time Points for an OINDP Registration Leachables Study (*4*)**

| Condition (temperature/relative humidity) | Time Points (months) |
|---|---|
| 25 ± 2°C/60 ± 5%RH | 3, 6, 12, 18, 24, 36 (to end of shelf-life) |
| 30 ± 2°C/65 ± 5%RH | 3, 6, 12, 18, 24, 36 (to end of shelf-life) |
| 40 ± 2°C/75 ± 5%RH | 3, 6 |

# ORALLY INHALED AND NASAL DRUG PRODUCTS DOSAGE FORM TYPES

## Metered Dose Inhaler

MDIs or pressurized MDIs (pMDIs) are defined as "drug products that contain active ingredient(s) dissolved or suspended in a propellant, a mixture of propellants, or a mixture of solvent(s), propellant(s), and/or other excipients in compact pressurized aerosol dispensers" (*2,4*). Typical MDIs include a metal canister (stainless steel or aluminum; coated or uncoated), a fixed-volume metering valve (with plastic or elastomeric components), elastomeric seals, and a plastic actuator or mouthpiece (see *Inhalation and Nasal Drug Products: Aerosols, Sprays, and Powders—Performance Quality Tests* ⟨601⟩). MDIs are multidose drug container closure and delivery systems that can contain sufficient formulation for up to several hundred actuations (label claim) per container. Because many of the critical packaging components are in continuous contact with an organic solvent-based formulation, the MDI has the highest risk for formulation-packaging component interaction, and therefore the highest risk for leachables, of all OINDP dosage forms (or any other dosage form). Because of the leaching potential of their organic solvent-based formulations, MDIs would typically be expected to show complete qualitative and quantitative leachables–extractables correlations. Leachables in MDIs should be characterized (i.e., identified and quantitated) at levels above a calculated analytical evaluation threshold (AET). An AET can be calculated for any OINDP dosage form with consideration of the SCT for OINDP (i.e., 0.15 µg/day for an individual organic leachable). An example AET calculation for an MDI follows.

Given an MDI drug product with 200 labeled actuations per canister, a maximum recommended patient exposure of 12 actuations per day, and a critical valve component mass per valve of 200 mg, for an individual organic leachable derived from this valve component, the following AET can be estimated:

$$\text{Estimated AET} = \left(\frac{0.15\ \mu\text{g/day}}{12\ \text{actuations/day}}\right) \times (200\ \textit{labeled}\ \text{actuations/canister})$$

$$\text{Leachables Estimated AET} = 2.5\ \mu\text{g/canister}$$

To convert to an estimated AET, which would be a useful guide for characterizing potential leachables via extraction studies of this particular valve component (see ⟨1663⟩):

$$\text{Extractables Estimated AET} = \left(2.5\ \mu\text{g/Canister}\right) \times \left(\frac{1\ \text{canister/value}}{0.2\ \text{g elastomer/value}}\right)$$

$$\text{Extractables Estimated AET} = 12.5\ \mu\text{g/g}$$

The AET calculation should not be modified to account for variables, such as manufacturing overfill in the canister to compensate for leak rate or fill variability, unless such modification can be scientifically justified.

Analytical methods for leachables testing of MDI drug products can be based on processes such as "cold filtration" of suspension formulations to remove active ingredient and excipient particles (*5*) or careful venting of the volatile organic propellant, which retains leachables in a residue within the canister (*6*). Because sample preparation procedures for MDI formulations can be complex and typically require the volatile propellant to be reduced to dryness at some point, creating the possibility for loss of leachables before sample analysis, it is particularly important to demonstrate adequate recoveries of leachables through the use of spiked MDI samples.

Although it is unlikely to contribute leachables to the emitted drug product aerosol plume, potential patient exposure to chemical entities from the MDI plastic actuator or mouthpiece should be assessed at a threshold of 20 µg/g (see ⟨1663⟩). Additional studies and references required to assess patient exposure to actuator- or mouthpiece-derived chemicals include reference to indirect food additive regulations and the application of *Biological Reactivity Tests, In Vitro* ⟨87⟩ and *Biological Reactivity Tests, In Vivo* ⟨88⟩ (*2*). Note that "spacers" and other devices designed for use with MDIs should also be characterized if a particular device is specified on the drug product label.

When constructed from materials acceptable for food contact, MDI actuators and mouthpieces, "spacers", and other components and devices specified in the drug product labeling generally only require appropriate characterization (i.e., extraction studies and routine extractables testing) in order to assure continued consistent composition of the component or device.

In addition, based on applicable regulatory guidance (*2*), drug product applicants should consider the following (see ⟨1663⟩):

- Development and validation of surface organic residue release tests for incoming uncoated metal canisters, with appropriate acceptance criteria
- Development and validation of extractables release tests for the inner surfaces of incoming coated canisters, with appropriate acceptance criteria
- Development and validation of extractables release tests for incoming metering valve critical components, with appropriate acceptance criteria
- Development and validation of extractables profile release tests for incoming actuators or mouthpieces, with appropriate qualitative and quantitative acceptance criteria.

## Nasal Sprays

Nasal sprays are defined as "drug products that contain active ingredients dissolved or suspended in a formulation, typically aqueous-based, which can contain other excipients and are intended for use by nasal inhalation" (*1,4*). Nasal sprays include a plastic container and components (usually plastic) that are responsible for formulation metering, atomization, and delivery to

@2024 USPC

the patient (see ⟨601⟩). Critical components include those that are in constant contact with the formulation (e.g., the container, dip tube) and components that are in the liquid pathway during actuation of the device and that do not permit quick evaporation of residual surface liquid (*3*). Because nasal sprays are typically aqueous-based formulations, and the vast majority of potential organic leachables are relatively lipophilic, the risk for formulation-packaging component interaction is lower relative to the organic propellant-based MDIs, and the risk for organic leachables is lower. Leachables in nasal sprays should be characterized (i.e., identified and quantitated) at levels above a calculated AET. An AET can be calculated for any OINDP dosage form with consideration of the SCT for OINDP (i.e., 0.15 µg/day for an individual organic leachable). An example AET calculation for a nasal spray follows.

Given a nasal spray drug product with 120 labeled actuations per container, a maximum recommended patient exposure of 4 actuations per day, and a critical component (plastic dip tube) mass of 250 mg, for an individual organic leachable derived from this component, the following AET can be estimated:

$$\text{Estimated AET} = \left(\frac{0.15\ \mu\text{g/day}}{4\ \text{actuations/day}}\right) \times (120\ \textit{labeled}\ \text{actuations/container})$$

$$\text{Leachables Estimated AET} = 4.5\ \mu\text{g/container}$$

Given a total fill volume of 10 mL:

$$\text{Estimated AET} = (4.5\ \mu\text{g/container})/(10\ \text{mL/container})$$

$$\text{Estimated AET} = 0.45\ \mu\text{g/mL}$$

To convert to an estimated AET, which would be a useful guide for characterizing potential leachables via extraction studies of this particular plastic dip tube (see ⟨1663⟩):

$$\text{Extractables Estimated AET} = (4.5\ \mu\text{g/container}) \times \left(\frac{1\ \text{container}}{0.25\ \text{g material/tube}}\right)$$

$$\text{Extractables Estimated AET} = 18\ \mu\text{g/g}$$

The AET calculation should not be modified to account for variables, such as manufacturing overfill, unless such modification can be scientifically justified.

All nasal spray packaging system critical components should be subjected to extractables assessments (see ⟨1663⟩). Potential patient exposure to chemical entities from nasal spray critical components not in continuous contact with the drug product formulation should be assessed at a threshold of 20 µg/g (see ⟨1663⟩). Additional studies and references required to assess patient exposure to nonformulation contact critical component derived chemicals include reference to indirect food additive regulations and the application of ⟨87⟩ and ⟨88⟩ (*1*).

When constructed from materials acceptable for food contact, nasal spray critical components not in continuous contact with the drug product formulation generally only need to be appropriately characterized (i.e., extraction studies and routine extractables testing) in order to assure continued consistent composition of the component.

In addition, based on applicable regulatory guidance (*1*), drug product applicants should consider the following (see ⟨1663⟩):

- Development and validation of extractables release tests for incoming container closure and pump critical components, with appropriate qualitative and quantitative acceptance criteria.

## Inhalation Solutions, Suspensions, and Sprays

Inhalation solutions, suspensions, and sprays are defined as “drug products that contain active ingredients dissolved or suspended in a formulation, typically aqueous-based, which can contain other excipients and are intended for use by oral inhalation” (*1,4*). Inhalation solutions and suspensions are intended for use with a nebulizer (*1,4*). Inhalation sprays, like MDIs and nasal sprays, are combination products where the components responsible for the metering, atomization, and delivery of the formulation to the patient are a part of the container closure system (*1,4*). Critical components include components that are in constant contact with the formulation and components that are in the liquid pathway during actuation of the device and that do not permit quick evaporation of residual surface liquid. Leachables in inhalation sprays should be characterized (i.e., identified and quantitated) at levels above a calculated AET. An AET can be calculated for any OINDP dosage form with consideration of the SCT for OINDP (i.e., 0.15 µg/day for an individual organic leachable). An example AET calculation for an inhalation spray follows.

Given an inhalation spray drug product with 120 labeled actuations per container, a maximum recommended patient exposure of 4 actuations per day, and a critical component (plastic dip tube) mass of 400 mg, for an individual organic leachable derived from this component, the following AET can be estimated:

$$\text{Estimated AET} = \left(\frac{0.15\ \mu\text{g/day}}{4\ \text{actuations/day}}\right) \times (120\ \textit{labeled}\ \text{actuations/container})$$

$$\text{Leachables Estimated AET} = 4.5\ \mu\text{g/container}$$

Given a total fill volume of 4.5 mL:

$$\text{Estimated AET} = (4.5\ \mu\text{g/container})/(4.5\ \text{mL/container})$$

DOI: https://doi.org/10.31003/USPNF_M8146_03_01

$$\text{Estimated AET} = 1\ \mu g/mL$$

To convert to an estimated AET, which would be a useful guide for characterizing potential leachables via extraction studies of this particular plastic dip tube (see ⟨1663⟩):

$$\text{Estimated AET} = \left(\frac{0.15\ \mu g/\text{day}}{4\ \text{actuations/day}}\right) \times (120\ \textit{labeled}\ \text{actuations/container})$$

$$\text{Extractables Estimated AET} = 11.3\ \mu g/g$$

The AET calculation should not be modified to account for variables, such as manufacturing overfill, unless such modification can be scientifically justified.

Because inhalation solutions and suspensions are similar to nasal spray and inhalation spray drug products in that they are typically aqueous-based formulations, and the vast majority of potential organic leachables are relatively lipophilic, the risk for formulation-packaging component interaction is lower relative to the organic propellant-based MDIs, and the risk for organic leachables is lower. However, unlike MDIs, nasal and inhalation spray drug products, inhalation solutions, and suspensions are typically packaged in plastic unit dose containers (i.e., nebules). Leaching can potentially occur from the unit dose container [e.g., low-density polyethylene (LDPE)], which is in long-term continuous contact with the drug product formulation. It is also possible that organic chemical entities associated with paper labels, adhesives, inks, etc. in direct contact with the permeable unit dose container can migrate through the container and into the formulation. Leachables from tertiary packaging systems (e.g., cardboard shipping containers) are also possible. Leachables in inhalation solutions and suspensions should be characterized (i.e., identified and quantitated) at levels above a calculated AET. An AET can be calculated for any OINDP dosage form with consideration of the SCT for OINDP (i.e., 0.15 µg/day for an individual organic leachable). An example AET calculation for an inhalation solution follows.

Given an inhalation solution with 3 mL of drug product contained in a LDPE unit dose vial (1 g total weight of LDPE), with a maximum recommended patient exposure of three vials per day, for an individual organic leachable derived from this component, the following AET can be estimated:

$$\text{Estimated AET} = \left(\frac{0.15\ \mu g/\text{day}}{3\ \text{doses/day}}\right) \times (1\ \textit{labeled}\ \text{dose/container})$$

$$\text{Leachables Estimated AET} = 0.05\ \mu g/\text{container}$$

$$\text{Estimated AET} = (0.05\ \mu g/\text{container})/(3\ mL/\text{container})$$

$$\text{Estimated AET} = 0.017\ \mu g/mL$$

To convert to an estimated AET, which would be a useful guide for characterizing potential leachables via extraction studies of this particular plastic unit dose vial (see ⟨1663⟩):

$$\text{Extractables Estimated AET} = (0.05\ \mu g/\text{container}) \times \left(\frac{1\ \text{container}}{1\ \text{g material/container}}\right)$$

$$\text{Extractables Estimated AET} = 0.05\ \mu g/g$$

The challenge of characterizing drug product leachables at levels of 17 ng/mL in an aqueous drug product is considerable, even given the capabilities of modern analytical chemistry. For this particular inhalation solution example, it might be appropriate to implement a simulation study (see ⟨1663⟩ and ⟨1664⟩) to facilitate the discovery and identification of probable leachables, with actual drug product leachables being quantitated (if required) with high-sensitivity target compound analytical techniques and methods.

All inhalation solution, suspension, and spray packaging system critical components should be subjected to extractables assessments (see ⟨1663⟩). Potential patient exposure to chemical entities from inhalation solution, suspension, and spray critical components not in continuous contact with the drug product formulation should be assessed at a threshold of 20 µg/g (see ⟨1663⟩). Additional studies and references required to assess patient exposure to nonformulation contact critical component-derived chemicals include reference to indirect food additive regulations and application of ⟨87⟩ and ⟨88⟩ (*1*). When constructed from materials acceptable for food contact, inhalation solution, suspension, and spray critical components not in continuous contact with the drug product formulation generally only need be appropriately characterized (i.e., extraction studies and routine extractables testing) in order to assure continued consistent composition of the component. Critical components of nebulizers and other devices designed for use with inhalation solutions and suspensions should also be characterized with respect to extractables and leachables if a particular device is specified in the drug product labeling.

Based on applicable regulatory guidance for inhalation solutions, suspensions and sprays (*1*), drug product applicants should consider the following (see ⟨1663⟩):

- Development and validation of extractables release tests for incoming container closure and pump critical components, with appropriate qualitative and quantitative acceptance criteria
- Consideration of validated tests for probable leachables from labels, inks and adhesives, etc., with appropriate acceptance criteria (should these be appropriate and applicable).

## Dry Powder Inhalers and Inhalation Powders

DPIs are defined as "drug products designed to dispense powders for inhalation" (*2,4*). The drug substance in an inhalation powder has a particle size distribution in the respirable range, and may be a physical mixture of active pharmaceutical ingredient(s) with carrier particles or a formulated combination of active ingredient and excipients (see ⟨601⟩). The powder may be contained in a unit dose packaging system (e.g., capsule, blister), or reside in bulk in a reservoir inside the delivery device itself. In the latter case, the dose is metered by the device. The delivery device may actively disperse the powder from the container or rely on patient inspiration to supply the energy necessary to disperse the particles. The components and the design of the device are integral to the aerosol characteristics (i.e., mass and particle size distribution) of the formulation delivered to the patient. There is a wide diversity of DPI designs and characteristics (*2*).

Of all OINDP, the DPI has the lowest risk of exposing a patient to leachables at significant levels. The reasons for this are:

1. The DPI drug product formulation is a dry powder, and contains no solvent, either organic or aqueous, which can promote leaching of organic (or inorganic) chemical entities.
2. In a unit dose DPI, the drug product formulation is contained in a separate packaging system, and is usually only in transient contact with critical components of the device itself.

The most likely source of leachables in a unit dose DPI would be the material composing the unit dose container, such as a foil laminate blister or capsule material, or the material composing the drug product reservoir in a multidose DPI (including antistatic surface additives). Leaching would have to occur either via direct contact of the drug product powder with the packaging material, via volatilization of organic chemical entities from the container closure material with deposition on the dry powder, or via migration of organic chemical entities through the primary packaging material with deposition on the dry powder. The possibility of observing leachables from the DPI unit dose container is best evaluated with detailed extraction studies on the container material to identify potential leachables, which could possibly migrate to the dry powder by either solid-solid contact or volatilization and have potential safety concerns.

The device and packaging materials are typically evaluated for potential leachables by extraction and simulation studies (see ⟨1663⟩) to determine whether there are chemical entities at levels that would pose a safety concern. The evaluation of materials that contain the inhalation powder must consider the inks and any other processing aids used in the manufacture of the container so that all potential leachables are characterized. The types of compounds of greatest concern for inhalation powders are those that may migrate from the primary packaging (i.e., unit dose container or multidose reservoir) into the formulation. Extraction and simulation studies should consider all possible mechanisms of leaching, including volatilization. Actual and potential leachables in inhalation powders derived from critical components of the packaging system or device that may have continuous long-term contact with the drug product formulation should be characterized (i.e., identified and quantitated) at levels above a calculated AET. An AET can be calculated for any OINDP dosage form with consideration of the SCT for OINDP (i.e., 0.15 µg/day for an individual organic leachable). An example AET calculation for an inhalation powder follows.

Given a DPI containing 13 mg of inhalation powder in a unit dose blister with 50 mg of blister material either in direct contact with the formulation or capable of volatilizing leachables into the headspace above the formulation, with a maximum recommended daily exposure of 2 actuations per day, for an individual organic leachable derived from this material, the following AET can be estimated:

$$\text{Estimated AET} = \left(\frac{0.15\ \mu g/day}{2\ \text{doses/day}}\right) \times (1\ \textit{labeled}\ \text{dose/blister})$$

$$\text{Leachables Estimated AET} = 0.075\ \mu g/\text{blister}$$

To convert relative to the total mass of drug product in a blister:

$$\text{Estimated AET} = (0.075\ \mu g/\text{blister})/(0.013\ \mu g\ \text{drug product/blister})$$

$$\text{Estimated AET} = 5.8\ \mu g/g\ \text{drug product}$$

To convert to an estimated AET, which would be a useful guide for characterizing potential leachables via extraction studies of this particular blister material (see ⟨1663⟩):

$$\text{Extractables Estimated AET} = (0.075\ \mu g/\text{blister}) \times \left(\frac{1\ \text{blister}}{0.05\ g\ \text{material/blister}}\right)$$

$$\text{Extractables Estimated AET} = 1.5\ \mu g/g$$

The challenge of characterizing drug product leachables at levels of 5.8 µg/g in an inhalation powder is considerable, even given the capabilities of modern analytical chemistry. For this particular DPI example, it might be appropriate to implement a simulation study (see ⟨1663⟩ and ⟨1664⟩) to facilitate the discovery and identification of probable leachables from the blister material, with actual drug product leachables being quantitated (if required) with high-sensitivity target compound analytical techniques and methods.

All inhalation powder packaging system and DPI device critical components should be subjected to extractables assessments (see ⟨1663⟩). Potential patient exposure to chemical entities from inhalation powder packaging system and DPI device critical components not in continuous contact with the drug product formulation should be assessed at a threshold of 20 µg/g (see ⟨1663⟩). Additional studies might be required to assess patient exposure to nonformulation contact critical component derived chemicals, including reference to food additive regulations and application of ⟨87⟩ and ⟨88⟩ (*2*).

When constructed from materials acceptable for food contact, inhalation powder packaging system and DPI device critical components not in continuous contact with the drug product formulation generally only need be appropriately characterized (i.e., extraction studies and routine extractables testing) to assure continued consistent composition of the component.

In addition, for DPIs and inhalation powders, and based on applicable regulatory guidance (*2*), drug product applicants should consider the following (see ⟨1663⟩):

- Development and validation of extractables release tests for incoming inhalation powder packaging system and DPI device critical components, with appropriate qualitative and quantitative acceptance criteria.

# ADDITIONAL CONSIDERATIONS

## Analytical Uncertainty

An AET is that concentration above which unknown leachables should be characterized and reported for toxicological assessment. Target leachables (previously characterized as potential or probable leachables from extractables or simulation studies) will have known safety profiles and previously established leachables thresholds. In addition, reference compounds for previously characterized potential leachables will allow for accurate and precise quantitation of those target leachables as actual drug product leachables. Characterization of unknown leachables requires consideration of analytical uncertainty, as the location of an AET in a given leachables profile (e.g., a gas chromatography/mass spectrometry [GC/MS] chromatogram) must be accomplished relative to an internal standard(s) within the leachables profile. Analytical uncertainty for a particular analytical technique or method can be estimated based on the analysis of a series of reference compounds to create a response factor database. The reference compounds included in this database should represent all known potential leachables (i.e., as determined from extractables assessments). For OINDP, it is recommended (*4*) that the estimated AET be lowered by a factor defined as 1% relative standard deviation in an appropriately constituted response factor database, or a factor of 50% of the estimated AET, whichever is greater. Detailed examples of response factor databases and AET determinations are available (*4*).

## Special Case Compounds

Polycyclic Aromatic Hydrocarbons (PAHs) or Polynuclear Aromatics (PNAs), *N*-nitrosamines, and 2-mercaptobenzothiozole (2-MBT) are considered to be "special case" compounds (i.e., compounds with special safety and historical concerns), requiring special characterization studies using specific analytical techniques and methods (*1,2,4*). Thresholds for characterization of these compounds as extractables or leachables in OINDP are typically based on the limits of these specific analytical techniques and methods. *Table 2* lists the PNAs and *N*-nitrosamines that, along with 2-MBT, are typically investigated as extractables and leachables in OINDP.

**Table 2. PAHs, PNAs, and *N*-Nitrosamines Typically Investigated as Extractables and Leachables for OINDP**

| Target PAHs/PNAs | Target *N*-nitrosamines |
|---|---|
| Naphthalene | *N*-Nitrosodimethylamine |
| Acenaphthylene | *N*-Nitrosodiethylamine |
| Acenaphthene | *N*-Nitrosodi-*n*-butylamine |
| Fluorene | *N*-Nitrosomorpholine |
| Phenanthrene | *N*-Nitrosopiperidine |
| Anthracene | *N*-Nitrosopyrrolidine |
| Fluoranthene | — |
| Pyrene | — |
| Benzo(*a*)anthracene | — |
| Chrysene | — |
| Benzo(*b*)fluoranthene | — |
| Benzo(*k*)fluoranthene | — |
| Benzo(*e*)pyrene | — |
| Benzo(*a*)pyrene | — |
| Indeno(123-*cd*)pyrene | — |
| Dibenzo(*ah*)anthracene | — |
| Benzo(*ghi*)perylene | — |

PNAs have been associated with carbon black filler used in many types of elastomer. Analysis of PNAs, either as elastomer extractables or as drug product leachables, usually involves quantitative extraction followed by highly specific and sensitive analysis of resulting extracts. GC/MS with selected-ion-monitoring has been reported for analysis of target PNAs as leachables in MDI drug products, for example (*5*). *N*-Nitrosamines are reaction products between specific organic precursor molecules, secondary amines ($R_2NH$), and a "nitrosating agent". In the compounding of rubber, secondary amines are likely formed from certain vulcanization accelerators such as thiurams and dithiocarbamates. Potential nitrosating agents include $NO^+$, $N_2O_3$, $N_2O_4$, etc., certain of which can be formed from commonly used chemicals such as sodium nitrite ($NaNO_2$), which has many industrial uses. Analysis of *N*-nitrosamines in rubber as potential leachables involves quantitative

Printed by: USP NF
Do Not Distribute

extraction followed by analysis of extracts with gas chromatography/thermal energy analysis detection (GC/TEA) (*7*). Analysis of *N*-nitrosamines as leachables in MDI drug products using GC/TEA has been reported (*6*). The 2-MBT is a vulcanization accelerator, which is used in certain sulfur-cured elastomers, and can be analyzed by extraction followed by LC/MS (*4*).

# ⟨1664⟩ ASSESSMENT OF DRUG PRODUCT LEACHABLES ASSOCIATED WITH PHARMACEUTICAL PACKAGING/DELIVERY SYSTEMS

## PURPOSE

This general chapter presents a framework for the design, justification, and implementation of assessments for drug product leachables derived from pharmaceutical packaging and delivery systems. A scientifically sound leachables assessment is important to manufacturers and their various suppliers primarily as a means of establishing the suitability for use of pharmaceutical packaging/delivery systems, as leachables can potentially affect drug product efficacy, safety, and quality. Additionally, such a leachables assessment could provide an understanding of the sources of leachables and how to evaluate and manage leachables during the drug development and manufacturing processes. The chapter establishes critical dimensions of a leachables assessment and discusses practical and technical aspects of each dimension. The chapter does not establish specific analytical methods or leachables specifications and acceptance criteria for any particular dosage form or packaging system or drug product combination; nor does it delineate every situation in which a leachables assessment is required. It is not possible for a general discussion of drug product leachables to anticipate and cover all situations which can occur in the pharmaceutical industry where a leachables assessment might be required. Designing an individual leachables assessment is a process that strikes a balance between sound science, prudent resource allocation, and effective risk management with an emphasis on patient safety and product quality. Achieving this balance is the responsibility and obligation of the drug product manufacturer, and assumes due consideration of applicable legal and regulatory requirements. The principles and best demonstrated practices outlined in this general chapter represent a consensus interpretation of sound science and can therefore be extrapolated and applied to any situation in which a leachables assessment is required for pharmaceutical application.

In many cases, drug product leachables assessments are based on or facilitated by knowledge from extractables assessments accomplished on drug product packaging systems, packaging components, and packaging materials of construction (see *Assessment of Extractables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1663⟩).

## KEY TERMS

This general chapter uses the following key terms (*1*,*2*; also see *Packaging and Storage Requirements* ⟨659⟩). Note that the terms *Packaging System*, *Packaging Component*, *Primary Packaging Component*, *Secondary Packaging Component*, and *Materials of Construction* are also defined in ⟨659⟩, and the definitions below are intended for clarification purposes within the context of this chapter and are not intended to supersede those provided in ⟨659⟩.

*Packaging Systems* are the sum of packaging components that together contain and protect the dosage form. Packaging systems are also referred to as *Container Closure Systems* and may include primary, secondary, and tertiary packaging.

A *Container* is a receptacle that holds an intermediate compound, active pharmaceutical ingredient, excipient, or dosage form and is in direct contact with the product.

A *Closure* is a material that seals an otherwise open space on a container and provides protection for the contents. It also provides access to the contents of the container.

A *Packaging Component* is any single part of the package or container–closure system including the container (e.g., ampuls, prefilled syringes, vials, bottles), closures (e.g., screw caps, stoppers), ferrules and overseals, closure liners, inner seals, administration ports, overwraps, adminstration accessories, labels, cardboard boxes, and shrink wrap.

A *Primary Packaging Component* is in direct contact or may come into direct contact with the product (e.g., IV bag).

A *Secondary Packaging Component* is in direct contact with a primary packaging component and may provide additional protection of the product (e.g., overpouch or dustcover for an IV bag).

A *Tertiary Packaging Component* is in direct contact with a secondary packaging component and may provide additional protection of the product during transportation and/or storage (e.g., shipping carton for an overpouched IV bag).

An *Ancillary Component* is a component or entity that may come into contact with a tertiary packaging component during the distribution, storage, and transportation of the packaged product (e.g., pallets, skids, shrink wrap, active containers).

*Packaging Materials of Construction* are substances used to manufacture packaging components. These are also referred to as *Raw Materials*.

A *Delivery System* is the sum of components and materials that are used to transport a drug product from its packaging to the point of administration into the patient. For example, an administration set is a delivery system that is used to transfer liquid drug products from their plastic packaging system to the site of administration to the patient.

*Extractables* are organic and inorganic chemical entities that can be released from a pharmaceutical packaging/delivery system, packaging component, or packaging material of construction and into an extraction solvent under laboratory conditions. Depending on the specific purpose of the extraction study (discussed below), these laboratory conditions (e.g., solvent, temperature, stoichiometry, etc.) may accelerate or exaggerate the normal conditions of storage and use for a packaged dosage form. Extractables themselves, or substances derived from extractables, have the potential to leach into a drug product under normal conditions of storage and use and become leachables. Thus extractables are potential leachables.

*Leachables* are foreign organic and inorganic chemical entities that are present in a packaged drug product because they have leached into the packaged drug product from a packaging/delivery system, packaging component, or packaging material of construction under normal conditions of storage and use or during accelerated drug product stability studies. Because leachables are derived from the packaging or delivery system, they are not related to either the drug product itself or its vehicle and ingredients. Leachables are present in a packaged drug product because of the direct action of the drug product on the source of the leachable. Thus leachables are typically derived from primary and secondary packaging, because the primary and secondary packaging can serve as a barrier between the packaged drug product and other potential sources of foreign chemical

Official

https://pharmacopeia.com/
Printed on: Fri Jan 05 2024 06:31:42 AM(EST)
Printed by: USP NF
Do Not Distribute

entities (e.g., tertiary packaging and ancillary components). In certain circumstances, packaging may directly contact the patient under typical clinical conditions of use (e.g., the mouthpiece of a metered dose inhaler). As a result of this contact, patients may be exposed to leachables from the packaging without the action of the drug product. Leachables are typically a subset of extractables or are derived from extractables. Note that chemical entities can also migrate from packaging/delivery systems to patients via direct contact.

Migrants are also foreign organic and inorganic chemical entities that are present in a packaged drug product because they have leached into the packaged drug product from a packaging/delivery system, packaging component, or packaging material of construction under normal conditions of storage and use or during accelerated drug product stability studies. However, migrants are differentiated from leachables by the circumstance that migrants accumulate in the packaged drug product after the migrant has crossed a physical barrier, such as that provided by primary and secondary packaging. Because migrants cross a physical barrier, they are not present in the packaged drug product due to direct action of the drug product on the source of the migrant because the barrier prevents such direct action. Thus migrants are derived from secondary and tertiary packaging and ancillary components.

Regardless of whether a substance is a leachable or migrant, it is still a foreign substance in the packaged drug product, and thus its impact must be assessed in the same manner. However, as the means by which a leachable and a migrant become entrained in a packaged drug product may be different, extractables studies meant to address leachables may be designed and implemented differently than extractables studies meant to address migrants.

*Leachables Studies* are laboratory investigations into the qualitative and quantitative nature of a particular leachables profile(s) over the proposed shelf-life of a particular drug product.

*Characterization* is the discovery, identification, and quantitation of each individual organic and inorganic leachable present in a drug product formulation above a predetermined level or threshold. Such thresholds should be based mainly on patient safety considerations, with consideration also given to the capabilities of analytical technology, and other related issues.

*Identification* is the process of assigning a molecular structure to an organic leachable, or assigning constituent elements in the case of an inorganic leachable.

*Quantitation* is the process of measuring the level, or concentration, of an individual organic or inorganic leachable contained in a drug product formulation.

*Leachables Profiles* are qualitative and/or quantitative analytical representations of the leachables content of a particular drug product formulation.

*Leachables–Extractables Correlations* are established when observed drug product leachables are linked both *qualitatively* and *quantitatively* to extractables from associated packaging/delivery systems, packaging components, or materials of construction.

*Threshold of Toxicological Concern* (TTC) is a level of exposure for all chemicals, whether or not there is specific toxicity data, below which there would be no appreciable risk to human health (*6*). The TTC approach is a form of risk characterization in which uncertainties arising from the use of data on other compounds are balanced against the low level of exposure.

*Safety Concern Threshold* (SCT) is the threshold below which a leachable would have a dose so low as to present negligible safety concerns from carcinogenic and noncarcinogenic toxic effects.

*Qualification Threshold* (QT) is the threshold below which a given noncarcinogenic leachable is not considered for safety qualification (toxicological assessments) unless the leachable presents structure-activity-relationship (SAR) concerns.

*Analytical Evaluation Threshold* (AET) is the threshold at or above which a leachable should be characterized and reported for toxicological assessment. The AET can be mathematically derived from the SCT (or other threshold concepts) based on factors that include the dosing parameters of the drug product.

As noted, additional terminology and associated definitions are available (*1,2*; see also ⟨659⟩).

## BACKGROUND

Management of leachables is important to pharmaceutical and biotechnology/biologic product manufacturers and regulatory authorities because certain leachables above specific concentrations can present safety concerns for patients and/or compatibility issues for drug product formulations. During the 1980s, the U.S. Food and Drug Administration (FDA) began to formally and comprehensively address leachables in drug products after findings of patient sensitivity induced by leachables and other potential safety concerns related to leachables (*2–4*). Since then, management of both extractables and leachables for packaging systems and final drug products has become an important part of pharmaceutical development and regulatory submissions for many dosage form types, particularly for those deemed of relatively high risk for dosage form interaction with the packaging system, along with a relatively high safety risk relative to the route of administration (see *Table 1*). Note that *Table 1* is a version of the original concept that appears in the FDA guidance *Container Closure Systems for Packaging Human Drugs and Biologics* (*1*), in which certain dosage forms in the above guidance have been downgraded to having lower potential for interaction with packaging components. Remaining relatively high-risk dosage forms include: inhalation aerosols and solutions, injectables and injectable suspensions, ophthalmics, and transdermal ointments and patches. It is important to note, however, that even low-risk dosage forms present some risk and that appropriately rigorous leachables assessments can be important to particular drug products in lower risk dosage form categories (e.g., topicals and oral dosage forms, etc.).

[a] While this table provides a convenient overview of the general level of regulatory concern with various dosage forms regarding leachables, it should not be inferred that "low-risk" dosage forms (e.g., oral tablets) by that definition carry no risk for leachables issues.

This chapter will describe scientific principles and best practices for the assessment of drug product leachables, and will cover various important concepts, including: 1) the requirement for leachables studies; 2) fundamental concepts for leachables studies; 3) the basis of thresholds for leachables and general guidance about application of these thresholds; 4) design and implementation of leachables studies; 5) leachables method development and validation; 6) correlation of results from extractables assessments and routine extractables testing with leachables studies; and 7) establishment of leachables specifications including acceptance criteria.

These scientific principles and best practices apply to all organizations and individuals involved in the manufacture, marketing, and qualification of drug products and in their stability studies, including but not limited to:

- Manufacturers of drug products for human and veterinary use where manufacturing may involve operations at the applicant holder's facilities (i.e., facilities that belong to the holder of an approved New Drug Application or Abbreviated New Drug Application) or at those of a contractor for the applicant holder
- Manufacturers of combination drug products
- Packaging operations by the manufacturer or a designated contractor for the applicant holder
- Repackaging operations in which the drug product may be owned by an organization other than the primary manufacturer.

Although it is ultimately the drug product applicant's responsibility to ensure that appropriate leachables assessments are completed, manufacturers and fabricators of pharmaceutical packaging/delivery systems, packaging components, and materials of construction should also apply these scientific principles and best practices as appropriate, and applicants are encouraged to work with component manufacturers and fabricators to this end.

Official

# CONCEPTS

## General Concepts for Leachables Assessment

During the course of manufacturing, packaging, storage, distribution, and administration, dosage forms and/or their formulation constituents contact components and materials of construction of manufacturing and packaging equipment, and primary and secondary packaging components and systems. Such contact may result in interactions between the dosage form and these components and materials. One such interaction is the migration, or leaching, of substances from any of these components and materials into the dosage form. Leachables, which can include both organic and inorganic (i.e., elemental) chemical entities with wide chemical diversity, are of concern due to their potential safety risk to patients and potential compatibility risks for the drug product. In order to assess these risks and manage the potential issues posed by leachables, it is necessary to know their identities and the levels to which they will accumulate in the finished drug product over its shelf-life. These two pieces of information can be used to establish the magnitude of patient exposure (dose) and therefore the safety risk posed by an individual leachable, as well as the likelihood of any drug product compatibility issues.

Regulatory guidelines, requirements, and various best practice recommendations all state that the definitive assessment of the potential impact of contact between a packaging/delivery system and a final dosage form involves testing the final drug product for leachables. In its most essential form, this impact assessment involves performing a migration, or leachables, study whose purpose is to discover, identify, and quantitate leachables that have migrated from the contacted system, components, or materials and accumulated in the finished dosage form under the product's actual manufacturing, storage and clinical use conditions. A leachables study is a laboratory investigation into the qualitative and quantitative nature of a particular leachables profile(s) over the proposed shelf-life of a particular drug product. The purpose of a leachables study is to systematically and rationally identify and quantify (i.e., characterize) drug product leachables to the extent practicable, and within certain defined analytical threshold parameters. The results of leachables studies are used in the overall leachables assessment to understand the impact of leachables on patient safety and drug product quality and stability.

Leachables studies can be used within the context of an overall leachables assessment to:

- Facilitate the timely development of safe and effective dosage form packaging/delivery systems, manufacturing systems, and processes by assisting in the selection of components and materials of construction
- Facilitate the establishment of qualitative and quantitative leachables–extractables correlations in drug products, when coupled with an appropriate extractables assessment(s)
- Establish the worst-case drug product leachables profile in a manner that facilitates the development of drug product leachables specifications and acceptance criteria (should these be required), and the safety evaluation/qualification of leachables

- Identify trends in drug product leachables accumulation levels over the shelf-life of a particular drug product
- Facilitate change-control processes for drug product packaging/delivery systems (as appropriate), packaging components, materials of construction, formulation constituents, etc.
- Facilitate investigations into the origin(s) of identified leachables whose presence causes out-of-specification (OOS) results for a marketed drug product.

In these ways, leachables studies and assessments can support Quality by Design (QbD) principles for the development and manufacture of pharmaceutical packaging/delivery systems and drug products.

A complete leachables assessment includes understanding the safety impact of individual leachables, safety qualification of individual leachables, and developing an understanding of the impact of individual leachables on drug product stability (i.e., compatibility) and stability. Although safety qualification is presented in general terms, the details of attaining this goal are beyond the scope of this chapter, which is limited to general scientific principles and best practices for the conduct of leachables studies and the other stated uses of the results of leachables studies within an overall leachables assessment. The reader is directed to authoritative manuscripts on this topic (*2, 8*).

Note that certain packaging and combination product medical device components are (or can be) in direct contact with a patient's mouth, nasal mucosa, or other body tissue(s) during normal use of the drug product. Such packaging components include metered dose inhaler and dry powder inhaler mouthpieces, transdermal patches, etc. Patients are potentially exposed to chemical entities by direct contact from such components. Assessment of patient exposure in such direct contact scenarios is best accomplished with appropriate extractables assessments and extraction studies, and the reader is referred to ⟨1663⟩.

## Safety Thresholds

Although leachables represent a particular class of drug product impurity, current regulatory guidance for drug product impurities specifically considers leachables to be out of scope (*5*). Thresholds that have been specifically proposed for drug product leachables are based on either patient safety considerations or the current capabilities of analytical technology. Safety thresholds are particularly important in a leachables assessment because current analytical technology allows detection of trace organic and inorganic chemical entities at extremely low levels (i.e., ng/mL; ng/g). Identification and risk assessment (or qualification) of every individual chemical entity in a typical leachables profile at the limits of current analytical technology is neither necessary from a toxicological perspective nor feasible in a typical drug product. Safety thresholds allow for a science- and risk-based determination of acceptable levels of leachables and can be based on established toxicological information, as well as additional safety risk factors that consider, e.g., route of administration, daily exposure, and treatment duration. Because safety thresholds are derived from exposure data they are considered in terms of units of exposure, such as Total Daily Intake (TDI). Thus, any safety threshold must be converted into units of concentration (e.g., µg/mL) so that it can be applied as an analytical threshold in the laboratory. The analytical threshold is a guide as to which chemical entities in the leachables profile should be considered for chemical characterization (i.e., confirmed identification) and safety evaluation and qualification.

An example of a safety threshold concept that has been practically applied in pharmaceutical development is the Threshold of Toxicological Concern (TTC) approach (*6*). The TTC concept was adopted by the European Medicines Agency (EMA) to evaluate genotoxic impurities, using an excess cancer risk factor of $10^{-5}$ (1 in 100,000) (*7*). The EMA's proposed safety threshold for genotoxic impurities using the TTC approach is 1.5 µg/day TDI. Other examples of safety thresholds include the Product Quality Research Institute (PQRI) Safety Concern Threshold (SCT) and Qualification Threshold (QT), derived and proposed for individual organic leachables in Orally Inhaled Nasal Drug Products (OINDP) (*2, 8*). The SCT is 0.15 µg/day TDI, and the QT is proposed at 5 µg/day TDI for an individual organic leachable. The development of the TTC approach provided a foundation, precedent, and guide for derivation of the PQRI SCT, which incorporates a $10^{-6}$ (1 in 1,000,000) risk factor rather than the $10^{-5}$ value used for the EMA threshold. This lower threshold was considered appropriate for leachables in OINDP because of considerations regarding the direct delivery of some of these dosage forms to diseased organs of a sensitive patient population, and assuming lifetime exposure. In addition, leachables are typically industrial chemicals with no direct structural relationship to any active ingredient or other formulation constituent. Below the SCT, identification and safety evaluation of leachables generally would not be required. Below the QT, leachables without structure alerts for carcinogenicity or irritation would not require compound-specific safety risk assessment. Note that neither the SCT nor the QT is a control threshold or safety-driven limit. Rather, they are leachables evaluation thresholds. The SCT in particular is designed to establish a threshold for characterization of unknown drug product leachables. Individual levels of safety concern, different from the SCT value, could be determined for known leachables and potential leachables (i.e., extractables).

For OINDP there are certain "special case" compounds and compound classes, that due to particular safety concerns (e.g., carcinogenic) were deemed to require lower thresholds based on the capabilities of specific analytical technologies and methods. These special case compounds for OINDP include: polyaromatic hydrocarbons or polynuclear aromatics (PAHs or PNAs), *N*-nitrosamines, and the individual chemical entity 2-mercaptobenzothiozole (see *Orally Inhaled and Nasal Drug Products* ⟨1664.1⟩).

## Information Sharing

To successfully manage leachables throughout the drug product lifecycle, it is critical to establish close and regular communication among those stakeholders throughout the development and drug product lifecycle responsible for the quality of the drug product: chemists, toxicologists, packaging engineers, manufacturing operations, procurement, etc. With respect to leachables, communication between the analytical chemist and toxicologist is critical. For example, if a leachable is found to be above an accepted limit, or a new leachable is found, a safety evaluation will need to be performed. The chemist will need to provide the toxicologist with information that will help to qualify the leachable, including the identity of the leachable, which may include compound class or more specific information, such as chemical formula and structure; and the amount and concentration of the leachable in the drug product.

Information sharing between packaging component manufacturers/suppliers and drug product developers/manufacturers is also important in order to guide packaging component and materials of construction selection, provide knowledge of potential extractables and leachables, and facilitate leachables–extractables correlations via knowledge of packaging component chemical compositions, etc. (also see ⟨1663⟩).

## LEACHABLES STUDY DESIGN

Although leachables studies may be accomplished at any time during the drug product development/manufacturing lifecycle, leachables studies are especially relevant during late stage product development or during formal product stability assessment. Ideally, leachables assessment is conducted as follows:

- The assessment is performed on the actual drug product and not simulations thereof (however, see *Simulation Studies*).
- The assessment is performed with the actual packaging and delivery system in the form it will be commercialized, not with a prototype or on system components.
- The related extractables assessments are accomplished on the same lots of packaging components used to manufacture the drug product lots on which the leachables assessments are performed.
- The assessment is performed on a product that is manufactured under conditions that reflect the actual commercial processes of production of the drug product and the packaging/delivery system, filling of the drug product into the packaging/delivery system, post-filling treatment of the filled packaging (e.g., terminal sterilization), distribution, storage, and clinical use of the drug product. Although leachables studies may include accelerated storage conditions, they cannot be limited to accelerated conditions and must include real-time assessment.

Leachables studies can also be performed early in the drug product development process (e.g., preclinical stage) in order to facilitate the selection of packaging components and their materials of construction. Such leachables studies are particularly useful for certain "high-risk" dosage forms (see *Table 1*) where selecting appropriate packaging components and materials of construction is critical. A variety of packaging components and materials of construction can be evaluated at the same time and drug product leachables profiles determined and evaluated for each configuration. For primary packaging systems or combination drug/device products this can be accomplished by using either the drug product formulation or a placebo formulation in contact with the proposed packaging system. In the latter case, the placebo formulation can be considered as a simulating solvent to characterize extractables as probable leachables (see *Simulation Studies*). In either case, the leachables study conditions (i.e., time, temperature, etc.) should be based on conditions that are relevant for either the use-life or shelf-life of the drug product. Preclinical development stage leachables studies can be designed in a systematic way in order to support QbD processes and principles. It is important to also note that during early stage drug product development for high-risk dosage forms, leachables characterization is recommended for any drug product batches that are used as test articles in any definitive toxicology or clinical studies. For "low-risk" dosage forms (e.g., solid orals, topical powders) leachables studies conducted throughout development might be appropriate in order to assess, and thereby avoid, problems with packaging systems that might appear either in later stage development or marketed product.

During later stage development of high-risk dosage forms in support of product registration, when the final market form of the packaged drug product is available, leachables studies may be accomplished on definitive registration batches of drug product during the course of overall product stability studies. The results of these leachables stability studies can be used to establish leachables–extractables correlations, identify trends in leachables accumulation levels, evaluate individual leachables and qualify them on a safety basis, and develop leachables specifications with acceptance criteria (should these be required). For inhalation aerosols and other OINDP, leachables testing should be an integral part of the larger ICH registration stability program (*2*), and storage conditions and stability time points should be planned accordingly. For cases where a packaging/delivery component is in direct contact with the patient (e.g., a metered dose inhaler or dry powder inhaler actuator mouthpiece), chemical entities that a patient might be exposed to can be evaluated as extractables (i.e., potential leachables) using appropriate simulating fluids under time/temperature exposure conditions relevant to the intended use (see ⟨1663⟩).

Additionally leachables assessments may be appropriate on certain occasions post-market. For example, drug product leachables studies may also be appropriate in many cases where necessary or desired changes in a marketed drug product are made. Such leachables studies are normally required to support change-control processes for many high-risk dosage forms, particularly those with in-place leachables specifications and acceptance criteria, and could also be appropriate for other dosage form types, drug/device combination products, etc. Changes may include but are not limited to: composition of the drug formulation; manufacturing processes for the drug product; primary and secondary packaging components or their materials of construction; manufacturing or assembly processes for primary and secondary packaging components or their materials of construction; and delivery system(s) that are part of the drug product labeling. Any change that results in the patient being exposed to a different leachables profile than the one approved during registration will require leachables studies as part of any change-control process unless adequate scientific justification is provided to the contrary.

Although low-risk dosage forms (e.g., solid orals, topical powders) typically do not rigorously require leachables studies as part of the drug product registration process (*Table 1*), it is possible that leachables could appear in drug product impurity profiles either during registration stability studies or in marketed products. For example, it has been documented that chemical additives in label adhesives can migrate through plastic primary packaging and appear in impurity profiles of solid oral dosage forms packaged within these containers. Thus, it is appropriate to consider performing leachables studies on "low-risk" dosage forms in certain cases. If leachables assessment is not performed proactively, such an event could lead to an OOS result for a development or marketed product and require an "emergency" leachables study as part of an investigation process. The design of this type of leachables study depends on the particular situation; however, in general it would be necessary to identify and quantify the leachable(s), evaluate safety and possibly qualify the leachable(s), and correlate the leachable(s) with packaging component extractables. It is also possible that leachables could result from contact with manufacturing equipment and tertiary packaging systems (e.g., shipping materials).

The design of a particular leachables study depends on the purpose and goals of the overall leachables assessment. Although the leachables studies described above have different purposes and overall goals, they require similar types of information for

DOI: https://doi.org/10.31003/USPNF_M7127_03_01

their proper design. First, it is important to have information as to the identities and maximum possible accumulation levels of all potential leachables. The packaging component manufacturers may provide chemical composition details for the packaging/delivery system and various materials of construction, as well as details regarding the manufacturing processes for these components and materials. Such information may be in the form of material safety data sheets, technical data sheets, test reports, or confidential communications, and can be used to infer potential leachables. An extractables assessment (including an extraction study) can also be accomplished on packaging components and/or their materials of construction to directly assess potential leachables (see ⟨1663⟩). Regardless of how the chemical information is obtained, it is important to ensure that all possible sources of potential leachables from the finished packaging system are considered. These may include chemical entities from any of the primary and secondary packaging components and their materials of construction, coatings, cleaning, lubricating, cutting, sterilization, assembly, or other processes associated with the manufacture of the final packaging/delivery system as used in the drug product. The chemical information on the packaging and delivery system is used to create a list of potential leachables and their possible accumulation levels.

Potential leachables have a significant chemical diversity, and therefore a diversity of physical and chemical properties, including polarity, volatility, solubility, etc. Whereas relatively volatile compounds can more readily migrate into any type of formulation through indirect contact, nonvolatiles generally require direct contact. Two aspects of formulation contact should be considered: the nature of the formulation contact (i.e., direct or indirect) and the time of contact (transient or continuous). If the formulation is not in direct contact with the packaging component (e.g., inhalation powder in a capsule packaged in a blister) then it is less likely that any relatively nonvolatile compounds would migrate into the formulation from the packaging system; however, volatile compounds might. If the formulation is only briefly contacting the packaging component (e.g., an inhaler mouthpiece) it is less likely that any migration of chemicals from the component would occur on this transient timescale. However, if the formulation is in continuous contact with the packaging component (e.g., parenteral in a bag delivered through an administration set) then all types of compounds could potentially migrate into the formulation.

A rigorous leachables assessment considers leachables from sources other than primary packaging, such as necessary secondary packaging and, in certain situations, tertiary packaging. If the primary packaging consists of a semipermeable polymer (e.g., a low density polyethylene container), then potential leachables from labels, inks, adhesives, etc. that are used in the secondary packaging must be evaluated. Similarly, volatile compounds that are present in tertiary packaging (e.g., wooden pallets, cardboard boxes, plastic overwraps, etc.) could migrate into a formulation contained in such a plastic bottle. These migrants that are derived from tertiary packaging should be considered in the event that an unknown impurity is detected or suspected in the drug product.

Various characteristics of the drug product formulation must also be considered in designing any leachables study. For example, formulations are typically either solids or liquids, and it is well documented that physical state affects the leaching process. In the event that a formulation has a change in state during the course of production (e.g., lyophilization; liquid to solid) then the leachables study should be designed taking into consideration the time periods that the formulation is expected to be in each physical state. In the event that a formulation has a change in state during the course of use (e.g., nebulization of a liquid to vapor) then consideration should be given to both the leachables acquired during storage from the container of the liquid and those acquired during use of the prescribed delivery device. In addition, typically only the final packaged product is evaluated for leachables; however, there may be cases in which an intermediate (e.g., bulk capsule for an inhalation powder) is stored for long periods of time in different primary packaging (e.g., foil pouch) from which compounds may leach. If these compounds that migrate from bulk packaging persist through the drug product's manufacturing process and are entrained in the finished drug product, then they are properly treated as leachables.

The nature of any contact that the packaging and delivery system has with the patient must also be considered. If the contact is only surface contact, then the likelihood of direct chemical migration to the patient is much less than if the contact is with mucosa, tissue, bone, or dentin. The various contact categories are described in *The Biocompatibility of Materials Used in Drug Containers, Medical Devices, and Implants* ⟨1031⟩ or ISO 10993 (*9*).

## LEACHABLES CHARACTERIZATION

The primary goal of any leachables study is leachables characterization; i.e., the discovery, identification, and quantitation of leachables present in a particular drug product. Analytical methods for leachables characterization are developed based on the nature of the drug product matrix, the identities and possible accumulation levels of potential leachables, and the required sensitivity based on an adopted leachables evaluation threshold and the capabilities of the analytical methods employed. Unlike a typical drug product impurity method where target analytes are related to the drug substance, leachables have a wide chemical diversity and can come from various sources in the packaging/delivery system. Leachables also have a wide range of possible accumulation levels in a drug product. Taken in total, these factors present a significant challenge for trace analysis, especially in the case of organic leachables identification. Under certain circumstances, this challenge can be mitigated by performing the process of potential leachables identification outside of the leachables assessment, for example via extractables assessment in simulated extractables studies (see *Simulation Studies*).

Before describing the processes, analytical techniques, and methods involved in leachables characterization, it is appropriate to state that the ultimate objective of thorough leachables characterization as defined above cannot be realized in all cases, even when state-of-the-art analytical chemistry is practiced with best available skill and diligence. It is a reality that there is no analytical technique or combination of analytical techniques that is capable of the discovery, identification, and quantitation of any and all organic and inorganic leachables. For example, authentic reference compounds for organic leachables may not be available in all cases for confirmation of identifications or for quantitative instrument calibration. Given these circumstances, the practical objective of leachables characterization must therefore be the discovery, identification, and quantitation of individual leachables present in a drug product above a predetermined level, or "threshold", to a reasonable degree of scientific certainty and exercised with appropriate due diligence.

## Analytical Thresholds

The starting action in leachables method development is to establish the level at which the method must perform at to accomplish the appropriate leachables characterization functions. This level is known as the analytical threshold. Minimally, an appropriate method must function at all levels greater than or equal to the analytical threshold. As discussed previously, such an analytical threshold can be based on various criteria, including safety considerations. An example of a safety-based threshold is the SCT as established for OINDP. In order to define the SCT in terms that facilitate laboratory analysis, it must be converted from units of exposure (i.e., µg/day) to units of concentration (e.g., µg/mL, µg/g, µg/canister, µg/vial, etc.). This is accomplished by considering the dose parameters for a given drug product per the drug product's label claim. The resulting analytically useful threshold is termed the Analytical Evaluation Threshold (AET) (*2*). Previously characterized target leachables will have known safety profiles and previously established leachables thresholds. In any event, thresholds can be used for the basis for analytical method development unless other product considerations, such as compatibility, dictate a lower level is necessary.

A general formula for converting the SCT (0.15 µg/day) to an AET is as follows:

$$\mathrm{AET}\left(\frac{\mu g}{\text{container}}\right) = \left(\frac{0.15 \mu g/\text{day}}{\text{doses/day}}\right) \times \left(\frac{\text{labeled doses}}{\text{container}}\right)$$

Further, for liquid dosage forms:

$$\mathrm{AET}\left(\frac{\mu g}{mL}\right) = \frac{\mu g}{\text{container}} \div \frac{mL}{\text{container}}$$

Further, for solid dosage forms:

$$\mathrm{AET}\left(\frac{\mu g}{g}\right) = \frac{\mu g}{\text{container}} \div \frac{g}{\text{container}}$$

This AET establishes the level at which unknown leachables should be identified and quantified in a particular drug product, and can therefore be used as a basis for analytical method development.

## Analytical Method Requirements

Analytical method requirements for leachables characterization are based on the determined AET (or an alternative valid threshold concept), and information on potential leachables obtained from extractables assessments of packaging components and materials, including information from component/material suppliers. Since leachables are typically a subset of extractables or chemically linked to extractables, it may be the case that analytical methods used for leachables characterization can be based on those used for extractables characterization (see ⟨1663⟩). Any analytical method for leachables that is used for drug product stability studies in support of product registration, establishing leachables–extractables correlations for high-risk dosage forms, or the development of leachables specifications and acceptance criteria must be subject to complete validation using industry-accepted validation practices.

## Preparing the Drug Product for Analysis—Sample Preparation

Sample preparation for leachables characterization is a function of the chemical nature of the potential leachables, the chemical nature of the drug product sample matrix, and the analytical technique(s) to be applied. The drug product matrix can present a significant challenge for organic leachables characterization. Drug product matrices contain the active pharmaceutical ingredient and excipients, which are typically present at high levels relative to leachables (except in certain high potency drug products). Analytical methods for organic leachables usually incorporate sample preparation procedures to separate leachables from the drug product matrix and concentrate them for analysis. The exact details of sample preparation procedures are unique to the individual drug product and while it is impossible to anticipate every scenario, the following general statements can be made:

- *Aqueous dosage form* (e.g., inhalation solutions, small and large volume parenterals, ophthalmic solutions, etc.) leachables can be recovered using liquid-liquid extraction with water immiscible organic solvents, such as dichloromethane, hexane or petroleum ether, etc. The pH of the aqueous sample can be manipulated (i.e., raised or lowered) in order to enhance extraction of weakly acidic or basic leachables, or reduce extraction problems caused by the relatively high concentration of active pharmaceutical ingredient and excipients. The resulting organic extract can be dried if required (e.g., with magnesium sulfate drying agent) and concentrated if required by techniques that remove the solvent, such as evaporation with a gentle stream of dry nitrogen, rotary evaporation, or a Kuderna-Danish concentrator, etc. Concentrated organic extracts can be analyzed directly by GC-based methods; however, for HPLC-based methods using aqueous mobile phases the organic extract can be reduced to dryness (or near dryness) and the resulting residue of leachables taken up in a water miscible solvent (e.g., acetonitrile, methanol, etc.). Volatile leachables (e.g., solvents) can be analyzed directly from aqueous drug product samples with GC combined with headspace sampling. Note that recoveries of certain leachables can be affected by extraction and extract concentration procedures.
- *Solid dosage form* (e.g., solid orals, inhalation powders, lyophilized powders, etc.) leachables can be recovered (for example) by dissolving the drug product with an aqueous solution and applying liquid-liquid extraction and extract concentration, as above. Headspace sampling and GC analysis of volatile leachables can be accomplished on the aqueous samples or, in some cases, directly on the solid dosage form. It is also possible to dissolve the drug product sample in another appropriate and analytically expedient medium (e.g., an organic solvent) for direct analysis by GC; however it is possible that matrix effects and interferences from the active ingredients and excipients could result.

Official

https://pharmacopeia.cn/v29240/

- *Oral liquid dosage form* leachables can be recovered by diluting the drug product sample in aqueous solution and applying liquid-liquid extraction and extract concentration, as above. Headspace sampling and GC analysis of volatile leachables can be accomplished on the aqueous samples or, in some cases, directly on the oral liquid dosage form. It is also possible to dissolve the drug product sample in another appropriate and analytically expedient medium (e.g., an organic solvent) for direct analysis by GC; however, it is possible that matrix effects and interferences from the active ingredients and excipients could result.
- *Cream and ointment dosage form* leachables can be recovered by dissolving the drug product sample in an aqueous solution, filtering, and applying liquid-liquid extraction and extract concentration, as above. Headspace sampling and GC analysis of volatile leachables can be accomplished on the aqueous samples. It is also possible to dissolve the drug product sample in another appropriate and analytically expedient medium (e.g., an organic solvent) for direct analysis by GC; however, it is possible that matrix effects and interferences from the active ingredients and excipients could result.
- Dosage forms with nonaqueous drug product vehicles (e.g., metered dose inhalers with organic solvent propellants) require special sample preparation procedures, which are discussed in ⟨1664.1⟩.

Development of sample preparation methods for leachables characterization can be accomplished through the use of appropriate test samples, such as accelerated drug product samples that have been aged under accelerated conditions (e.g., 40°/75%RH on 3-month storage), drug product or placebo samples spiked with known potential leachables, and/or a simulated drug product matrix spiked with known potential leachables. Recoveries of spiked potential leachables should be assessed and optimized during method development. Internal standards can be included to improve quantitative accuracy and precision.

Note that the sample preparation for leachables characterization must create a test sample in a form amenable to the analytical technique to be applied, and appropriately concentrated so that individual leachables can be characterized relative to the selected threshold.

## Analytical Techniques

Analytical techniques applied to leachables characterization are the same as those applied to extractables characterization, which are summarized and discussed in ⟨1663⟩. Scouting analyses in general are not applied to leachables characterization, as the drug formulation may interfere with the scouting methods (see ⟨1663⟩). The most useful analytical techniques for discovery, identification (either by qualitative or structural analysis), and quantitation of organic leachables are those that combine GC and HPLC with mass spectrometry [i.e., GC/MS and HPLC (or LC)/MS]. Headspace sampling can also be interfaced with GC/MS to address volatile compounds. Other detection systems for both GC and HPLC that are not compound specific (e.g., FID, UV, etc.) are potentially useful for leachables discovery and quantitation, but not in general for identification. The combination of GC and HPLC techniques has the sensitivity and specificity required to characterize the diversity of chemical compounds found in many leachables samples. Analytical methods for leachables should be capable of characterizing target as well as new (or unspecified) leachables (e.g., scanning GC/MS or LC/MS); however, when additional sensitivity is required due to the use of analytically challenging thresholds, dedicated target compound methods (e.g., GC/MS with selected ion monitoring) can be used. It is also possible, with appropriate validation, to use methods based on techniques that are not compound specific (i.e., GC/FID, HPLC/UV, etc.).

Structural analysis of leachables should be accomplished with a systematic process identical to that described in ⟨1663⟩ for extractables, and to a level of confidence sufficient for safety assessment. A discussion of the principles of both gas and liquid chromatography is available in *Chromatography* ⟨621⟩. A discussion of the principles of mass spectrometry (including both GC/MS and LC/MS) is available in *Mass Spectrometry* ⟨736⟩. Although chromatographic-based hybrid analytical techniques are most commonly applied to leachables characterization, other analytical techniques with compound-specific detection capability (e.g., nuclear magnetic resonance spectroscopy) can be employed.

## Quantitative Methods—Validation Considerations

Validation of quantitative leachables methods should be accomplished according to industry accepted practices, criteria, and standards, such as *Validation of Compendial Procedures* ⟨1225⟩ and (*10*). The extent of validation required depends on the goals of the leachables study in which the analytical method is being utilized. Validation parameters may include: accuracy, precision (repeatability, intermediate precision), specificity, limit-of-detection, limit-of-quantitation, linearity and range, and robustness. System suitability tests and criteria should also be developed for each leachables method. Special considerations for individual validation parameters relative to leachables methods are as follows:

- *Accuracy and precision*—The validation parameters of accuracy and precision (repeatability and intermediate precision) are typically evaluated using drug product samples spiked with known amounts of target leachables. The choice of drug product spiking matrix used for these evaluations should be one that has had little-to-no contact with the packaging materials used in the final drug product, and therefore little-to-no measurable levels of endogenous leachables. Suitable spiking matrices can include freshly manufactured drug product and simulated drug product vehicles. Spiking levels should be determined based on results from accelerated stability studies or estimated from the known amounts of potential target leachables determined from extraction studies. Accuracy is typically performed at three spiking levels, which can also be determined based on results from accelerated stability studies or estimated from the known amounts of potential target leachables determined from extraction studies.
- *Linearity and range*—Since potential leachables are present in packaging components at widely varying levels, actual drug product leachables can likewise appear at widely varying levels. The best accuracy and precision are achieved when the validated linear range considers the potential maximum accumulation levels of each target leachable or chemical class of leachables.
- *Limit of detection/Limit of quantitation*—To detect and quantitate unknown leachables, the limit of quantitation should be at or below the designated analytical threshold (e.g., AET).

@2024 USPC
DOI: https://doi.org/10.31003/USPNF_M7127_03_01

- *Specificity*—Evaluation of method specificity can be accomplished by evaluating chromatographic peak purity in spiked and nonspiked drug product samples. For GC-based quantitative methods, this can be accomplished by GC/MS. For HPLC-based methods, either LC/MS or LC/DAD (diode array detection) can be used. Specificity can be qualitatively demonstrated if there are no observable method interferences related to the chemical entities present in the drug product.
- *Robustness*—A design-of-experiments statistical approach with consideration of critical analytical method parameters (e.g., HPLC flow-rate, HPLC column, mobile phase gradient, etc.) should be used to create robustness evaluation protocols. Other approaches, such as serial change of critical parameters, can also be applied.
- *System suitability*—Chromatography-based analytical methods, such as those described in ⟨621⟩, should include appropriate system suitability criteria for routine method evaluation, including tests for method linearity, precision, sensitivity, and specificity as appropriate. These parameters should be evaluated with an appropriately constituted test mixture(s) each time the quantitative leachables method is used, and should include appropriate system suitability acceptance criteria based on the method validation results. For example, sensitivity may be confirmed by analysis of standards prepared at the analytical threshold.

Several examples of validated leachables methods from the scientific literature have been documented in the chemical literature (*11*–*16*).

## ESTABLISHING A LEACHABLES–EXTRACTABLES CORRELATION

A leachables–extractables correlation is established when actual drug product leachables can be linked either qualitatively or quantitatively with extractables from corresponding extractables assessments of individual materials of construction, packaging components, or packing systems. Leachables–extractables correlations are important for several reasons, including justifying the use of routine extractables release tests of packaging components as an alternative to leachables testing during stability studies for high-risk drug products, establishing the source of a leachable producing an OOS result for a low-risk drug product, change control, and ongoing quality control, etc.

A *qualitative correlation* is demonstrated when a leachable is linked either *directly* or *indirectly* to an extractable (i.e., potential leachable). For example, hexadecanoic acid observed in a leachables profile can be directly linked with hexadecanoic acid observed in the extractables profiles of one or more primary packaging components. The ethyl ester of hexadecanoic acid observed in the same leachables profile can be indirectly linked with hexadecanoic acid observed in one or more extractables profiles, if ethanol is a known drug product formulation constituent and it is shown that an esterification reaction can occur in the drug product during storage. For an appropriate quantitative leachables–extractables correlation to exist, the quantity of any individual leachable over the shelf-life of a drug product must be mathematically related to the quantity of the corresponding extractable in its source. One of the more simple mathematical relationships between an extractable and a leachable is that the quantity of the leachable in the drug product should be less than or equal to the quantity of the corresponding extractable. For example, the concentration of butylatedhydroxytoluene (BHT) present in a drug product formulation was determined to be 5 µg/mL. BHT was extracted from a primary packaging system component at a level of 300 µg/component. If the drug product packaging system incorporates one of these components per dosage form and the packaged formulation has a volume of 50 mL, then a quantitative leachables–extractables correlation is established, as BHT was extracted in the amount of 300 µg (300 µg/component × 1 component) and was leached in the amount of 250 µg (5 µg/mL × 50 mL). As a result, it can be concluded that on the average 50 µg of BHT is unaccounted for (300 µg extracted – 250 µg leached), and that this quantity was either not leached from the packaging component into the formulation (more likely) or lost by some other process (less likely).

For high-risk drug products, leachables–extractables correlations may be established over multiple batches of drug product (accelerated or at end of shelf-life) and multiple batches of packaging components. Extractables studies should ideally be conducted on the same lots of components that were used to manufacture the drug product batches used in primary stability studies (and therefore on the drug product batches on which leachables testing was conducted to establish leachables–extractables correlations).

If the maximum level of any specific leachable in the formulation during stability studies was substantially greater than the calculated maximum potential accumulation levels of that same leachable as established by the extraction study, and the extraction studies were conducted on the same lots of components used to make the primary drug product stability batches, it can be concluded that the extraction study was incomplete and therefore a leachables–extractables correlation for that specific leachable cannot be established. In this case, either the extraction study can be augmented with experiments that produce an extractable level exceeding the maximum level of the leachable, or the leachable can be controlled via the drug product specifications for shelf-life stability testing, and release testing as an extractable at the component level is inadequate to control this leachable.

If a leachable–extractables correlation cannot be established, possible explanations include: inadequate extractables assessments of packaging components (see ⟨1663⟩); unreported changes in packaging component composition or manufacturing processes; unreported changes in the identity of packaging components.

## CONSIDERATIONS IN DEVELOPING LEACHABLES SPECIFICATIONS AND ACCEPTANCE CRITERIA

The validated analytical methods and information obtained from those methods in a drug product leachables study can be used to develop drug product leachables specifications and acceptance criteria (i.e., limits). In certain circumstances, most commonly encountered with high-risk dosage forms (such as OINDP), it may be meaningful, useful, and at times required to routinely monitor finished drug products for leachables. Under such circumstances, leachables specifications and acceptance criteria must be established. One means by which such specifications and acceptance criteria could be developed includes testing a minimum of three drug product batches to determine their leachables levels. After thorough chemical and safety

@2024 USPC

evaluation, the test data from the three or more batches can be used to establish acceptance criteria for targeted leachables, consistent with 1) the qualitative and/or quantitative results of leachables studies, 2) a consideration of the capabilities of the drug product's manufacturing process, and 3) a consideration of the potential safety, compatibility, and/or drug product quality impact of the leachables. It is important to note that leachables specifications should be applicable to a product during all stages of its shelf-life, including release and at end of shelf-life. This is the case since leachables accumulate over the entire shelf-life of a drug product.

When a change occurs in a product for which leachables specifications and acceptance criteria have been established, it is important to review the analytical method and re-evaluate the acceptance criteria and make adjustments to the specifications and acceptance criteria as appropriate and scientifically justified. A change in components that results in an increase in leachables concentrations beyond the levels qualified will necessitate the toxicological evaluation of the proposed levels, as would be the case for any impurity.

Acceptance criteria can be both qualitative and quantitative for both known and unspecified leachables. For example, a typical leachables specification could include:

- Quantitative end of shelf-life limits for target leachables, which apply over the shelf-life of the drug product
- A quantitative limit for "unspecified" (i.e., previously unidentified and uncorrelated) leachables (identification of unspecified leachables is required for accurate quantitation and toxicological evaluation).

## ADDITIONAL CONSIDERATIONS

### Simulation Studies

Occasions may arise in which it is not analytically feasible (due to challenging thresholds, for example) to successfully discover and identify all actual leachables in a drug product leachables study. This circumstance can be managed if the activities of discovery and identification of probable leachables are accomplished in an extraction study, where samples and analyte concentrations are more easily manipulated to achieve the necessary analytical performance. In such a circumstance, the actual drug product leachables assessment is simplified to a high-sensitivity quantitation of targeted leachables that have been discovered and identified as part of this extraction study.

In order to facilitate the discovery and identification of probable leachables, the extraction study must be similar in design to a drug product leachables study. Such an extraction study seeks to simulate the circumstances experienced by the drug product but should produce a test sample that is easier to characterize than the drug product itself. For such a study to be relevant in establishing appropriate target leachables, the solvent(s) used to generate the test sample must have nearly the identical propensity to leach as the drug product formulation. Such a study should be accelerated versus the leachables study so that the extractables, reflecting potential target leachables, can be discovered and identified in a timely fashion. Differences in the study design between this simulation study and the drug product leachables study are: 1) that the drug product formulation has been replaced with a simulating solvent that mimics the formulation; 2) that the conditions of contact have been accelerated, so as to increase both the concentrations of probable leachables and the rates of migration of probable leachables into the simulating solvent; and 3) that the test article can be either the complete packaging and delivery system or separate components of that system. Factors to consider in designing and justifying the simulating solvent(s), along with recommendations on the analytical approach used to characterize the simulating extract for extractables as potential target leachables are discussed in ⟨1663⟩. Given the intent of the simulation study, which is the discovery and identification of extractables as target leachables, simulation studies must also be driven by relevant thresholds.

It is possible that in cases of very low thresholds (e.g., AETs), quantitation of drug product leachables might still not be analytically feasible, even with high sensitivity target compound analytical methods. In such cases, the results of the simulation study (probable leachables identities and concentrations) may be sufficient to establish patient safety and the quality impact of the actual drug product leachables. **To the extent that the simulation study mimics the drug product leachables study**, the potential safety or quality impact of a compound as an extractable is an estimate of the potential safety or quality impact of the compound as an actual leachable. If it can be established that a compound quantitated as an extractable under these conditions has an acceptably small impact on safety and quality, then it follows that the same compound as a leachable in the drug product formulation may be assumed to have a similarly low impact on safety and quality as a leachable in the drug product formulation. The acceptability of this approach for any particular drug product needs to be scientifically justified by the drug product applicant.

If a compound is measured as an extractable in a simulation study and targeted as a leachable in a drug product leachables study, the extractables and leachables data for that compound become the basis upon which a leachables–extractables correlation can be made. For such a correlation to be considered to be valid, it is necessary that each leachable concentration in the drug product be less than or equal to the corresponding extractable concentration in the simulated extract, accounting for the uncertainty in the analytical measurements and any justifiable "exaggeration factors" that may have been utilized in the simulation study. Note that in certain justifiable circumstances drug product placebo batches may be used as test articles in drug product leachables studies (stability studies). However, there are also circumstances when placebo batches are not acceptable, such as when there is significant reason to believe that leachables might have an adverse effect on an active pharmaceutical ingredient (e.g., therapeutic proteins).

### Inorganic (Elemental) Leachables

The topic of leachables as elemental impurities in pharmaceuticals can be addressed within the overall context of elemental impurities in drug products (e.g., *Elemental Impurities—Limits* ⟨232⟩. Elemental impurities leached from packaging or delivery systems represent only one source of elemental impurities in a drug product, and thus testing a drug product for elemental impurities does not establish that the impurities are leachables.

https://pharmacopeia.com/
Printed on: Fri Jan 05 2024 06:31:42 AM (EST)
Printed by: USP NF
Do Not Distribute

Testing of the plastic packaging systems and their materials of construction will establish those extractable elemental impurities that are relevant to a particular packaging system, and it may be appropriate to quantify such elemental impurities as leachables in the drug product. Therefore, the results of testing plastic packaging systems should be used to establish those elemental impurities that should be monitored as targeted elemental leachables in the drug product.

In general, guidelines and recommendations about elemental impurities in drug products address safety concerns associated with the elemental impurities. However, it is proper to consider elemental leachables from the broader perspective of the overall quality of the drug product. Thus the process of evaluating elemental leachables may include both the aspects of user safety and product quality.

Note that one of the differences between the testing for organic leachables (and extractables) and for elemental impurities is the nature of the information generated. The testing for organic leachables is based on having established the identity of the chemical compound that is the leachable. Alternatively, the test methods most commonly employed to address elemental impurities (atomic spectroscopy) do not establish the compound, or form, that the detected element is present in. For example, sulfur might be present in the form of elemental sulfur ($S_8$), as the sulfate ($SO_4^{-2}$), or as a sulfur-containing organic compound (e.g., 2-mercaptobenzothiazole). Also, silicon might be present either as silicone oil or as silicon dioxide ($SiO_2$). As the form of the elemental impurity may have a marked effect on the impurity's impact on product quality or safety, it may be the case that testing beyond elemental impurity profiling may be necessary to establish the exact chemical form of the elemental impurity and thus ascertain its potential safety or product impact.

An important issue to consider in testing drug products for elemental leachables is establishing which elements to measure as leachables. Considering this, it is noted that testing of the plastic packaging systems and their materials of construction will establish those extractable elemental impurities that are relevant to a specific packaging system. Therefore, the results of testing plastic packaging systems should be used as one means of establishing those elemental impurities that should be monitored as targeted elemental leachables.

***Change to read:***

## SUMMARY

The requirement for, and completeness of, a leachables assessment for any particular drug product can only be determined by the drug product applicant with reference to appropriate regulatory guidance documents. Detailed recommendations for OINDP are presented in ⟨1664.1⟩.

## 1. INTRODUCTION

A manufacturing process is the sum of the steps required to convert starting raw materials into a manufactured biopharmaceutical drug substance (DS) or a pharmaceutical or biopharmaceutical drug product (DP). Manufacturing processes are performed utilizing manufacturing systems which are the sum of the components that together comprise the equipment that converts starting raw materials into biopharmaceutical DSs or pharmaceutical or biopharmaceutical DPs.

Manufacturing systems can be partially or completely constructed from plastic materials. Plastics used in manufacturing systems possess a range of molecular weights and contain plastic additives such as antioxidants, stabilizers, lubricants, plasticizers, and colorants. Several factors dictate the types of plastics that are used in manufacturing components, the types and amounts of additives and polymeric resins that are used in plastic materials and the processes used to convert the plastic materials into components or systems.

The process stream, production intermediates, DS, or the DP itself could directly come in contact, and potentially interact, with one or more plastic components of the manufacturing system at some point during the manufacturing process. During contact, substances could leach from a manufacturing component and become incorporated into the process stream. If these substances persist in the process stream through subsequent process operations, they could accumulate in either a DS or DP as process equipment-related leachables (PERLs). If they are present in the DP, PERLs have the potential to alter critical quality attributes of the DP, such as safety, efficacy, and stability.

*Plastic Components and Systems Used to Manufacture Pharmaceutical Drug Products and Biopharmaceutical Drug Substances and Products* ⟨665⟩ addresses these interactions by providing a risk-based means for chemically characterizing and qualifying plastic components used to manufacture biopharmaceutical DSs and pharmaceutical and biopharmaceutical DPs. That chapter provides guidance on qualification procedures applicable to manufacturing components and systems that are within its scope. Chapter ⟨1665⟩ communicates the key concepts behind and provides additional information and guidance regarding the applicability and the application of ⟨665⟩.

## 2. SCOPE

In general, components of pharmaceutical and biopharmaceutical manufacturing systems can be grouped based on the function or operation that the component performs, including:

- Fluid transfer and transport (e.g., tubing and connectors)
- Mixing, reacting, and fermenting (e.g., tank liners, mixer bags, bioreactors, impellers, tubing, and container ports)

https://pharmacopeia.com/
Printed on: Fri Jan 05 2024 06:37:07 AM(EST)
Printed by: USP NF

@2024 USPC

- Storage (e.g., containers [and associated ports and/or tubing] for raw materials, production reagents, and process intermediates)
- Processing (e.g., filters and chromatography columns)
- Filling devices (e.g., filling needles)
- Ancillary components (e.g., o-rings, gaskets, check valves, septa, diaphragms, polymer pump surfaces, and sensors)

This chapter is applicable to all manufactured DPs, including pharmaceuticals ("traditional" or "small molecule" products) and biopharmaceuticals (biologics), and is also applicable to manufactured biopharmaceutical DSs. This chapter is also applicable to substances that are manufactured (collected, isolated, purified, etc.) with plastic components and systems and used in gene and cell therapies or as antibody–drug conjugates (ADCs). Active pharmaceutical ingredients (APIs) that are the precursors to non-biologic and non-biopharmaceutical drug products and are typically manufactured via chemical, as opposed to biological, processes are referred to as "traditional" or "small molecule" drug substances and are out of scope with regard to ⟨665⟩ and this chapter as they are well-characterized substances that have sufficiently low levels of PERLs that they do not require characterization. Thus, manufacturing components used in the production of APIs are considered to be suitable for use without the chemical testing required in ⟨665⟩. However, APIs formulated in upstream processes, which include reactive process streams (i.e., containing organic solvents in large proportion, exceptionally high or low pH), high contact temperatures, long contact durations and/or multiple plastic components followed with limited purification processes, are considered to be at a higher risk. Applying ⟨665⟩ to the qualification of plastic components for such processes is determined on a case-by-case basis using good scientific judgment such as the concepts and processes described in ⟨665⟩.

This chapter is applicable to plastic manufacturing components that are used once and discarded (single-use systems) and components that are used once, rendered suitable for re-use (e.g., cleaning, sterilization) and then re-used in multiple-use systems.

Manufacturing components such as o-rings and gaskets may be constructed of rubber-based elastomers, which could be a source of PERLs and thus must be qualified. However, rubber-based components are not within the scope of ⟨665⟩ and thus qualification tests and specifications must be found elsewhere. Although rubber components used in manufacturing are outside the scope of *Elastomeric Components in Injectable Pharmaceutical Product Packaging/Delivery Systems* ⟨381⟩, that chapter contains tests and specifications that might be relevant to rubber-based elastomeric manufacturing components.

This chapter and ⟨665⟩ exclude items that are referred to as auxiliary items. While assorted plastic auxiliary items (e.g., scoops, funnels, pipettes, graduated cylinders, weighing dishes, and beakers) could be used in manufacturing operations for the dispensing and transferring of ingredients into a process stream or solution, their conditions of use are such that they are unlikely to contribute PERLs to the process stream. For example, such auxiliary items contact manufacturing ingredients for relatively short periods of time. Furthermore, many auxiliary items are used to transfer solid ingredients, which present a low risk of PERL transfer. The use of auxiliary items poses little risk in terms of the transfer of PERLs to the process stream. Thus, such auxiliary items are outside the scope of ⟨665⟩ and such items are considered to be qualified for use without ⟨665⟩ testing.

The applicant who secures and is responsible for the regulatory approval of a manufacturing system or the manufactured pharmaceutical or biopharmaceutical drug product derived from that system is accountable for establishing that the product's manufacturing system meets these expectations and is suited for its intended use.

This is accomplished by ensuring that the manufacturing system itself and/or the manufactured pharmaceutical DP or biopharmaceutical DS or DP has been appropriately tested and that the test results have been appropriately evaluated. The avenues through, and means by, which the applicant obtains test results and secures test result evaluations are left to the discretion of the applicant.

## 3. GENERAL PRINCIPLES

### 3.1 Discussion

The most effective means of ensuring that a manufacturing system is suitable for its intended use is to use well-characterized and intentionally selected components.

While the selection process for components increases the likelihood that a component and a system composed of components will be suitable for use, it does not necessarily establish that the component is actually suitable to use. Qualification testing of a component and/or system is required to establish the component's (or system's) ability to produce an acceptable DS or DP. When appropriate, system qualification may be augmented by DS or DP testing to directly establish what effect the manufacturing system had on the DS's or DP's key quality attributes.

This chapter and ⟨665⟩ both deal with the qualification of manufacturing components, where ⟨665⟩ specifically establishes the testing requirements for the qualification of plastic components.

Given the nature of manufacturing processes and systems, certain components may be isolated from the DS or DP. Although such components are essential aspects of the production system, they do not add PERLs to the DS or DP because they are isolated. If the isolation of a process component can be established (e.g., waste bag), then characterization of the component per ⟨665⟩ is not required.

### 3.2 Material Characterization

The most effective means of ensuring that a manufacturing component is suitable for its intended use is to use well-characterized and intentionally selected materials of construction. Thus, a component manufacturer is advised to collect chemical characterization data on candidate materials for the component, as such information may guide material selection. Guidance on how to chemically characterize materials of construction can be found in the following *USP* chapters:

- ⟨381⟩
- *Plastic Materials of Construction* ⟨661.1⟩

https://pharmacopeia.cn/v29240/

Although chemical characterization of materials may enable appropriate material selection, chemical characterization of materials is not a prerequisite for the qualification of manufacturing components or systems.

### 3.3 Component Characterization

Components shall be characterized to the extent that is consistent with the risk that the component could add PERLs into a process stream and that the PERLs could persist through the manufacturing process and adversely affect the suitability for use of the process output. Matching the risk with the required level of characterization is achieved by a two-stage component assessment approach consisting of an initial assessment followed by a risk assessment.

## 4. ASSESSMENT PROCESS

### 4.1 Initial Assessment

The initial assessment as illustrated in ⟨665⟩, *Figure 1* addresses three aspects of the component and its use:

1. Is the component with a process stream, a biopharmaceutical DS, or a pharmaceutical or biopharmaceutical DP during use?
2. Is the process stream, DS, or DP that contacts a manufacturing component either a liquid or semisolid?
3. Does a potential comparator component or system exist, and, if so, can equivalence be established between the comparator and the component or system under consideration?

Aspect 1 addresses whether the component contacts a process stream, biopharmaceutical DS, or pharmaceutical or biopharmaceutical DP directly. If the component contacts an auxiliary stream, then it is isolated from the process stream. It is unlikely that such a component's PERLs will become entrained into the biopharmaceutical DS, or pharmaceutical or biopharmaceutical DP. In this circumstance, the component is deemed to be qualified for use with no further assessment and is out of scope for ⟨665⟩.

Aspect 2 addresses the physical state of the process stream and is based on the generalization that interactions between a process stream and a component are likely to be more extensive if the process stream is a liquid or semisolid (as opposed to a gas or solid). Moreover, liquid and semisolid process streams are more common in pharmaceutical manufacturing than are solid or gaseous process streams. Thus, when components are contacted by either solid or gaseous process streams, the risk associated with PERLs is very low, no characterization is required, and the component is deemed to be qualified for use with no further assessment.

An example of such a component is one that is used during the transfer of drug product powders into their final packaging. As another example, it is noted that a DS may be stored frozen in a container at some point in the manufacturing process, raising the question as to whether the container is actually within the scope of ⟨665⟩ (a frozen DS is a solid). As such storage typically includes periods in which the DS is thawed in the container; this situation is within the scope of ⟨665⟩ and requires risk assessment and appropriate testing. As the PERL's risk during frozen storage is very low, such an assessment focuses solely on the conditions during which the DS exists in a liquid or semisolid form.

A component that does not contact a liquid or semisolid process stream is out of scope for ⟨665⟩. If the component or system is contacted by a liquid or semisolid process stream, process intermediate, biopharmaceutical DS, or biopharmaceutical or pharmaceutical DP, then Aspect 3 is addressed.

Aspect 3 addresses the concept of a comparator component. When a manufactured pharmaceutical or biopharmaceutical product has been approved for commercial marketing, then by direct association, the process and system used to manufacture that product has been established to be suitable for their intended purpose. Once a manufacturing system has been established to be suitable to manufacture a biopharmaceutical DS, or pharmaceutical or biopharmaceutical DP by the relevant regulatory authority, then every component used in that manufacturing system has been established to be acceptable. These manufacturing components or systems may then be used as comparators and may provide the means of establishing whether a component or system under consideration for use in another manufacturing process and/or to produce a different biopharmaceutical DS, or pharmaceutical or biopharmaceutical DP is suitable.

If equivalence can be established between a component under consideration and a comparator component, then this justification is adequate to establish that the component under consideration is suited for its intended use without testing the component per ⟨665⟩. In this case, a justification should be provided and the qualification process is complete.

Equivalence can be established if both the component under consideration and the comparator are:

1. Constructed from the same materials of construction
2. Manufactured via the same process and the same processing conditions
3. Equivalent in terms of the function they perform
4. Equivalent in terms of how they have been processed (e.g., sterilized) and/ or reprocessed, if appropriate, prior to their use, either by the component's vendor or the component's user. For multiuse components/systems, equivalence with respect to how they have been processed post use.
5. Equivalent in terms of their conditions of use in the manufacturing process
6. Prepared for use (e.g., flushed, sterilized) in the same manner
7. Used to produce the same type of output (biopharmaceutical DS or pharmaceutical or biopharmaceutical DP), and the outputs are administered in the same clinical manner (route of administration and dose)

Although it is highly desirable that the equivalence in all seven aspects be exact, it may be the case that essential equivalence can be established based on strong similarities between the component under consideration and the comparator. The concept of strong similarities implies that the differences in any of the above-listed seven items of comparison are minor. Here "minor" means the differences are sufficiently small that the PERLs derived from the component in question:

@2024 USPC

- Will be the same in identity and amount to the PERLs from the comparator, or
- Will have the same process or patient effect as the PERLs derived from the comparator

Any minor differences between the component under consideration and a largely representative comparator component may be addressed by risk assessing the minor differences in a manner consistent with ⟨*665*⟩ and this chapter. Alternatively, minor differences between the component of interest and a largely representative comparator component may be addressed by an alternate risk assessment process. The purpose of this risk assessment is to ensure that a minor difference will have a minor impact on the suitability of a component for its intended use. If it is established that the minor difference will likely have a minor and insignificant impact on a component's suitability, then the comparator approach is an appropriate means of qualifying the component. However, if it is possible that the minor difference could have a significant effect on the component's suitability, then the comparator approach is not an appropriate means of qualifying the component and the component must be qualified by testing as established by risk assessment.

Ultimately, it is the responsibility of the component's user to establish and justify equivalence, or essential equivalence, to a comparator.

## 4.2 Risk Assessment of Components

Components that have direct contact with a liquid or semisolid process stream, starting material, reagent, process intermediate, biopharmaceutical DS, or pharmaceutical or biopharmaceutical DP, and that do not have comparators, must be characterized to the extent dictated by their risk profiles whereby a greater risk is associated with a more extensive characterization. The risk profile of a component or system, used in a particular circumstance, is established by the application of a risk evaluation matrix constructed so that it:

- Establishes the appropriate contributors to, or dimensions of, risk
- Provides a means of quantifying the risk, in each of its dimensions (e.g., see *Table A-1*)
- Provides a means of quantifying the total risk as a combination of the individual risks established for each dimension
- Links the quantified total risk to appropriate characterization strategies (e.g., see *Table A-3*)

### 4.2.1 DEVELOPMENT AND APPLICATION OF THE RISK EVALUATION MATRIX

The risk evaluation matrix establishes the relative risk that a plastic component or system will be leached with sufficient tenacity that a process stream contacting the plastic component will likely contain potentially impactful PERLs and that the PERLs will likely persist in the process stream to be incorporated in the production output. The matrix then links that risk to a prescribed level of chemical characterization.

If the contact conditions between a process stream and a manufacturing component are mild, then it is unlikely that the leaching of PERLs will occur. On the other hand, if the contact conditions are harsh, then it is very likely that PERL leaching will occur.

Secondly, a PERL generally is likely to have an adverse effect on a key drug product quality attribute only if it persists through the manufacturing process and is incorporated into the finished DP. If the PERL is cleared from the process stream by subsequent manufacturing steps, then it will not persist to the end of the manufacturing process. As a result, the PERL will not be incorporated into the DP, and it will not have an effect on any of the DP's key quality attributes. Conversely, if the PERL is not removed from the process stream, then it will likely be entrained into the DP. [NOTE—For biologics, key quality attributes and process performance parameters can also be potentially impacted by a PERL during drug substance manufacturing prior to the finished DP.]

These two actions, leaching and persistence, can be used as dimensions in a risk evaluation diagram (see *Figure 1*), where the risk that is being evaluated is whether the finished DP will contain PERLs at high enough levels that they could have an adverse effect on a key quality attribute of the DP. The level of risk is associated with the nature and amount of testing that is required for components per ⟨*665*⟩.

@2024 USPC

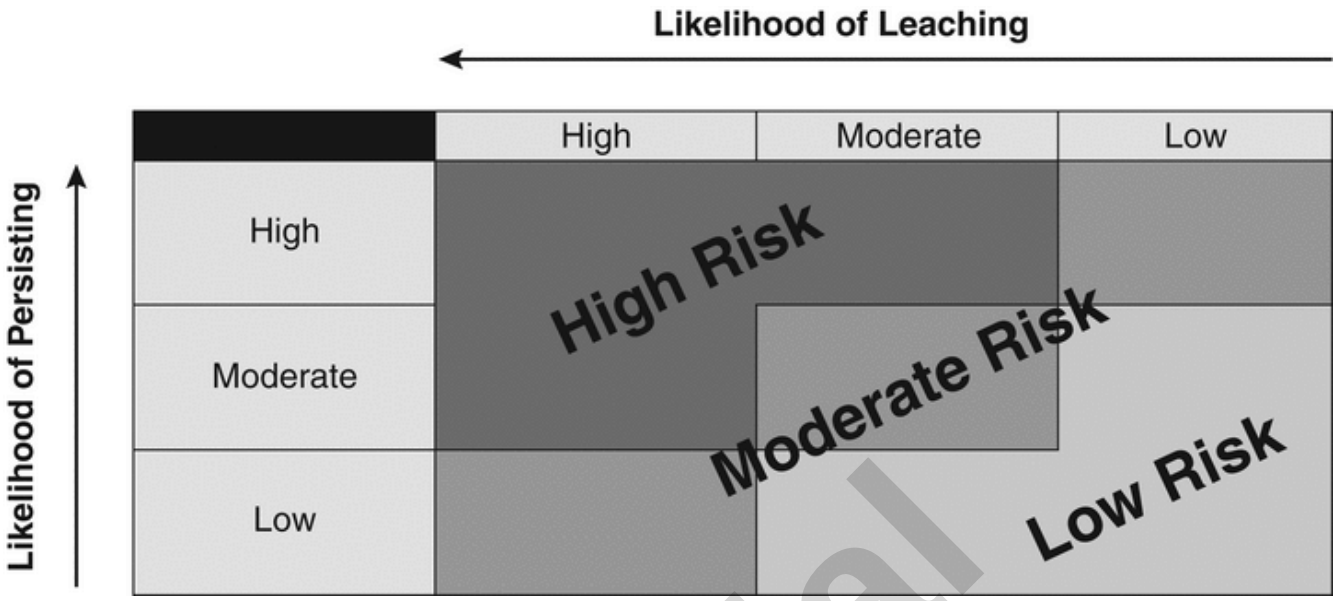

Figure 1. Risk evaluation diagram.

An individual manufacturing circumstance (e.g., component type or process conditions under which the component is contacted by the process stream) is positioned in this risk evaluation diagram to establish the component's required level of testing per ⟨665⟩. Although each individual drug product sponsor must establish the manufacturing circumstance's position in the risk evaluation diagram, the means by which this is accomplished is not specified in ⟨665⟩, and it is the responsibility of the sponsor to establish and justify these means. In establishing and justifying the means, the sponsor must consider the multitude of factors that impact the likelihood of leaching and the likelihood of PERLs to persist. Although general comments on how to fit a specific circumstance into the risk evaluation diagram can be found in this chapter, the finished drug product's sponsor has the ultimate responsibility for performing and justifying the risk evaluation.

While the individual details of individual sponsors' risk evaluation processes may differ, it is proper and reasonable to expect that the processes would be similar in terms of the general concepts applied. To properly address the issue of PERLs, the risk evaluation process should address the following points:

1. The chemical and physical nature of the contacted component, establishing the component's "propensity to be leached"
2. The chemical nature of the contacting process stream, establishing the process stream's "leaching power"
3. The conditions of contact, addressing the "driving force" for leaching (e.g., temperature, duration)
4. The ability of purification process operations to eliminate the PERL from the process stream or to dilute the PERL to such an extent that an adverse effect is unlikely
5. The inherent risk associated with the manufactured drug product, considering such factors as the nature of the manufactured dosage form, e.g., inhalation solution (higher risk) versus parenteral solutions (moderate risk) versus aqueous-based oral and topical (lower risk); the clinical dosing of the DP (e.g., daily dose volume); and the duration of the clinical therapy (acute versus chronic)

Regardless of the justified means by which the risk assessment is carried out, the outcome of the risk assessment must be that the risk is defined as low, moderate, or high, consistent with the risk levels illustrated in *Figure 1*. However, it is recognized that the final risk output from some drug product sponsors may differ from the three levels of risk evaluation matrix as shown in *Figure 1*. Other risk models outputs may yield two or more risk evaluation levels. In these cases, it is the responsibility of the drug product sponsor to align their risk outputs with the three risk levels required in ⟨665⟩. In addition, at least one of the sponsor's risk evaluation levels must be aligned with the ⟨665⟩ high risk level.

An example of a risk evaluation matrix can be found in the *Appendix*. As the purpose of this example is education and illustration, it is not required that the matrix in the *Appendix* be adopted in order for a sponsor to claim that their assessment complies with ⟨665⟩.

### 4.2.2 LINKING RISK TO CHARACTERIZATION METHODOLOGIES

The various adjusted characterization levels established previously are linked to the following characterization processes:

- Low Risk = general chemistry testing, "worst-case" extraction solution
- Moderate Risk = organic extractables profiling, "worst-case" extraction solution
- High Risk = organic extractables profiling, multiple extraction solutions reflecting the effects of pH and polarity on extractions, and extracted elements as deemed appropriate by the component's user

## 4.3 Establishing the Level of Component Chemical Characterization

### 4.3.1 LOW RISK ASSESSMENT

Low risk chemical characterization data are generated by subjecting the component of interest to an extraction involving the ethanol–water solvent *Solution C1* from the standard extraction protocol described in ⟨665⟩, *4.2 Test Methods*. The ethanol–water extraction solution is chosen as it is generally recognized as producing the most substantial organic extractables profile of all three extraction solutions specified in the standard extraction protocol, where substantial means the largest number of extractables at their highest levels. This extraction solution is profiled, in general, for organic extractables by measuring its level of nonvolatile residue (NVR) and UV absorbance, where NVR provides a level of total extracted nonvolatile substances and UV absorbance provides an indication of the amount and type of UV-absorbing organic extractables. NVR and UV absorbance are chosen because they are tests that are compatible with the extraction solution. Although pH and total organic carbon (TOC) are useful general chemistry tests, they are not compatible with the extraction solution.

Although these general chemical properties of the extracts may not serve as the only basis for a risk assessment, they are important and relevant indicators that the component in question may have levels or types of extractables that could present a higher risk than was indicated by the risk assessment. For example, a large value for NVR would suggest that large amounts of non-volatile extractables were present in the extract. In such a circumstance, even though the component has been judged to be low risk, the judgment may have underestimated the risk. The conclusion that the risk has been underestimated would mean that the risk level should be elevated to moderate risk, triggering the generation of full extractables profiling in *Solution C1*. It is reasonable to expect that the extractables profile would establish those extractables responsible for the general test result that triggered the extractables profiling effort.

### 4.3.2 MODERATE RISK ASSESSMENT

Consistent with the greater risk, moderate risk components require a more rigorous chemical characterization whereby extractables are addressed by full organic extractables profiling of extraction *Solution C1*. As noted under *Low Risk Assessment*, *Solution C1* is chosen as the extraction solution as it is generally the case that, of the three extraction solutions specified in ⟨665⟩, the most complex organic extractables profile is obtained with this extraction solution, where "most complex" means the greatest number of individual extractables at their individually highest concentration in the extract.

### 4.3.3 HIGH RISK ASSESSMENT

High risk components must be characterized to the extent that a full organic extractables profile has been established, addressing potentially extreme process conditions such as process solutions with a high "leaching power" or conditions of contact with a high "driving force" for leaching (e.g., higher temperatures or longer duration periods of contact). Such a rigorous and complete characterization is obtained by implementing the standard extraction protocol, which adds two more extraction solutions (low pH and high pH aqueous *Solution C2* and *Solution C3*) to the ethanol–water solution, whereas *Solution C1* is required in the low and moderate risk cases. This extraction protocol is discussed in detail in *5.1 Standard Extraction Protocol*.

# 5. TESTING OF PLASTIC COMPONENTS AND SYSTEMS

## 5.1 Standard Extraction Protocol

Components and systems are used in many different ways and perform many different functions in manufacturing systems. Because it is reasonable to anticipate that the conditions of contact between the process stream and a manufacturing component may be strongly influenced by the function of the component (and the chemical nature of the process solutions at the relevant stage of manufacturing), component extraction procedures vary across the various component functions.

Given the diversity of components used in manufacturing systems and the widely varying conditions of contact in manufacturing operations, it is not possible to establish a single extraction procedure that is a perfect match for every manufacturing circumstance. On the other hand, it is unreasonable and impractical to impose a large set of extraction conditions because it would inevitably lead to testing and test results that are irrelevant. The compromise between universal applicability and practicality is to establish a standard extraction protocol, based on a minimum set of extraction conditions, which provides information that is useful in a majority of circumstances and is more completely relevant in the more commonly encountered circumstances.

The standard extraction protocol was designed to produce extracts whose analytical characterization would generate extractables profiles that can be used to drive component qualification in commonly encountered situations. As such, it represents a compromise between completeness and practicality.

### 5.1.1 EXTRACTION SOLUTIONS

From a practical perspective, it is desirable to limit the number of extraction solutions to a minimal number of solutions with a sufficiently varied chemical composition that effectively addresses the diversity in the composition of process streams. Furthermore, the solvents themselves should be analytically expedient, facilitating the chemical analysis of the extracts.

Three extraction solutions are specified in ⟨665⟩: a 50% by volume ethanol–water solution to address process streams that contain organic solvents, organic solubilizing or stabilizing agents, lipids (up to 15% of the process stream's composition by weight), proteins, and blood or blood-derived components (*Solution C1*); a pH 3 salt solution to address low pH (*Solution C2*); and a pH 10 buffer to address high pH (*Solution C3*). The pH values or ethanol content of the extraction solutions encompass many of the process streams encountered in typical manufacturing operations. The differing nature of the solvents could

Official

https://pharmacopeia.cn/

produce three separate extractables profiles, the combination of which would be relevant to the most commonly encountered manufacturing situations.

Other solvents may be used in addition to the three solvents specified in the standard extraction protocol at the discretion of the assessor. For example, there may be process situations where the pH of the process solutions falls outside the range encompassed by *Solution C2* and *Solution C3*, and in those situations it may be appropriate to consider alternative or additional extraction solutions.

Considering aqueous solvents, the pH range specified in the standard extraction protocol was chosen to 1) reflect a reasonable range of pH values for process solutions commonly encountered in pharmaceutical manufacturing processes and 2) encompass the pH range over which pH materially impacts the "extracting power" of the solvent.

For extraction at a low pH specifically, studies that included the pH 3 extraction solution (*Solution C2*) specified in ⟨665⟩ and a more acidic 0.1 M phosphoric acid extraction solution have demonstrated that the extractables profiles produced are sufficiently similar that these solvents can be considered interchangeable. Thus, an extraction performed with 0.1 M phosphoric acid as the extraction solution meets the extraction requirements in ⟨665⟩ for *Solution C2*. Furthermore, extraction solutions that achieve pH 3 by various means (e.g., the use of different acids to achieve the pH) are considered to be appropriate surrogates for the pH 3 solution specified in the standard extraction protocol, so long as the surrogate solvent is analytically viable.

For extraction at a high pH, studies that included the pH 10 extraction buffer *Solution C3* specified in ⟨665⟩ and more caustic extraction solutions (e.g., 0.5 N sodium hydroxide) have demonstrated that the extractables profiles produced may be sufficiently dissimilar that these solvents cannot be considered interchangeable. This circumstance is noteworthy as high pH caustic solutions such as 0.5 N sodium hydroxide are used in certain commonly encountered process situations. For example, it is fairly commonplace in biopharmaceutical manufacturing for manufacturing components to be cleaned and/or sanitized prior to use by contact with caustic solutions. Although extractables may be released from the components and become entrained in the caustic solution, such situations are not of concern with respect to ⟨665⟩, as the caustic solutions are directed to waste and contact between the component and the caustic solution is usually followed by rinsing, with the rinsate also being directed to waste. Thus, the released extractables do not enter the process stream and cannot become PERLs.

On the other hand, caustic solutions are frequently used in biopharmaceutical manufacturing to adjust the pH of process solutions (e.g., media fills in bioreactors). Such caustic solutions may be stored in plastic containers, clarified by plastic filters, or delivered to the process stream by plastic tubing and connectors. In these situations, extractables from the plastic components that become entrained in the caustic solution enter the process stream and become PERLs, making this situation relevant to ⟨665⟩. However, the manufacturing process is such that the caustic solutions are greatly diluted by the process streams. The levels of these PERLs in the actual process stream are small and likely to be inconsequential.

These circumstances notwithstanding, if all of the following criteria are met, then the pH 10 extraction solution specified in ⟨665⟩ can be replaced with the contact solution or the proposed simulating solvent. Alternatively, if an extraction study has already been performed with the contact solution or the proposed simulating solvent, the extractables profile obtained from that study can be used in place of the organic extractables data obtained with the pH 10 extraction solution.

1. The pH of the contacting solution is >10
2. There is a reasonable expectation that extractables resulting from the action of the high pH contacting solution will remain in the process stream (or else the component is isolated from the process stream and extraction is not required per ⟨665⟩, *3.1 Initial Assessment)*
3. Assessment of the risk associated with this contact situation produces a high risk characterization (as other risk characterizations do not require a high pH extraction)
4. The contact solution itself, or a proposed simulating solvent, are analytically expedient (meaning that the analytical process of extractables discovery, identification, and quantitation can be accomplished at the necessary concentration levels via the expert application of generally practiced, state-of-the-art analytical practices and technology)

A component that is tested with the replacement extraction solution and meets the requirements of ⟨665⟩ is considered to be compliant with ⟨665⟩.

Substitution of a high pH contact solution or simulating solvent for the pH 10 extraction solution (*Solution C3*) in circumstances where all four of these criteria are not met is an inappropriate application of ⟨665⟩.

An alternative solvent should not be used in place of *Solution C1, Solution C2*, or *Solution C3* if the "extraction (or leaching) power" of the process stream used in the manufacturing process is less than that of the corresponding solution (*Solution C1, Solution C2* or *Solution C3*).

The options available for extractions solvents are summarized in *Figure 2*.

Official

https://pharmacopeia.cn/v29240/

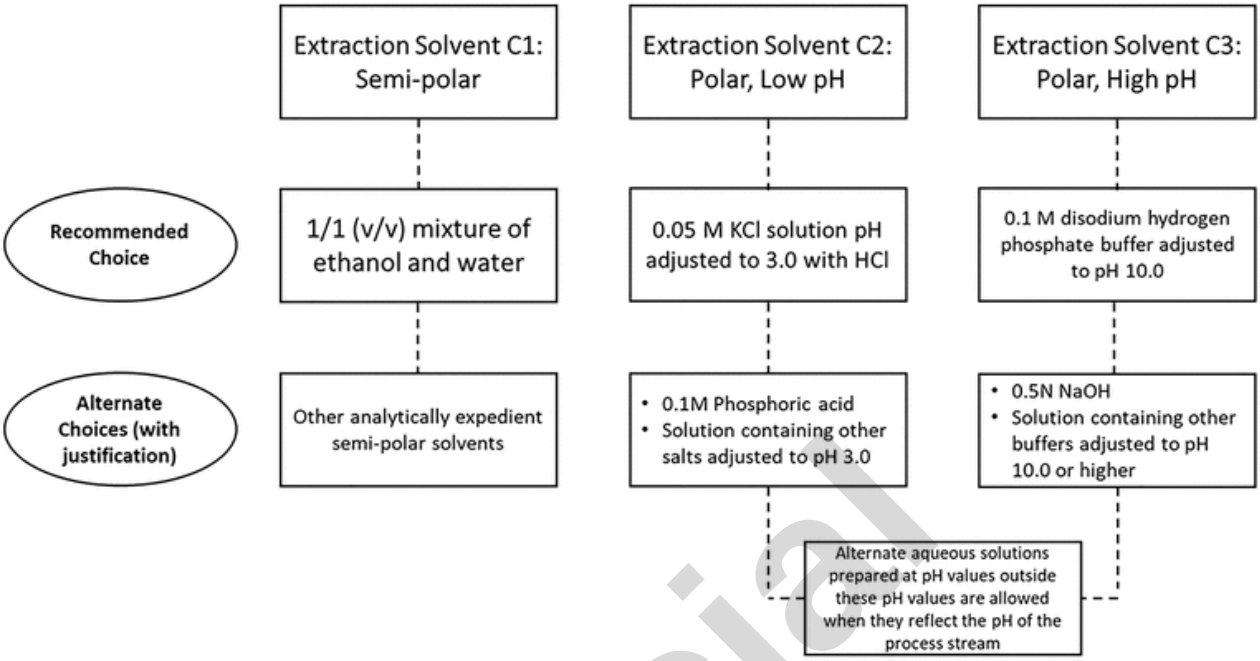

Figure 2. Extraction solution selection for manufacturing components.

The required extraction solutions do not include water, as the extractables profile obtained in water will be intermediate between the combined extractables profiles obtained from the pH extreme aqueous solvents. The extraction solutions do not include a high inorganic salt solution (e.g., 5 M sodium chloride), as the high salt will reduce leaching. The extraction solutions do not include solvents containing surfactants as the "leaching power" because the ethanol–water solvent generally has the same or greater "leaching power" as a surfactant-containing process stream. Additionally, extraction solutions containing surfactants are more difficult to analyze than an ethanol–water solutions.

### 5.1.2 EXTRACTION TEMPERATURE

The choice of the extraction temperature (40°) was dictated by the desire to accelerate, but not alter, the extraction process. A 40° extraction temperature provides an appropriate acceleration factor. Still, it is not so much higher than the temperature of typical manufacturing operations that the nature of the components at the extraction temperature would differ greatly from the nature of the component at the manufacturing temperature.

### 5.1.3 EXTRACTION DURATION

Durations of extraction were established specifically for individual components, consistent with the duration of contact between the component and a process stream during typical manufacturing operations. In some cases, such as bioreactor bags, the duration of contact specified in the standard extraction protocol is a value intermediate between the shortest and longest possible contact time during manufacturing operations. Profiles generated by testing extracts obtained at such intermediate durations will generally apply to manufacturing conditions at both contact duration extremes and will be sufficient to facilitate and justify component qualification.

Extraction durations longer than contact time during typical use are used for manufacturing situations where the contact between the component and the process stream is short, such as manufacturing operations involving a flowing process stream. The shortest extraction time was established as 1 day.

Extraction durations shorter than contact time during typical use are used for manufacturing situations where the contact between the component and the process stream is long, such as long-term storage of process intermediates. Nevertheless, the longest extraction time established, 21 days, still reflects approximately 2.5 months of contact at ambient temperature and 8 months storage under refrigerated conditions, estimated as follows.

The accelerated aging techniques noted in ASTM F1980-16 (*1*) are based on the hypothesis that the chemical reactions being considered follow the Arrhenius reaction rate function and can be applied generally to temperatures between 2° (non-frozen) and 70° (depending on the glass transition temperature of the plastic being considered).

The technique is based on an accelerated aging factor (AAF), which is expressed mathematically in *Equation 1*.

$$\text{AAF} = Q_{10}^{\left[\left(T_{AA} - T_{RT}\right)/10\right]} \quad \text{Equation 1}$$

$Q_{10}$ = aging factor, which has a conventionally accepted value of 2.0 for a first-order chemical reaction
$T_{AA}$ = elevated temperature to be used for extraction

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M11136_02_01
@2024 USPC

$T_{RT}$ = temperature at which the manufacturing operation is performed

For example:

If $T_{AA}$ = 40° and $T_{RT}$ = 22° (ambient temperature), then the AAF = 3.48.

If $T_{AA}$ = 40° and $T_{RT}$ = 5° (refrigerated temperature), then the AAF = 11.3.

The AAF value is used to calculate the accelerated aging time (AAT) as expressed in *Equation 2*.

$$t_{RT} = \text{AAT} \times \text{AAF} \quad \text{Equation 2}$$

$t_{RT}$ = contact time at $T_{RT}$

Using the example of the values of AAF obtained above and a 21 days extraction period, the calculated AATs for process steps that occur at ambient or refrigerated temperatures become 73 and 237 days, respectively. Even if these values are not exactly correct due to the assumptions inherent in the calculation, they establish the extent to which the duration specified in the standard extraction protocol reflect actual manufacturing conditions.

For extrapolation of 21 days of extraction at 40° to the equivalent storage duration at ambient room temperature (22°), *Equation 2* becomes:

$t_{RT}$ = AAT × AAF

$t_{RT}$ = 21 days × 3.48

$t_{RT}$ = 73.1 days

For extrapolation of 21 days of extraction at 40° to the equivalent storage duration at nominal refrigerated temperature (5°), *Equation 2* becomes:

$t_{RT}$ = AAT × AAF

$t_{RT}$ = 21 days × 11.3

$t_{RT}$ = 237.3 days

### 5.1.4 DYNAMIC EXTRACTION

Many manufacturing operations involve flowing or agitated process streams. Additionally, extractions may be facilitated by movement of extraction solutions by either agitation or recirculation. Thus, dynamic extractions are performed on components via either agitation or recirculation. Specific dynamic requirements are detailed for individual components in ⟨665⟩.

### 5.1.5 EXTRACTED SURFACE AREA TO EXTRACT SOLUTION VOLUME RATIO (SA/V)

It is generally the case that extractions described in relevant regulatory guidelines and relevant standards are defined in terms of the ratio of a test article's contact surface area and the volume of the extraction solution. To be consistent with these precedents, extractions in ⟨665⟩ are defined in terms of SA/V. Additionally, since components used in manufacturing are available in multiple sizes and configurations, specifying extractions based on SA/V allows for a consistent basis of comparison. The target SA/V of 6 $cm^2$/1 mL was adopted from relevant regulatory guidelines and standards. In all cases, the SA/V used in an extraction must be specified. In cases where components are extracted via immersion, reporting the mass/extraction volume or the number of components/extraction volume ratios may also facilitate the assessment of the extractables data.

### 5.1.6 NON-STANDARD EXTRACTIONS

Extractions that replace those specified in the standard extraction protocol may be necessary and appropriate in certain circumstances. It is a fundamental aspect of extractables assessment that the item being extracted is compatible with the conditions of extraction; that is, the item should not be altered chemically or physically by the extraction process. Although the extreme circumstance of complete dissolution of the test item is an obvious indication of an incompatibility (as it is surely the case that a manufacturing component is not dissolved by a process stream during use), less extreme indicators of incompatibility exist (e.g., deformation or discoloration of the test item or generation of a precipitate-laden extract).

If an extraction solution specified in the standard extraction protocol is incompatible with the component being tested (i.e., the component is rendered nonfunctional by the extraction), then an alternate extraction solution should be established, and the alternate solution should replace the specified solution. The alternate extraction solution must be suitable for determining either the NVR and UV absorbance or the organic extractables profile and, as appropriate, extractable elements, meaning that the solvents must be analytically compatible with the analytical techniques used for organic and inorganic extractables and profiling.

Considering the required surface area to solution volume ratio of 6 $cm^2$/1 mL specifically, when such an extraction ratio cannot be readily achieved, then an alternate extraction should be designed so that it is based on the highest possible surface area to solution volume ratio and a justification for the alternate extraction ratio must be provided.

Additionally, the standard extraction protocol was established to be applicable to a majority of the most commonly encountered manufacturing circumstances. However, one can encounter extreme manufacturing circumstances where the contact conditions between the process stream and a manufacturing component are more aggressive, in terms of extraction potential, than the extraction conditions in the standard extraction protocol. An example of such a circumstance is the situation where the pH of the process stream exceeds the pH of the basic extraction *Solution C3*. In this specific circumstance, the use of an extraction solution with a pH greater than *Solution C3* (pH 10) as a substitute for *Solution C3* may be appropriate (see *5.1.1 Extraction Solutions*).

As another example, higher temperature or longer extraction duration may be appropriate based upon the worst-case conditions of use in the manufacturing process (e.g., maximum component use time including holding/pause and restart). In

DOI: https://doi.org/10.31003/USPNF_M11136_02_01
@2024 USPC

this case, the higher temperature and/or longer duration is used in place of the temperature or duration established in the standard extraction protocol.

In other circumstances of extreme manufacturing conditions, an alternate extraction process that is as aggressive as the manufacturing conditions must be designed and justified. This alternate extraction process is then used in place of the process established in the standard extraction protocol.

On the other hand, it is possible that the extraction conditions of the standard extraction protocol are more aggressive than the manufacturing conditions of contact. The substitution of a less aggressive extraction for the extraction specified in the standard extraction protocol is not appropriate, as it is the intent of the standard extraction protocol to produce an extractables profile in the laboratory that is at least as complex as the PERL profile under actual process conditions, where complex refers to the number of compounds and their concentrations.

The generation and testing of extracts produced by alternate extractions will generate extractables profiles that could replace those profiles generated by the implementation of the standard extraction protocol at the discretion of the component's assessor. However, the generation and testing of such additional extracts cannot be used to replace or substitute for the extractables profiles generated by implementation of the standard extraction protocol unless:

1. The substitution is driven by incompatibilities, or
2. The substitution can be justified by a rigorous technical discussion of the "extracting power" of the proposed substitution solvent and the solvent (*Solution C1*, *Solution C2*, or *Solution C3*) it is replacing, or
3. The alternative testing condition represents the worst-case scenario of the extraction power of the process stream during manufacturing.

An example of such a justification would be the discussion about the interchangeability of the pH 3 extraction *Solution C2* and an extraction solution consisting of 0.1 M phosphoric acid.

It is noted that any alternate extraction process can only replace the extraction conditions that it directly addresses. For example, the use of a high pH process stream in manufacturing means that while *Solution C3* can be replaced with an alternate extraction solution, it does not mean that testing with *Solution C1* and *Solution C2* can be eliminated; testing of these solutions must still be performed.

The circumstances just discussed address the substitution of an alternate extraction process for an extraction process specified in the standard extraction protocol. Extractions performed in addition to those specified in the standard extraction protocol may be performed at the discretion of the component's assessor.

#### 5.1.7 ACCOUNTING FOR CONDITIONING AND RELATED STEPS EMPLOYED IN MANUFACTURING

Certain components used in manufacturing suites may be subjected to processes during manufacturing that have the potential to affect their extractables profiles. For example, tubing may be cleaned, rinsed, or sterilized by autoclaving or irradiation prior to, or between, manufacturing events. In addition to cleaning, rinsing, and sterilization, filters and chromatography columns may be conditioned prior to or after use.

Two aspects of such process steps are potentially important. The first aspect is whether manufacturing components must be tested by extracting them with solutions and under conditions that mimic such process steps. Since it is likely that the solutions used in these processing steps are isolated from the process stream, and thus that the finished DP is not exposed to extractables leached during such steps, the components do not have to be extracted with the cleaning, rinsing, or conditioning solutions. Nevertheless, it still may be necessary to establish that the components are compatible with these manufacturing processes and solutions.

The second aspect is that such process steps could alter the extractables profile of the affected components. Especially when such process steps are repeated numerous times over the component's useful lifetime (e.g., if the component is reused after processing), it is necessary to establish a component's extractables profile at various points during its useful lifetime, unless the assessor can provide evidence that the extractables profile does not change with each successive processing and reuse.

### 5.2 Testing the Extracts and Generating the Extractables Profile

#### 5.2.1 ORGANIC EXTRACTABLES

For moderate and high risk components, the extracts shall be analytically tested to establish the identities of the organic extractables and to estimate their concentration in the extracts using appropriate and orthogonal analytical methods, consistent with *Assessment of Extractables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1663⟩. Thus, chromatographic methods with appropriate sampling and detection processes are used to screen extracts for organic extractables.

The reporting of organic extractables must be consistent with the application of relevant and appropriate reporting thresholds. An example of such a reporting threshold is the analytical evaluation threshold (AET), as defined in ⟨1663⟩. The reporting threshold should be clearly communicated and justified in conjunction with the extractables profile.

Chromatographic methods used to address organic extractables should be qualified as being suited for this intended use.

#### 5.2.2 EXTRACTED ELEMENTS (POTENTIAL ELEMENTAL PERLS)

Techniques such as atomic spectroscopy (e.g., inductively coupled plasma–optical emission spectroscopy [ICP–OES]—see *Elemental Impurities—Procedures* ⟨233⟩) can be used to screen extracts for extracted elements.

Considering the reporting of extracted elements, the relevance of extractable elements testing should be considered by the component's potential user. Should such testing be deemed necessary, it is the user's responsibility to establish and justify the means by which testing is accomplished, taking into account extraction conditions, target elements, and reporting requirements. Furthermore, the component's user may wish to consult ⟨233⟩ when establishing its manufacturing components'

extracted elements strategy, recognizing that ⟨233⟩ is specifically applicable to finished drug products and elements listed in the chapter do not reflect all potentially impactful elements but rather those elements for which permissible daily exposures (PDEs) could be derived.

### 5.3 Evaluation of the Extractables Profile Established by Implementing the Standard Extraction Protocol

Although the generation of a component's extractables profile is a necessary step in component qualification, the mere existence of an extractables profile does not establish whether a component is appropriate for use. Rather, the extractables profile must be interpreted in terms of the probable impact that the extractables would have on key performance and/or key quality attributes of either the process itself or the process output if the extractables were to become PERLs.

It is beyond the scope of this document to specify the exact means by which the probable impact of a component's extractables (as potential PERLs), as revealed by application of the standard extraction protocol, is established. However, *Section 6* discusses certain aspects of such a qualification process.

## 6. QUALIFICATION OF MANUFACTURING COMPONENTS AND SYSTEMS

### 6.1 General

A manufacturing system is chemically suited and qualified for its intended use if:

1. The manufacturing system is constructed from well-characterized components that have been intentionally chosen for use as established by testing.
2. The manufacturing system has been established to be safe by means of the appropriate chemical testing of components, such as extractables profiling, or DPs, leachables testing as necessary and appropriate, and toxicological assessment of the test data. In this context, a manufacturing system is considered to be safe if the DS or DP it produces contains PERLs at levels sufficiently low that they pose a negligible risk to patient safety. This combination of chemical testing and toxicological assessment is termed "chemical suitability for use assessment".

In certain circumstances and at the drug product sponsor's discretion, the suitability for use assessment could consider the possibility that the efficiency and/or effectiveness of the manufacturing process would be adversely impacted by PERLs that are derived from manufacturing components and present in the process stream(s).

This section of this chapter deals solely with manufacturing components and systems and should not be applied to materials from which manufacturing systems are constructed. It is also noted that it is relatively rare that the entire manufacturing system is qualified by performing extraction studies on the entire system, given the practical difficulties in so doing, and that, most commonly, a manufacturing system is qualified by performing extraction studies on the components that make up the system and then using the individual components' extractables profiles to establish the components' cumulative potential effect as a system. The means used to establish either the cumulative extractables profile and/or its cumulative potential effect must be justified.

In certain circumstances, individual manufacturing components may be connected to produce a manufacturing assembly and it may be desired that the assembly be tested per ⟨665⟩. Such a desire potentially complicates the testing of an assembly versus the component particularly when the assembly is comprised of components that individually would be tested in different manners, for example, duration of extraction.

It is beyond the scope of ⟨665⟩ to envision all possible assemblies that could be used in manufacturing and to provide extraction conditions for such assemblies. Ultimately, it the assembly user who is responsible for establishing and justifying the extraction conditions used to ascertain the assembly's compliance with ⟨665⟩. If appropriate, the justification must specifically address the situation where the extraction conditions used for the assembly are less rigorous (e.g., of shorter duration) than the most rigorous extraction conditions specified in ⟨665⟩ for the assembly's individual components.

### 6.2 Chemical Qualification

A manufacturing system is qualified as being suitable for use based on relevant and appropriate chemical testing of the manufacturing system, its components of construction, or the system's output. Generally, an appropriate and rigorous chemical assessment would include extractables testing of the manufacturing system (and/or its components) and/or PERL testing of the manufactured biopharmaceutical DS or pharmaceutical or biopharmaceutical DP. It is expected that the design of the extractables study would be based on sound and justifiable scientific principles and that the studies themselves would be consistent with the:

- Composition of the components
- Conditions of use of the components
- Chemical properties of the process stream
- Clinical use of the process output
- Perceived risk associated with the manufacturing system and the process output

No manufacturing system or process output is excluded from extractables or leachables testing; however, the nature and degree of testing depends on factors listed above and the risk that PERLs from the manufacturing component could affect the effectiveness of the manufacturing process or the quality of the manufactured DS or DP. Thus ⟨665⟩ has established a process for qualifying components that establishes three levels of risk and utilizes three levels of testing.

Considering a component that has been classified as low risk, such a component is deemed to be qualified for use, consistent with ⟨665⟩ if:

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M11136_02_01
@2024 USPC

1. The tests specified for low risk components have been performed.
2. The test results have been reviewed in the context of the validity of the risk classification.

As an example of the second point, consider one of the required tests for a low-risk component, NVR. If the component assessor establishes that the potential process- or patient-impact of the measured NVR is likely to be low, then the risk classification is verified, and the component is qualified for use. On the other hand, if the component assessor establishes that the impact of the measured NVR could be significant, then the risk classification of "low" is refuted, and the component can only be qualified by performing the required moderate- or high-risk testing, as established by the assessor.

The concept of an NVR result being “high” is subjective and can only be established on a case by case basis by the assessor based on the exact manufacturing process being considered, the exact DS or DP being assessed, and the component’s conditions of use.

Considering a component that has been classified as either moderate or high risk, such a component is deemed to be qualified for use, consistent with ⟨665⟩, if:

1. The test(s) specified for moderate or high risk components have been performed.
2. The resulting extractables profiles have been assessed for possible process impact and to establish the suitability of the manufactured DS or DP for use.
3. The outcome of the assessment is that the impact of the extractables (as PERLs) is such that process efficiency and/or product suitability for use is not adversely affected by the PERLs.

The means by which a component assessor establishes that the extractables (as PERLs) would have no adverse impact on the efficiency or effectiveness of the manufacturing process must be established by the assessor. Similarly, the means by which the component assessor establishes that the extractables (as PERLs) would not adversely affect the output’s (DS or DP) suitability for use must be established by the assessor. Most typically, interpretation of the chemical data includes the toxicological assessment of extractables and/or PERL data, supported, as appropriate, by other relevant testing to establish the potential patient safety impact of PERLs in the DS or DP. In this circumstance, the toxicological assessment should be performed for each individual relevant extractable (or each relevant PERL as appropriate) to demonstrate that patient safety is not adversely affected by each individual PERL (or extractable as worst-case PERLs). The term “relevant extractable” or “relevant PERL” refers to those extractables that are present in a manufacturing system and those PERLs that are present in a DS or DP at levels sufficiently high that they could affect a key quality attribute of the drug product such as patient safety (e.g., extractables or PERLs whose levels are greater than the AET).

Considering the impact of PERLs on the suitability for use of a DP or DS, the previously mentioned approach of interpreting extractables data (as potential PERLS) is one means of establishing that a component is qualified. A second means would be the actual characterization of the manufactured DS and DP for PERLs. If it is established that the actual levels of PERLs in the DS and DP are acceptable (meaning that assessment of the PERLs has concluded that the PERLs do not compromise the DS’s or DP’s suitability for use), then the manufacturing system, and each of the individual manufacturing components, have been qualified.

### 6.3 Alternate Approaches for Qualification

Chapter ⟨665⟩ establishes qualification procedures and qualification acceptance criteria applicable to manufacturing components that are within its scope. Alternative chemical qualification procedures and acceptance criteria may be appropriate in justified circumstances, subject to agreement by an appropriate regulatory authority. When considering such alternate approaches, the sponsor is advised to consult with the regulatory authority during the development of such alternate procedures so that regulatory concurrence with the outcome of the alternate qualification is more likely.

Chapters ⟨1663⟩ and *Assessment of Drug Product Leachables Associated with Pharmaceutical Packaging/Delivery Systems* ⟨1664⟩, are applicable to pharmaceutical packaging/delivery systems but may be helpful resources for designing and justifying rigorous and appropriate studies by establishing general essential principles and demonstrated best-practice recommendations for extractables and leachable studies and assessments.

## GLOSSARY

Additional terms are defined in *Packaging and Storage Requirements* ⟨659⟩.

**Auxiliary stream:** A solution or semisolid that is used during manufacturing but is decoupled from the process stream and thus the manufactured DP. For example, filling lines may be rinsed with cleaning solutions in preparation for product manufacturing. Additionally, filters and chromatography columns may be rinsed and conditioned prior to use. As these rinsing and conditioning solutions are directed to waste, they do not become part of the process stream and they are designated as auxiliary streams. As substances extracted from components, or systems by auxiliary streams cannot be entrained into the manufactured DP as leachables, auxiliary streams are not tested for process equipment-related leachables and components or systems contacted solely by auxiliary streams do not require rigorous chemical assessment supported by testing.

**Characterization:** The process of establishing the characteristics or properties of a test article. In the context of this chapter, characterization is defined as the process of establishing physicochemical and chemical characteristics of components used in manufacturing operations. Characterization is accomplished by extraction testing of components as specified in ⟨665⟩.

**Comparator component:** A component that can be established as equivalent (or nearly equivalent) to another component in terms of its composition, design, processing, performance, and conditions of use in the manufacturing process. Generally, the comparator component is (or has been) used in a regulatory-approved manufacturing process or is used to produce a regulatory-approved and marketed biopharmaceutical DS, or pharmaceutical or biopharmaceutical DP. Linking a component under consideration to a comparator component is the sole necessary justification that is required to approve and qualify the component under consideration for use.

**Component:** An item consisting of one or more materials that performs a single function in a manufacturing system or process. Silicone tubing is an example of a component that consists of a single material. A filter is an example of a component

Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M11136_02_01
@2024 USPC

that likely consists of multiple materials such as its membrane (a single material), its housing (a single material), and its various gaskets (each of which may be a single material).

**Extractable:** An organic or inorganic chemical entity that is released from a manufacturing component or system into an extraction solution under laboratory conditions. Depending on the specific purpose of the extraction study, these laboratory conditions (e.g., solvent, temperature, stoichiometry, and others) may accelerate or exaggerate the normal conditions of use for a manufacturing component or system.

**Extractables profile:** A list of all substances that are extracted from a test article including the substance's identity and concentration (or amount) in the extract. The extractables profile typically includes only those substances whose level in the extract is above a chosen and justified reporting threshold.

**Extraction study:** A study, performed under laboratory conditions, whose purpose is to establish what substances are extracted from a test article and at what levels the substances are extracted under the conditions of the study. Extraction studies are also referred to as "controlled extraction studies".

**Isolated component or system:** A component or system that is chemically isolated, in terms of process equipment related leachables, from the manufactured DP due to the nature of its use in the manufacturing process. For example, while a drain or waste bag contacts an auxiliary solution, its purpose is to collect waste solutions after their use. The waste solutions collected in the drain bag are meant to be discarded and thus are not part of the process stream.

**Leachable:** A foreign organic or inorganic chemical entity that is present in a manufactured biopharmaceutical DS, or pharmaceutical or biopharmaceutical DP because it has leached from a component used in the manufacturing system and has persisted through the entire manufacturing process.

**Manufacturing system:** The sum total of all components that together are used to convert inputs (starting raw materials) into an output (manufactured DS or DP).

**Process:** A series of steps involving the use of systems or components that start with a DP's ingredients, converts those ingredients into a process stream, and then converts the process streams into the manufactured DP.

**Process equipment-related leachable (PERL):** A foreign organic or inorganic chemical entity that is present in a process stream because it has leached from a component used in the manufacturing system. A PERL may be present in a manufactured biopharmaceutical DS or pharmaceutical or biopharmaceutical DP as a leachable if it persists through the entire manufacturing process.

**Process stream:** Those solutions encountered in manufacturing that can be directly linked throughout the manufacturing process to the manufactured DP. Process streams either carry process intermediates through the manufacturing process or are process intermediates themselves. In essence, the manufacturing process converts the various process streams into the manufactured DP.

**Qualification:** The process of establishing that a test article is suited for its intended use in terms of a key performance attribute. This process typically includes obtaining and documenting evidence that addresses suitability for use.

**System:** An entity, consisting of multiple components, that accomplishes the intended purpose of a manufacturing process, producing either a DS or a DP.

Official

# APPENDIX

## An Example of a Risk Evaluation Matrix

As noted in *4.2 Risk Assessment of Components* and in ⟨665⟩, components are risk assessed with respect to their ability to contribute PERLs to DPs and the outcome of the risk assessment establishes the level of chemical characterization that must be performed. Although the DP sponsor is responsible for developing and justifying the risk evaluation matrix used to accomplish the risk assessment, ⟨665⟩ provides requirements for the risk dimensions that must be addressed in the matrix. This appendix provides one example of a risk evaluation matrix that meets these requirements.

The risk evaluation matrix evaluates those dimensions that address the risk that a plastic component will be leached by a process stream to such an extent that its extractables may be impactful. These dimensions include the:

1. Duration of contact
2. Temperature of contact
3. Chemical composition of the process stream
4. Nature of the component's materials of construction

The matrix then evaluates each dimension separately and assigns a level of risk based on certain measures relevant to each dimension (see *Table A-1*).

In most cases, the individual risk dimensions are considered to be equal in terms of their impact and in terms of their use in the risk evaluation matrix. However, in certain cases, especially those at the boundaries between the characterization levels, the logical application of the risk evaluation matrix is facilitated if a distinction is made between the dimensions in terms of their effect on the accumulation of PERLs. When it is necessary and appropriate to do so, the dimensions of temperature, solvent, and duration are weighted more heavily than the material dimension as it is logical that these dimensions could have a greater effect on leaching than does the material dimension.

**Table A-1. Dimensions Relevant to Risk Level**

| Risk Dimension | Duration of Contact | Temperature of Contact[a] | Chemical Composition of the Process Stream | Chemical Composition of the Component |
|---|---|---|---|---|
| Level 1 | <24 h | Refrigerated (2°–8°) | Aqueous (≤5% organic v/v; pH ≥3 and pH ≤9) | Low risk |

https://pharmacopeia.cn/v29240/

**Table A-1. Dimensions Relevant to Risk Level** *(continued)*

| Risk Dimension | Duration of Contact | Temperature of Contact[a] | Chemical Composition of the Process Stream | Chemical Composition of the Component |
|---|---|---|---|---|
| Level 2 | 1–7 days | Ambient (15°–25°) | Somewhat organic (>5% and ≤40% v/v) | Intermediate risk |
| Level 3 | >7 days | Elevated (>30°) | Highly organic (>40% v/v) or aqueous, extreme pH (pH <3 or pH >9) | High risk |

[a] The gaps in the temperature ranges reflect temperature ranges that are rarely experienced in manufacturing processes.

## DURATION OF CONTACT

It is observed that as the duration increases, the magnitude of leaching increases. Durations of contact between components or systems and manufacturing process streams were established and the duration of contact dimension was divided into three levels: short term (<24 h, Level 1), intermediate term (1–7 days, Level 2), and long term (>7 days, Level 3). When determining the duration of contact, any holding and pausing times should be included so that the worst-case scenario for the manufacturing process is represented.

## TEMPERATURE OF CONTACT

It is observed that as the temperature increases, the magnitude of leaching increases. Temperatures relevant to components or systems used in manufacturing systems were established and the temperature dimension was divided into three levels: low (refrigerated, Level 1), intermediate (ambient, Level 2), and high (elevated, Level 3).

## CHEMICAL COMPOSITION OF THE PROCESS STREAM

The terms “aqueous”, “somewhat organic”, and “highly organic” are defined as shown in *Table A-2*:

**Table A-2. Chemical Composition of the Process Stream**

| Process Streams Containing... | Definition of Process Stream | | |
|---|---|---|---|
| | Aqueous | Somewhat Organic | Highly Organic |
| Organic solvents | <5% by volume | >5% and ≤40% by volume | >40% by volume |
| Surfactants, (e.g., polysorbate 80) | ≤0.1% by weight | >0.1% and ≤0.5% by weight | >0.5% by weight |
| Blood or blood-derived substances, (e.g., albumin) | <1% by weight | ≥1% and <25% by weight | ≥25% by weight |
| Lipids and proteins | <1% by weight | ≥1% and <5% by weight | ≥5% by weight |

Some process streams could possess multiple solubilizers (e.g., protein solutions that also contain surfactants). In such circumstances, the process stream is risk assessed as the compounded risk associated with the individual agents. For example, a process stream containing 2% protein would be classified as “somewhat organic” and a process stream containing 0.2% surfactants would also be classified as “somewhat organic”. A process stream that contains both 2% protein and 0.2% surfactants would be classified as “highly organic”, reflecting the compounding of the classifications of the individual agents.

Solubilizers could also include agents such as cyclodextrins, chelators, and niacinamide. As the effect of such agents on leaching has not been extensively studied and quantified, distinctions such as those applied to surfactants cannot be proposed for these additional agents, and it is therefore the risk assessor’s responsibility to properly account for these agents in the risk assessment.

## CHEMICAL COMPOSITION OF THE COMPONENT

Certain materials are more likely to contribute extractables to solutions they contact, based on their composition and physical properties. For example, the greater the number and level of additives in a plastic material, the greater the total pool of potential extractables and the greater the risk that extractables will migrate into a contacting solution. Additionally, high energy processing of materials such as sterilization may cause degradation of the plastic and its plastic additives, further increasing the number and pool of potential extractables. Lastly, in-use processing of materials and components, such as rinsing, could reduce extractables levels.

The term “chemical composition of the component” is used to assess the component’s likely overall risk of extractables. It is based on the logic that the greater the number of additives (or the greater the level of the additives), the greater risk of extractables, as additives are logical sources of extractables. The terms “low risk”, “intermediate risk”, and “high risk” are applied to the material’s contribution and are defined as follows:

- If the total level of plastic additives in the component is ≤0.1% by weight, then the component is considered to be “low risk”
- If the total level of plastic additives in the component is > 0.1% and ≤ 1% by weight, then the component is considered to be “intermediate risk”
- If the total level of plastic additives in the component is >1% by weight, then the component is considered to be “high risk”.

Official

https://pharmacopeia.cn/

If the component is irradiated or heated at high temperature (e.g., autoclaved) prior to its use during manufacturing, then the component is considered to be "high risk".

If the assembly of the component requires the use of bonding solvents, adhesives, or other chemical means of connecting a component's materials or subassemblies, then the component must be considered either "intermediate risk" or "high risk", depending on the amount of bonding agents used and documented evidence of their loss from the component prior to its use.

If the component is flushed or rinsed during use and the flush/rinse solution is directed towards waste and thus is not part of the process stream, then the flushing and rinsing has the potential to reduce the number or amount of extractables. If the ability of flushing/rinsing to eliminate or reduce extractables has been established, then such flushing/rinsing can be used to reduce the material reactivity term's risk level by one level; for example, a rinsed "high risk" component becomes an "intermediate risk" component.

This assessment of component composition focuses on the concept that the greater the number and quantity of plastic additives, the greater the likelihood that the plastic additives and their related substances will become extractables. Furthermore, when components are stressed as part of their processing, plastic additives degrade, producing additional extractables that may be more soluble. The assessment notes that certain processes used to prepare a component for use can either reduce the levels of extractables available to the process stream (such as rinsing) or increase the number of potential extractables (such as solvent bonding).

Other factors, such as the diffusion of compounds through a component, may affect the compound's ability to be extracted from the component. As diffusivity through a component is impacted by the nature of the component, this is a reasonable factor to consider in assessing a component's propensity to be leached.

Additional factors may also be relevant. For example, the propensity of a component to be leached could be assessed by considering information other than merely the levels of additives and the component's treatment prior to use. The use of additives levels discussed previously is one approach to assess risk and its inclusion in this chapter is not meant to imply that all risk assessors be limited to using this approach.

Component evaluators should consider taking these additional factors and information into account in assessing the component's propensity to be leached. Such assessments must be science-based in that they are supported by information or data that justify the ranking of the component in terms of its propensity to be leached.

## USING THE RISK EVALUATION MATRIX

The risk evaluation matrix uses a 3-step process:

**Step 1—Establish values for each risk dimension:** A component being assessed for risk is "rated" with respect to these four dimensions shown in *Table A-1*, and the resulting rating results in a level assignment of 1, 2, or 3 in each of the four dimensions. A numerical risk sequence can be generated based on these assignments. For example, a component or system that is rated as highest risk in all four dimensions has a generated numerical risk sequence of 3333. The numerical order of the risk sequence values is largely inconsequential, and the proper use of the numerical risk sequence requires that the sequence be given in order of decreasing digit values. Although the numerical risk sequences 3212 and 3221 reflect different risk profiles, both sequences are linked to the same level of characterization. Both risk sequences can be expressed as 3221 for ease of use in establishing the proper level of characterization.

**Step 2—Link the numerical risk sequence with a level of characterization:** On the basis of a consideration of all possible outcomes of the application of the risk evaluation matrix, links between the numerical risk sequence and the characterization level have been established (see *Table A-3*).

**Step 3—Use mitigating factors to adjust the characterization level:** Mitigating factors take into account the fact that the leaching of a component alone does not necessarily mean that the leached substance will have an adverse effect on the production process output. For example, extractables from a component that are removed (or cleared) from a process stream by a process step that comes after the leaching cannot affect the safety of a manufactured DP because the extractables will not be present in the DP as leachables. Furthermore, the clinical use of the manufactured DS or DP may be such that any adverse effect of the PERL would be moderate. The potential adverse patient safety impact of a leachable in a low-risk dosage form (e.g., liquid oral or topical) used in acute therapy is much less than the potential adverse patient safety impact of the same leachable in a high-risk dosage form (liquid injectable) used in a chronic therapy. Therefore, both clearance and clinical mitigating factors must be taken into account when establishing the component's risk and characterization level.

**Clearance:** Is there a post-contact (downstream) processing step that clears extracted substances?

- If yes, then use the factor (mitigating factor = 1)
- If no, then do not use the factor

To a certain extent, dilution can be considered similar to clearance in terms of its ability to mitigate the effect of extractables. While some process steps may not eliminate extractables from the process stream, they can reduce the concentration of extractables by diluting them via the process stream, for example, the addition of a concentrated acid or base used for pH adjustment. In such circumstances, extractables associated with the small volume reagent are diluted by the process stream, mitigating their potential hazard. In such cases, dilution can be the basis of assigning a value of 1 to the clearance mitigating factor if the effect of dilution can be quantified and the use of the factor can be justified.

**Clinical use:** What is the risk of leachables given the clinical use of the process output (DS or DP)? Factors to consider include dosage form, duration of clinical use, and daily dose volume (if applicable).

- **a.** If the dosage form is a solid oral, liquid oral (not containing surfactants, co-solvents [such as alcohols] or other solubilizing agents) or topical (semisolid or solid), then use the factor (mitigating factor = 1)
- **b.** If the duration of clinical use is <7 days, then use the factor (mitigating factor = 1)
- **c.** If the daily dose volume is <10 mL, then use the factor (mitigating factor = 1)
- **d.** Otherwise, do not use the factor

[NOTE—A mitigating factor is used only in the first instance that requirements *a–c* are met. Mitigating factors obtained by considering requirements *a–c* are not additive; so the highest value that the mitigating factor can have due to clinical use is 1.]

The mitigating factors are used as follows. Add the clearance mitigating factor and the mitigating factor due to clinical use. Possible values of this sum are 0, 1, and 2.

- If the sum = 0, then there is no adjustment of the characterization level
- If the sum = 1, then the characterization level established by the other dimensions is reduced by one level of testing (e.g., Level B testing is reduced to Level A testing or Level C testing is reduced to Level B testing)
- If the sum = 2, then characterization Level A is applicable in all circumstances.

**Table A-3. Linking the Numerical Risk Sequence with a Level of Characterization**

| If... | And... | Then the Characterization Level is... |
|---|---|---|
| Four of the dimension scores are Level 3 | There is no additional qualifier (3333) | Level C (High Risk) |
| Three of the dimension scores are Level 3 | The other dimension score is Level 2 (3332) | Level C |
| | The other dimension score is Level 1 (3331) | Level C |
| Two of the dimension scores are Level 3 | The other two dimension scores are both Level 2 (3322) | Level C |
| | One dimension score is Level 2 (3321) | Level B (Moderate Risk) or C[a, b] |
| | The other two dimension scores are Level 1 (3311) | Level A (Low Risk) or B[b, c] |
| One of the dimension scores is Level 3 | All of the other dimension scores are Level 2 (3222) | Level B |
| | One of the other dimension scores is Level 1 (3221) | Level B |
| | Two of the other dimension scores are Level 1 (3211) | Level A or B[b, c] |
| | All of the other dimension scores are Level 1 (3111) | Level A |
| None of the dimension scores is Level 3 | All of the dimension scores are Level 2 (2222) | Level B |
| | Not all of the dimension scores are Level 2 | Level A |

[a] If the Level 2 score is in temperature, solvent, or duration dimensions, then Level C; otherwise, Level B.
[b] In these cases the temperature, solvent, or duration dimensions have a greater influence on risk than do component composition.
[c] If one of the Level 1 scores is in the component composition dimension, then Level A; otherwise, Level B.

GLOSSARY
REFERENCES

## INTRODUCTION

A common cause for failure to meet specifications of packaged solid oral dosage forms (SODFs) is their instability as a result of moisture uptake during storage. Failures are usually related to out-of-specification or out-of-range values in any of the following quality attributes (alone or in combination with other physical properties): assay, related substances, degradation by-products, and dissolution rate. Therefore, the moisture barrier properties of the packaging system must be characterized properly to demonstrate the relative moisture vapor transmission rate (MVTR) performance required to protect SODFs from moisture uptake.

Common packaging systems used for SODFs are plastic bottles that include a plastic closure with a foil seal over the bottle opening, or formed plastic and aluminum blisters, with a foil seal over the blister cavity. Plastic packaging systems are considered to be permeable, and therefore the moisture barrier properties must be characterized.

*Containers—Performance Testing* ⟨671⟩ includes desiccant-based MVTR methods for SODF packaging systems that align with the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) accelerated storage conditions for stability testing [40°/75% relative humidity (RH)] and a water-based method that aligns with the ICH storage condition of 40°/25% RH. These methods have the accuracy to measure the performance of high-barrier packaging systems, which has been traditionally difficult to measure. They provide specific MVTR values for packaging systems with sufficient sensitivity and precision to allow clear differentiation across packaging systems. This chapter provides guidance on the application of these methods to determine MVTR and the use of MVTR data to support demonstrating the equivalence of packaging systems when packaging SODFs.

### Scope

For packaging systems containing more than one unit of product, the concept of normalizing the MVTR of the packaging system to the number of units contained in the system (MVTR/unit) allows for a relative comparison of barrier performance. This ratio can be used to demonstrate equivalent moisture protection, when comparing a variety of packaging systems that contain different numbers of units. Thus, to complement—and in some cases, reduce—product stability testing for SODFs, the use of MVTR/unit can provide evidence that a proposed packaging system may provide adequate moisture protection to maintain product stability. However, annual stability may never be replaced by MVTR studies and changes based upon MVTR studies are made with some risk that stability failures may occur.

This chapter is intended to:

- Describe the methodology of providing evidence for the moisture barrier equivalency of two similar packaging systems (e.g., bottle A to bottle B, blister 1 to blister 2), based on the MVTR measurements described in *Containers—Performance Testing* ⟨671⟩*, Moisture Vapor Transmission for Plastic Packaging Systems*
- Define the upper limit of the MVTR for an SODF
- Compare the desiccant-based and water-based MVTR methods
- Explain how to leverage MVTR data to complement and, possibly, reduce stability studies when a new packaging system, a new packaging configuration for a marketed drug product, or a change to an existing packaging system is introduced

The scope of this chapter is restricted to:

- SODFs

Official

https://mhathaway.com/

- MVTR based on *Method 1*, *Method 2*, and *Method 3* (desiccant-based) described in *Containers—Performance Testing* ⟨671⟩*, Moisture Vapor Transmission for Plastic Packaging Systems*
- MVTR based on *Method 4* (water-based) described in *Containers—Performance Testing* ⟨671⟩*, Moisture Vapor Transmission for Plastic Packaging Systems*
- Repackaging of SODFs

This chapter is applicable to:

- Pharmaceutical manufacturers
- Packagers
- Repackagers

## PACKAGING SYSTEMS

Pharmaceutical products are manufactured in different dosage forms and are packaged in a packaging system for storage and distribution. A packaging system performs multiple functions, among which protection is the most fundamental. Such protection ensures that the quality of the packaged drug product is maintained and not affected by physical hazards during the shipping and distribution process or by environmental hazards such as moisture, light, and oxygen throughout the shelf life of the drug product.

For SODFs, the most commonly used packaging systems are plastic bottles and blisters. A number of different plastic materials are used to manufacture SODF packaging, including cyclic olefins, polyethylene (PE), polyethylene terephthalate (PET), polyethylene terephthalate G (PETG), polypropylene (PP), and polyvinyl chloride (PVC). A general chemical description of these plastics is contained in *Evaluation of Plastic Packaging Systems and Their Materials of Construction with Respect to Their User Safety Impact* ⟨1661⟩, and the specifications for use in oral dosage packaging systems are defined in *Plastic Materials of Construction* ⟨661.1⟩. Two other plastic materials used to form blisters are polyvinylidene chloride (PVDC) and polychlorotrifluoroethylene (PCTFE).

Chapter ⟨671⟩ classifies these packaging systems into three main categories: multiple-unit containers, single-unit containers, and unit-dose containers as defined in *Packaging and Storage Requirements* ⟨659⟩. In the context of this chapter, packaging systems for SODFs are categorized as:

1. Multiple-unit container: a sealed plastic bottle that contains more than one unit of drug product. An example of a multiple-unit container is a high-density polyethylene (HDPE) bottle containing 30 tablets. *Method 1* or *Method 4* in *Containers—Performance Testing* ⟨671⟩*, Moisture Vapor Transmission for Plastic Packaging Systems* should be used to determine the MVTR of the multiple-unit container.
2. Single-unit or unit-dose container: A sealed blister card that contains 1 or more blister cavities and 1 unit of drug product per blister cavity. An example of such a container is a sealed PVDC blister card containing 7 cavities. *Method 2* or *Method 4* in *Containers—Performance Testing* ⟨671⟩*, Moisture Vapor Transmission for Plastic Packaging Systems* should be used to determine the MVTR of the container unless the container is a low-barrier blister (see *Glossary*), in which case *Method 3* or *Method 4* in *Containers—Performance Testing* ⟨671⟩*, Moisture Vapor Transmission for Plastic Packaging Systems* should be followed.

## DESICCANT VERSUS WATER MVTR METHOD

Traditionally, the MVTR of container–closure systems for solid oral drug products has been determined by using desiccant-filled test containers stored in an environmental chamber to create a difference in RH or vapor pressure between the inside and outside of the test containers. The use of desiccants can be problematic because an inadequate amount of desiccant or incompletely dried desiccant may result in variability in the vapor-pressure differences between the inside and outside of the container during the study. This potential variability in the vapor-pressure difference can increase variability in MVTR determinations.

### Use of Desiccants for MVTR Determination

According to MVTR *Method 1*, *Method 2*, and *Method 3* described in ⟨671⟩, test containers are filled with sufficient anhydrous desiccant to maintain an inside RH close to 0%. This RH is maintained if the prescribed desiccant preparations are handled properly. However, mishandling of the desiccant during shipping to the filling site or during filling of the blisters will compromise the dryness of the desiccant. Desiccant-filled test containers are held in an environmental chamber under controlled environmental conditions, and weight determinations are made over time. The inside RH remains constant during testing if adequate anhydrous desiccant is present, which becomes more challenging to achieve with a low-barrier blister (*Method 3*) because the desiccant can become saturated before the completion of testing. The weight gain of the desiccant is determined during this steady-state condition and is translated into a permeation rate MVTR (i.e., water vapor) for the test packaging system.

Percent relative humidity (%RH) is used to express the environmental chamber conditions and the headspace inside the test containers. To obtain reliable MVTR determinations, humidity must remain constant inside and outside the test container throughout the study. Results from desiccant-filled test containers do not account for potential variability introduced if the internal RH of the test containers neither starts at 0% nor remains at 0% during the study. The desiccant methods are designed to maintain the internal RH below 10% throughout the study. However, this internal RH can range between 0% and 10%, which can translate to the variability of the internal RH. In test containers filled with water, the RH is maintained at a constant (100%) from the beginning to the end of the MVTR study, thereby reducing potential variability.

## Use of Water as an Alternative Fill Medium

*Method 4*, as described in ⟨671⟩, is an alternative approach for the determination of MVTR for packaging systems for SODFs. While desiccant-filled test containers stored in a 40°/75% RH chamber achieve a vapor-pressure difference of 65%–75% if the internal RH created by the desiccant is between 0% and 10%, water-filled test containers stored in an environmental chamber at 40°/25% RH achieve and maintain a constant vapor-pressure difference of 75%.

There are potentially multiple benefits of the MVTR method using water as the test medium. With water, the variability of the fill amount does not result in variability of internal RH, and no interaction with container walls is known to exist for the common blister plastic and lidding materials. The stability of the internal RH afforded by water facilitates holding the samples or reusing them at a later time, or in multiple studies (e.g., different storage conditions using the same samples). The concerns about shipping desiccant-filled samples and delays in testing are mitigated by the use of water. Additional measurements or extensions of studies are possible without concern about depleting the water.

The use of water eliminates special handling requirements to protect desiccant-filled blister samples from excessive exposure to moisture before testing. Also, samples filled with aqueous dye can be used for leak testing before or after MVTR testing, which can enhance visual detection of gross leaks during the study.

Sample preparation techniques are important for filling blisters with water. The best practice for delivering water into the cavities on the packaging line is to use a manual syringe filled with water; this method allows the delivery of a few drops of water to each cavity without causing sealing problems. However, there are concerns about introducing an inadequate amount of water. Chapter ⟨671⟩ describes how to estimate the amount of water to avoid the total loss of water before the completion of the test. In contrast to the desiccant method in which the saturation of desiccant is a concern, the water-filled method allows low-barrier blisters to be tested over an extended period in the same manner as high-barrier blisters.

*Table 1* summarizes recommended test methods to measure the MVTR of different packaging systems. *Method 3* in ⟨671⟩ is not recommended for measuring the MVTR of low-barrier blisters due to the rationales discussed earlier in this chapter.

**Table 1. Recommended MVTR Test Methods for Different Packaging Systems**

| Packaging System | Test Method (recommended) |
|---|---|
| Low-barrier blister | ⟨671⟩, *Method 4* |
| High-barrier blister | ⟨671⟩, *Method 2* or *Method 4* |
| Ultra-high barrier blister | ⟨671⟩, *Method 2* or *Method 4* |
| Bottle containers (e.g., multiple-unit containers) | ⟨671⟩, *Method 1* or *Method 4* |

## COMPARISON OF MVTR RESULTS FOR WATER AND DESICCANT METHOD

Several sets of data are provided in *Table 2* (*1*). The user should use an appropriate statistical tool to analyze the data and prove the equivalency from the statistical perspective. The raw data for each set are shown graphically in *Figure 1*.

**Table 2. Summary of MVTR Studies Comparing Desiccant-Filled and Water-Filled Samples**

| Sample Description | Fill Medium | Chamber Conditions | Number of Test Containers | Average MVTR |
|---|---|---|---|---|
| 7.5 mil PVC | Molecular sieves | 40°/75% RH | 10 | 1.46 mg/(day × cavity) |
| 7.5 mil PVC | Water | 40°/25% RH | 5 | 1.39 mg/(day × cavity) |
| 0.6 mil PCTFE | Calcium chloride | 40°/75% RH | 10 | 0.161 mg/(day × cavity) |
| 0.6 mil PCTFE | Water | 40°/25% RH | 6 | 0.162 mg/(day × cavity) |
| 2 mil PCTFE | Molecular sieves | 40°/75% RH | 10 | 0.104 mg/(day × cavity) |
| 2 mil PCTFE | Water | 40°/25% RH | 10 | 0.105 mg/(day × cavity) |
| 325-mL HIS[a] HDPE bottle | Calcium chloride | 40°/75% RH | 10 | 2.97 mg/(day × package) |
| 325-mL HIS[a] HDPE bottle | Water | 40°/25% RH | 5 | 3.20 mg/(day × package) |

[a] Heat induction sealed.

## EQUIVALENCY AND APPLICATION OF MVTR DETERMINATION METHOD

### Description

For SODF packaging systems containing more than one unit of product, the concept of normalizing the MVTR of the packaging system to the number of SODF units contained in the system allows for the comparison of the barrier performance and the demonstration of equivalent moisture protection for each SODF unit when comparing various packaging systems containing varying numbers of SODF units.

### Rationale

The moisture permeability of a packaging system can be a product Critical Quality Attribute (CQA) for SODFs. Once the stability performance has been assessed and suitability demonstrated in one or more packaging systems, a maximum demonstrated level of moisture permeability of the packaging systems, defined by MVTR normalized to the number of dosage units in the container (MVTR/unit), can be established. The MVTR/unit links the performance of the packaging system to the quality of the product in the container. Having established the maximum demonstrated level of MVTR/unit for a given SODF, and having demonstrated the suitability of one or more packaging systems through stability testing and/or other means, the MVTR/unit may be used as a measure of moisture protection to support changes to the packaging systems.

Use of a proper moisture permeation test method and a product-centric measurement of MVTR/unit for blisters and bottles permits the pooling of performance data from both packaging systems to establish a maximum demonstrated level for moisture permeability as a product CQA and accompanies stability study data to establish drug product quality attributes. For the pharmaceutical manufacturer, the product-centric model enables and facilitates a scientifically justified determination of the maximum demonstrated level of MVTR/unit unique to the product. This presents the ability to demonstrate that the new packaging system provides the equivalent or better MVTR/unit for a specific product, with the potential of not having to wait for the results of stability testing, providing that suitability of the bottle or blister packaging system is demonstrated through other means [such as compliance with the appropriate Code of Federal Regulations (CFR) and *USP* tests] and the packaging systems have previously been used in a regulatory-approved SODF.

### Application

By utilizing MVTR/unit and product-specific stability studies, scientifically justified limits for packaging moisture permeability can be defined. The moisture permeation test results and the maximum demonstrated level derived from those tests should be

@2024 USPC

discussed in the Pharmaceutical Development section of the regulatory submission to support the selection of the packaging systems and materials of construction. It is also important to indicate the control strategy and the steps that will be taken to ensure that the packaging system attributes, and specifically the MVTR, will be met in day-to-day production. Moisture permeation through a material is affected by the properties of the material and its thickness. The MVTR can be controlled through acceptance specifications to confirm material identity and the weight or thickness of the material, and in-process control checks to confirm seal quality.

A maximum demonstrated level for moisture permeability of packaging systems can be ascertained based on the MVTR/unit for each package configuration and the acceptable product stability performance. Consider the following hypothetical example for SODF product X, in which MVTR and stability testing were performed on unit-dose blisters, using two different blister films, and an HDPE packaging system with a fill count of 30 tablets. In this example, the dissolution rate is a drug product CQA, and a decrease in the dissolution rate caused by moisture ingress was observed on stability.

**Table 3. MVTR for Different Packaging Systems (tested according to ⟨671⟩)**

| Packaging System | MVTR/Container (mg/day) | MVTR/Unit (mg/day) | Drug Product Dissolution |
|---|---|---|---|
| 250-µm PVC unit-dose blister | 3.1 | 3.1 | Fail |
| 250-µm PVC/60-gm² PVDC unit-dose blister | 0.8 | 0.8 | Pass |
| 60-cc HDPE bottle, 30-count | 1.2 | 0.04 | Pass |

In *Table 3* (*2*), PVC blisters with an MVTR of 3.1 mg/day/tablet were unable to provide adequate protection against moisture ingress, and the product failed to meet the specification for dissolution rate. However, the use of a higher-barrier PVDC-coated PVC blister packaging or a 30-count 60-cc HDPE bottle, with MVTR values of 0.8 mg/day/tablet and 0.04 mg/day/tablet, respectively (*Table 3*) (*2*), did provide adequate protection. A maximum demonstrated moisture permeability of ≤0.8 ▲mg▲ (ERR 1-Dec-2020)/day/tablet was established.

The maximum demonstrated level of MVTR may be leveraged in order to introduce new packaging presentations without the need of specific drug product stability testing prior to implementation. MVTR is one of many factors in assessing packaging system change including introducing new packaging configuration (e.g., HDPE bottle with a new count), the composition of the container–closure system, product requirements, and stability. However, MVTR may be useful in a product development setting, to decide on the packaging components before packaging exhibit batches, or in a pharmacy setting where the product is being repackaged.

For example, after launch, a commercial need may arise for a bottle containing a weekly dose of 7 tablets or a bottle containing 90 tablets. These two presentations may be considered based on the data shown in *Table 3* (*2*) and *Table 4* (*2*).

**Table 4. MVTR for Different Bottle Sizes and Counts (Tested According to ⟨671⟩)**

| Packaging System | MVTR/Container (mg/day) | MVTR/Unit (mg/day) | Maximum Demonstrated MVTR/Unit (mg/day) |
|---|---|---|---|
| 40-cc HDPE bottle, 7-count | 0.95 | 0.14 | 0.8 |
| 100-cc HDPE bottle, 90-count | 1.7 | 0.019 | 0.8 |

# REPACKAGING OF SODFs

## Repackaging an SODF into a Unit-Dose Container

Multiple-unit packages of SODFs (e.g., unit-of-use or bulk packaging systems) may be reprocessed or repackaged as instructed by the manufacturer. A blister package may not be reprocessed or repackaged after it has been deblistered from a unit-dose container. If the manufacturer's labeling includes "Protect from Moisture", the repackager must use a high-barrier or an ultra-high barrier film. If light protection is required for the SODF, the repackager should follow the requirements for spectral transmission established in ⟨671⟩. This testing should be conducted on the formed blister because the light-protective properties of the film are compromised once the film is thinned during the forming process. It is recommended that these tests, in conjunction with any guidance provided by the manufacturer, be considered for any packaging system used to repackage an SODF. The packaging system used to repackage an SODF must be at least as protective or provide better protection than the packaging system used by the original manufacturer of SODFs, taking into consideration the planned shelf life of the repackaged drug.

In the event that a product should not be repackaged, the manufacturer may state this in the labeling.

## Determination of Equivalence for Packaging Systems for SODFs

The suitability of a repackaging system for an SODF may be characterized by establishing equivalency compared to the original packaging system. Equivalence is established when the repackaging system is at least as protective as the original packaging system in terms of MVTR, oxygen transmission, light transmission, and compatibility of the materials of construction. Packaging system equivalency extends to any special protective materials, such as those used for light protection; seals; auxiliary packaging components, such as fillers (see *Auxiliary Packaging Components* ⟨670⟩); and desiccants and their canister or sachet,

Official

https://nhathuoc.org.vn/

which are associated with the original packaging system (see *Packaging and Storage Requirements* ⟨659⟩*, General Definitions, Packaging Definitions, Equivalent container–closure system*).

For moisture, the determination of MVTR should be made using a method provided in ⟨671⟩ (*Method 1*, *Method 2*, or *Method 4*) for both the original packaging system and the packaging system used to repackage the SODF to provide evidence of equivalence.

## GLOSSARY

**Blister:** Formed, lidded, and sealed plastic or foil dome that contains the capsule or tablet (usually a single-unit or unit-dose).

**Blister card:** A contiguous group of blisters formed and sealed with lid in place. The number of blisters per card commonly ranges from 1 to 10 but may be more. The blister card may sometimes be referred to as a packaging system.

**High-barrier blister:** A blister whose moisture vapor transmission rate, when tested at 40° and an RH difference of 75% between inside and outside the sealed blister, is less than 1.0 mg/cavity-day, but greater than 0.01 mg/cavity-day. An example of a high-barrier blister is a thermoformed PCTFE blister sealed with foil.

**Low-barrier blister:** A blister whose moisture vapor transmission rate, when tested at 40° and an RH difference of 75% between inside and outside the sealed blister, is greater than 1.0 mg/cavity-day. An example of a low barrier blister is a thermoformed PVC blister sealed with foil.

**Ultra-high barrier blister:** A blister whose moisture vapor transmission rate, when tested at 40° and an RH difference of 75% between inside and outside the sealed blister, is less than 0.01 mg/cavity-day. An example of an ultra-high barrier blister is a cold-formed foil blister sealed with foil.

**Cavity:** Formed, lidded, and sealed plastic or foil dome (see *Blister*).

**Equivalency:** A claim that two container–closure packaging systems for a particular dose of an SODF are suitable for maintaining the stability of the drug in accordance with its specifications. In this chapter, equivalency refers to equivalent packaging systems from a moisture barrier perspective.

**Equivalent container–closure system:** See *Packaging and Storage Requirements* ⟨659⟩*, General Definitions, Packaging Definitions, Equivalent container–closure system*.

**Moisture vapor transmission rate:** The steady-state moisture vapor transmission (in unit time) through a packaging system, under specific conditions of temperature and humidity. These test methods use gravimetric measurement to determine the rate of weight gain as a result of moisture vapor transmission into the packaging system and subsequent uptake by a desiccant enclosed within the packaging system or the rate of weight loss as a result of moisture vapor transmission out of the packaging system and subsequent loss of water enclosed within the packaging system.

**Test specimen (or specimen):** For multiple-unit containers, the bottle is the test specimen; and for single-unit or unit-dose containers, the blister card containing multiple blister cavities is the test specimen. For blisters, more than one card may be bundled to form a test specimen.

**Test unit:** For multiple-unit containers, the bottle is the test unit as well as being the test specimen; and for single-unit or unit-dose containers, the test unit is a group of test specimens (blister cards) processed together for temperature and humidity exposure and for weighing at each time point. The purpose of the test unit for single-unit or unit-dose containers is to gain the advantage of additive weight gain resulting from more blister cavities than are present on a single card. The test unit, when applied to bottles, is used to maintain congruence of naming among the three test methods.

# ▲⟨1711⟩ ORAL DOSAGE FORMS—PERFORMANCE TESTS

## INTRODUCTION

This general information chapter provides approaches for the development of performance tests, mainly dissolution and disintegration procedures for oral dosage forms intended for human and animal applications, which are not covered by *Disintegration* ⟨701⟩, *Dissolution* ⟨711⟩, *Drug Release* ⟨724⟩, *The Dissolution Procedure: Development and Validation* ⟨1092⟩, *Capsules—Dissolution Testing and Related Quality Attributes* ⟨1094⟩, and *Disintegration and Dissolution of Dietary Supplements* ⟨2040⟩.

The oral dosage forms referred to, but not restricted to, in this chapter are: effervescent tablets, chewable tablets, sublingual tablets, orally disintegrating tablets, gastroretentive tablets, delayed-release dosage forms, granules or pellets that are administered with food or beverages, suspensions, powder for suspension, granules for suspensions, tablets for suspension, lozenges, oral pastes, oral gels, chewable gels, Type A medicated articles, and Type B and Type C medicated feeds that deliver animal drugs and drug products in animal feeds.

## PRODUCT PERFORMANCE PROCEDURE DEVELOPMENT

The dissolution test should be, in most cases, discriminative for the critical quality attributes of the product. The FDA Guidance for Industry *Dissolution Testing and Acceptance Criteria for Immediate-Release Solid Oral Dosage Form Drug Products Containing High Solubility Drug Substances* (*1*) discusses the cases in which the dissolution test does not need to be discriminative. The test conditions (media, apparatus, tolerances/acceptance criteria) are typically defined in a case-by-case approach, supported and justified by data obtained with samples from the formulation(s) under evaluation. Generally, the compendial apparatus and procedures that can be used are described in ⟨711⟩, ⟨724⟩, and ⟨2040⟩. Any deviations from or modifications to the conditions stated in these chapters are acceptable with appropriate justification. For additional information see also ⟨1092⟩ and *In Vitro and In Vivo Evaluation of Dosage Forms* ⟨1088⟩. Other useful documents are FDA Guidance for Industry *Dissolution Testing of Immediate-Release Solid Oral Dosage Forms* (*2*) and FDA Guidance for Industry *Extended Release Oral Dosage Forms: Development, Evaluation, and Application of In Vitro/In Vivo Correlations* (*3*).

The dissolution media to be evaluated should have pH values within the physiological range, e.g. from 1.2–6.8. Dissolution media with pH values outside this range can be used with appropriate justification. The dissolution media for animal applications may be animal species specific.

Examples of dissolution tests can be found at the FDA Dissolution Methods database (*4*) and at the USP Dissolution Methods database (*5*).

### Solid Oral Dosage Forms

The general descriptions of and definitions for solid oral dosage forms can be found in *Pharmaceutical Dosage Forms* ⟨1151⟩.

#### TABLETS

**Effervescent tablets:** Effervescent tablets that result in a solution when handled according to the instructions to the patient do not require a dissolution test. In this case, a disintegration test is to be conducted.

For effervescent tablets that result in a suspension after being handled according to the instructions to the patient, a dissolution test should be developed. Depending on the size of the tablet, it may be necessary to position the paddles of USP *Apparatus 2* described in ⟨711⟩ at a distance higher than 2.5 cm, to avoid having the dosage form being hit by the paddle.

**Chewable tablets:** The dissolution test should be conducted using intact tablets. Since these types of tablets may be harder or more elastic than the regular immediate-release tablets, the dissolution procedure may require more aggressive conditions such as higher agitation speed and longer test time.

In the case of chewable tablets for use in animals, when developing a disintegration test, it is important to consider their size as they may be too big to fit in the equipment described in ⟨701⟩. An alternative is *Apparatus B* described in ⟨2040⟩. When developing a dissolution test, depending on the size of the tablet, it may be necessary to position the paddles of USP *Apparatus 2* described in ⟨711⟩ at a distance higher than 2.5 cm, to avoid having the dosage form being hit by the paddle.

In addition to dissolution testing, a disintegration test should be conducted using intact tablets in an appropriate medium using the appropriate equipment described in ⟨701⟩ or ⟨2040⟩ [see FDA Guidance for Industry *Quality Attribute Considerations for Chewable Tablets* (*6*)].

**Sublingual tablets:** Typically, sublingual tablets are immediate-release formulations which disintegrate very rapidly and contain a drug substance that has a good solubility at the pH value representing the pH of the buccal cavity. A dissolution test should be developed for this type of dosage form. However, the dissolution test may be replaced by a disintegration test, when justified. It may be advantageous to use a dissolution medium with a pH close to the saliva pH. Normal, healthy, human saliva in the oral cavity has, typically, a pH between 6.7 and 7.4. Other media may be used with appropriate justification.

**Orally disintegrating tablets:** The technological concept and manufacturing process have a great influence on the disintegration behavior of orally disintegrating tablets. The tablets manufactured by lyophilization will have a very short disintegration time, typically 1–3 s, when compared to orally disintegrating tablets manufactured by conventional means that have a disintegration time of around, or more than, 30 s.

Products labeled as orally disintegrating tablets require disintegration and dissolution tests [see FDA Guidance for Industry *Orally Disintegrating Tablets* (*7*)].

Official

https://pharmacopeia.com/

The evaluation of the amount of drug dissolved at early time points (less than 5 min) may be useful.

**Gastroretentive tablets:** Gastroretentive tablets are tablets intended to be retained in the stomach for a sufficient time while withstanding gastric mobility, and releasing the drug substance in a controlled manner. The advantages of this type of dosage form are the enhanced bioavailability of drugs having a narrow absorption window at the upper part of the gastrointestinal tract or drugs showing a higher solubility, stability, or absorption at an acidic pH. They can also be advantageous for drugs which are locally active in the gastric mucosa.

Different strategies have been proposed to prolong the gastric residence time, including floating, expanding, high density and bioadhesive systems. Floating formulations should float on the gastric contents preventing its passage through the pylorus. Floating hydrodynamically balanced systems or effervescent matrix systems are the most common approaches for floating dosage forms. Depending on the formulation, a lag time may precede the dosage form floating. Gas-generating coated floating tablets, which form balloon-like floating devices upon hydration, can have a shorter floating lag time independent from surrounding pH (*8*).

The dissolution medium should be hydrochloric acid in the concentration of 0.1 N or 0.01 N. Other dissolution media can be used with appropriate justification.

Besides the dissolution test, floating tablets may also require a buoyancy or a floating strength test.

## Delayed-Release Dosage Forms

Delayed-release dosage forms are, typically, formulated with acid-resistant, or enteric or gastro-resistant coatings or matrices to protect acid-labile drug substances from the gastric environment, to avoid absorption in the proximal segment of the gastrointestinal tract, to prevent local adverse effects such as irritation, or to target drug release at the site of action or where the absorption is desired (i.e., in the colon region).

If the release of the drug substance is intended to occur in the proximal portion of the intestine, the procedures described in ⟨711⟩, with one acid stage and one buffer stage, should be followed. If the release of the drug substance is intended for the distal portion of the intestine (colon), the dissolution test consists of up to three stages—one acid stage and one or two buffer stages.

For non-pH-dependent delayed-release dosage forms the onset of dissolution is not intended to occur in a specific segment of the gastrointestinal tract but at a defined time point. The release mechanism is usually not pH dependent but driven by the propagation rate of a moisture front within the dosage form. The medium pH switch from acid to base may not be applicable. Instead, the dissolution procedure is similar to that used for immediate-release dosage forms, with the use of only one dissolution medium. It may require multivariate specifications for the time of the onset of the dissolution and the amount dissolved. The sampling time points have to be defined to include the pivotal time point of the onset of drug release.

## Granules, Powders, or Pellets That Are Administered with Food or Beverages

These granules, powders, or pellets are sprinkled, according to the instructions to the patient, into a small amount of soft food (e.g., applesauce, fruit- or vegetable-based baby food, or yogurt) or into a small amount of liquid (e.g., infant formula, apple juice, or pediatric electrolyte solution).

Granules or pellets that result in a solution when used according to the instructions to patients do not require a dissolution test. In this case, a disintegration test is to be conducted.

For granules or pellets that result in a suspension when used according to the instructions to the patient, a dissolution test should be developed. In this case, the amount of sample to be transferred to the dissolution equipment should be equivalent to 1-unit dose. If the product has different doses according to body weight or age, the amount of sample to be transferred to the dissolution equipment should correspond to the highest unit dose that can be administered. If labeled for single use, each sample should come from a different container/packet.

Sometimes, such granules or pellets are filled in capsules, which are then opened prior to being administered by the patient. In this case, the dissolution test needs to be conducted only with the capsule contents.

Food and beverages may influence the bioavailability of the drug substance(s) incorporated into the granules or pellets. However, adding food or beverage to the dissolution media is typically not required. See FDA Draft Guidance for Industry *Use of Liquids and/or Soft Foods as Vehicles for Drug Administration: General Considerations for Selection and In Vitro Methods for Product Quality Assessments* (*9*).

## Suspensions

The product needs to be re-suspended according to the instructions to the patient before the test. The sample agitation procedure should be defined in order to ascertain a homogeneous and representative sample and to avoid introducing too many bubbles into the sample to ensure the precision of dosing. The sample preparation procedure should be well described and standardized in the final version of the method.

The amount of sample to be transferred to the dissolution equipment should be equivalent to 1-unit dose. If the product has different doses according to body weight or age, the amount of sample to be transferred to the dissolution equipment should correspond to the highest unit dose that can be administered at one time. If labeled for single use, each sample should come from a different container/packet.

The sample can be transferred to the dissolution apparatus by volume or by weight. Other alternative transferring procedures can be used.

The sample should be introduced into the dissolution medium in a way to be rapidly dispersed. The dispensing point/place and the dispensing time should be evaluated and defined in a case-by-case approach during method development. The evaluation of the amount of drug dissolved at early time points (5–10 min) may be useful. Lower paddle speeds may be appropriate for this type of dosage form.

## Powders for Oral Suspension, Granules for Oral Suspension, or Tablets for Oral Suspension

Powders, granules, or tablets for oral suspension are prepared according to the instructions to the patient to constitute a suspension, and the resulting suspension is placed into the dissolution equipment.

For additional information regarding dissolution test conditions for these type of dosage forms, see *Suspensions*.

## Lozenges

Lozenges can be, basically, manufactured in two ways: 1) molded, where the drug substance(s) is/are dissolved in a hot mixture of sugars, syrups, and other ingredients, the final mixture is transferred to molds and cooled down; and 2) compressed, where all the formulation components, in the powder form, are compressed together.

In case of molded lozenges, a dissolution or disintegration test may not be required. In the case of compressed lozenges, the development of the dissolution or disintegration test should follow the same steps as any other immediate-release solid oral dosage form.

## Oral Pastes and Oral Gels

In addition to the equipment described in ⟨711⟩ and ⟨724⟩, it may be useful to consider the equipment and procedures described in *Semisolid Drug Products—Performance Tests* ⟨1724⟩.

## Chewable Gels

The development of the dissolution test for chewable gels should follow the same steps as for any other immediate-release solid oral dosage form.

## Type A Medicated Articles and Type B and Type C Medicated Feeds

For definitions and general descriptions of animal drugs and drug products delivered in animal feeds, see *Animal Drugs for Use in Animal Feeds* ⟨1152⟩.

Usually, dissolution testing is not required for Type A medicated articles and Type B and Type C medicated feeds that deliver animal drugs and drug products in animal feeds, but it may be required to support certain formulation changes for approved products or bioequivalence determinations for generic products.

# ⟨1724⟩ SEMISOLID DRUG PRODUCTS—PERFORMANCE TESTS

***Change to read:***

## ▲SCOPE

This chapter provides general information about developing in vitro performance tests to evaluate drug release or skin permeation for topical and transdermal semisolid and liquid-based dosage forms, including but not limited to, creams, gels, ointments, pastes, suspensions, lotions, and foams. For information related to in vitro performance tests that evaluate drug release for transdermal delivery systems (TDS), refer to *Drug Release* ⟨724⟩.

In this chapter, the term "drug" is utilized to refer more generally to active ingredients, potentially including active ingredients that may not be considered drugs (e.g., sunscreen active ingredients).

For information related to product quality tests for topical and transdermal dosage forms, refer to *Topical and Transdermal Drug Products—Product Quality Tests* ⟨3⟩.

## INTRODUCTION

This chapter provides general information for developing in vitro release test (IVRT) methods to assess the rate of drug release from topical and transdermal semisolid and liquid-based dosage forms, including but not limited to, creams, gels, ointments, pastes, suspensions, lotions, and foams applied on the skin and other mucosal membranes. Definitions and descriptions of these dosage forms can be found in *Pharmaceutical Dosage Forms* ⟨1151⟩. This chapter also provides general information for developing in vitro permeation tests (IVPT) to assess the rate and extent of drug permeation into and through the skin from semisolid and liquid-based drug products. The same equipment and similar methodological principles/procedures may be relevant for IVPT methods with other epithelial membranes (for information on appropriate mucosal membranes, see *Biological Membrane* below).

### Drug Product Quality and Performance Tests

Drug product tests are divided into two categories: 1) those that assess general quality attributes i.e., product quality tests, and 2) those that assess product performance, e.g., using an IVRT/IVPT method. Product quality tests characterize the physicochemical and/or structural attributes (e.g., pH, particle size/morphology etc.) of the formulation. By contrast, product performance tests assess how a drug product functions under specified conditions, which may provide information relevant to its in vivo performance.

Product quality tests are generally useful to characterize and/or compare product quality attributes that can control the performance of the product, including, but not limited to, identity, strength, purity, uniformity, pH, particle size/morphology, and apparent viscosity. Details about these product quality tests can be found in ⟨3⟩. The performance tests that are the focus of this general chapter are specifically useful to characterize and/or compare the linear (steady state) drug release rate (using an IVRT) or the dynamic rate and extent to which a drug permeates into and through the skin (using an IVPT) from semisolid and/or liquid-based dosage forms, under the conditions of the test.

Potential contexts for use of IVRT and IVPT methods are summarized below.

#### IVRT

- Characterizes the steady-state drug release rate for a product batch. When the performance (release rate) of a topical product has been characterized by a validated IVRT method using the same batch of product that supported a demonstration of the safety and/or efficacy of the product, that performance (release rate) may have the potential to serve as a basis of reference for the product in the future
- Characterizes the influence of processes, formulations, and/or manufacturing differences on a drug product by comparing the steady-state drug release rate for the postchange (test) and prechange (reference) products, typically in the context of scale-up or post–approval changes for an approved drug product, which can support a demonstration of equivalence in certain situations
- Characterizes the influence of processes, formulations, and/or manufacturing differences on a drug product by comparing the steady-state drug release rate for a prospective generic (test) product and an approved (reference standard) product, which can support a demonstration of bioequivalence in certain situations

#### IVPT

- Characterizes the rate and extent to which a drug permeates into and through the skin for a product batch
- Characterizes the influence of process, formulation, and/or manufacturing differences on a drug product by comparing the rate and extent to which a drug permeates into and through the skin. This may occur in the context of comparing prototype formulations of a topical product, or potentially in the context of comparing postchange (test) and prechange (reference) products
- Characterizes the influence of process, formulation, and/or manufacturing differences on a drug product by comparing the rate and extent to which a drug permeates into and through the skin for a prospective generic (test) product and an approved (reference standard) product, which can support a demonstration of bioequivalence in certain situations

## IN VITRO RELEASE TEST (IVRT)

An IVRT is intended to characterize a steady-state drug release rate from a semisolid formulation under a specific set of conditions (i.e., a given set of method parameters). IVRT methods are typically precise and reproducible. However, if the parameters of the IVRT method change, then the release rate measured may also change. Notably, when the IVRT method is consistent, then changes in the release rate between a test and reference formulation are reflective of a difference in the physicochemical properties and/or the structural arrangement of matter in the formulations. Thus, IVRT methods can provide a sensitive and discriminating way to monitor for differences in the physicochemical or structural properties of a test versus the reference formulation.

The steady-state drug release kinetics are not representative of the finite dose (non-steady-state) kinetics of drug permeation through the skin. The drug release rate measured by an IVRT method should not be misconstrued to represent a “true” drug release rate for that formulation, or even a biorelevant release rate. For these reasons, IVRT methods are most appropriate to assess (compare) the "sameness" of formulations (e.g., before and after certain manufacturing or formulation changes).

If the drug release rate is found to be different between a test and reference formulation of comparable components and composition, it typically indicates that there is a difference in the physicochemical and/or structural attributes between the formulations. The IVRT methods discussed in this chapter are not expected to predict whether an observed difference in measured release rate may impact in vivo bioavailability, nor can they identify the exact nature of the difference. Instead, the utility of IVRT studies is that they can efficiently assess whether test and reference products perform in a manner that appears to be the same. When the drug release rates are equivalent for two formulations with similar components and compositions, it suggests that there may be a high degree of sameness in physicochemical and structural attributes between the formulations, thereby providing evidence that mitigates the risk of a potential difference in therapeutic performance. Consequently, IVRT studies may provide evidence to support a demonstration of equivalence between prechange and postchange batches of a product, or to support a demonstration of bioequivalence in certain situations.

### Theory

After a short lag period, release of drug from the semisolid dosage form is kinetically described by diffusion of a chemical out of a semi-infinite medium into a sink, by the following equation:

$$m = \sqrt{2 \times Q \times D_m \times C_s \times t}$$

Where $m$ is the amount of drug released, $Q$ is total amount of the drug in solution and suspended in the matrix, $D_m$ is the drug diffusion coefficient in the semisolid matrix, $C_s$ is the drug solubility, and $t$ is time.

A plot of $m$ versus $\sqrt{t}$ will be linear with a slope of:

$$m = \sqrt{2 \times Q \times D_m \times C_s}$$

### IVRT Method Development, Validation, and Transfer

IVRT method development should encompass key aspects that influence the IVRT results, including the IVRT receptor solution sample analysis method. IVRT method validation is outside of the scope of this chapter. An IVRT method transfer between laboratories should include a demonstration that the IVRT method and the associated IVRT receptor solution sample analysis method produces comparable, valid results when compared between the laboratory where the methods were validated and the laboratory to which the methods are transferred.

### Synthetic Membrane

Filter membranes (e.g., 0.45-µm pore size) comprised of synthetic materials (e.g., mixed cellulose esters, nylon, polysulfone, polyethersulfone) are frequently suitable for IVRT methods as they are typically resistant to binding most drugs, and they permit drugs to diffuse through the membrane. Filter membranes comprised of a synthetic material, sometimes with different pore sizes, are commonly evaluated during IVRT method development. Other types of simple, monolayer synthetic membranes, like dialysis membranes, may also be suitable for an IVRT method. The use of biological membranes or synthetic membranes developed to emulate a biological membrane are not appropriate for an IVRT method because such membranes may inappropriately influence the apparent rate of drug release.

### Diffusion Cells

Suitable equipment for the IVRT method includes various models of vertical diffusion cell (VDC) and immersion cells. The most commonly used equipment for IVRT methods are VDC (see *Figures 1–5*), although immersion cells (*Figure 6* and *Figure 7*) also have been used successfully. Equipment features (e.g., bubble-free cells or cells with a vent hole) other than the ones depicted below may be suitable once qualified. The total receptor compartment volume of VDC typically ranges from 5–15 mL, while the total vessel volume for the immersion cell typically varies between 50 and 200 mL; values outside of those typical

ranges may be available depending on the manufacturer of the equipment. VDCs may offer advantages over immersion cells; for example, in the assessment of lower strength dosage forms and/or dosage forms with low amounts of drug release, VDCs provide less drug dilution in the receptor solution, minimizing potential analytical challenges regarding drug quantification. Also, many VDC models allow the user to adjust the amount of the dosage form utilized, which can allow users to increase the amount of the dosage form in the donor compartment, thereby reducing the percent dose depletion and sustaining the pseudo-infinite dose conditions that support steady-state drug release kinetics. See *Equipment* for further details on the equipment used in IVRT.

## Analytical Method

The analytical method should be precise, accurate, and specific for the drug in the receptor solution. The use of validated analytical methods with multipoint calibration curves is encouraged. The validation of an analytical method for IVRT sample analysis is done separately from the validation of an IVRT method, which follows specific procedures not described in this chapter.

## Experimental Design

### DOSE

When utilizing an appropriately selected receptor solution, membrane, equipment, dose, and sampling duration (as well as other potential method parameters) the release rate of the drug should be linear (when plotted as the amount of drug released versus the square root of time) and reproducible. The amount of drug product in the donor compartment should ensure that dose depletion does not occur to an extent that alters the linear (steady state) release kinetics during the duration of the test (i.e., a pseudo-infinite dose amount should be utilized). Excessive dose depletion is characterized by a nonlinear region in the plotted cumulative amount of drug released curve (when plotted as the amount of drug released versus the square root of time).

The dose application can be done by different methods, such as, but not limited to, dispensing directly on the membrane from a tube, transferring and spreading on the membrane with a spatula, or transferring and dispensing with a positive-displacement pipette or a disposable harvester (which minimizes shear stress during dosing). The shear stress imposed upon the dosage form during the dispensing (e.g., from a product tube) and dosing (e.g., using a positive displacement pipette) should be considered, and the dosing method should preferably minimize and routinely control the shear stress in a consistent manner for all diffusion cells. It is also important that a consistent amount of the dosage form is applied uniformly upon the membrane, without air pockets, making a compact cylinder of the formulation. The diffusional surface area of the product on the membrane needs to be consistent and well controlled as it is a factor in the calculation of the release rate. The donor compartment should be occluded to avoid evaporation of volatile components (including water) from the dosage form that is in contact with the membrane, because that evaporative metamorphosis may lead to changes in the composition of the drug product and may alter its linear (steady state) drug release kinetics.

### RECEPTOR SOLUTION

The selection of the receptor solution is guided by the solubility of the drug substance(s) in potential solvents/solvent combinations. Most commonly, combinations of aqueous and alcoholic/organic solvents are used, and the solubility of the drug in the receptor solution should exceed the highest sample concentration in the IVRT study, ideally by an order of magnitude, but demonstrably sufficient to facilitate a linear (steady state) release rate for the duration of the study (even when evaluating a relatively higher release rate of a formulation that is 150% of the nominal reference strength).

The receptor solution should be adequately mixed, typically by stirring at a constant and well-controlled speed throughout the experiment. The stirring speed or the flow rate should also be part of system qualification and is further described under *Equipment*.

Another factor to consider is the stability of the drug in the receptor solution at the temperature of the test during the IVRT experiment.

### SYSTEM EQUILIBRATION

The system should be appropriately equilibrated under the predefined experimental conditions prior to the beginning of the IVRT run. No air bubbles should be present in the receptor solution (under the membrane) immediately prior to, or during the experiment; if appropriate, the receptor solution can be degassed. The system temperature (including the membrane surface temperature and the circulating water bath temperature, if applicable) should be stable and well controlled. IVRT membranes can be presoaked with receptor solution prior to assembling in the diffusion cell or equilibrated with the receptor solution in situ within the diffusion cell prior to dosing (e.g., for 30 min at a membrane temperature of 32°) depending upon the method.

### EXPERIMENT LENGTH AND SAMPLING

The test duration should be suitable to characterize the linear (steady state) drug release kinetics of the product formulation. This is typically demonstrated based upon a sustained steady-state release between 4-6 h. The data obtained during the first hour may not represent the steady-state release kinetics, and for many IVRT methods steady-state release kinetics are calculated based upon timepoints from 1 h onward (e.g., at 1, 2, 3, 4, and 5 h, or at 2, 3, 4, 5, and 6 h). At least 5 sampling time points should be planned to obtain a well-characterized release rate. Sampling durations of at least 4 h are suitable to assess steady-state release rates, whereas shortened (e.g., 2 h) sampling durations may not be representative of the steady-state release kinetics. The specific sampling times may be varied depending on the formulation (e.g., every 30 min, or every hour); however, caution should be taken regarding the precise timing of each sample collection to ensure that sample collections happen within the predefined tolerance range. Samples should be withdrawn within a tolerance of ±15 min or ±2% of the nominal time, selecting the tolerance that results in the narrowest time interval.

Sampling is dependent upon the equipment used and should follow instructions provided by the manufacturer, when appropriate. The receptor solution used to replace the volume removed during sampling may be pre-warmed to the temperature of the receptor solution in the receptor compartment, and it is important to ensure that air bubbles are not present beneath the membrane after sampling and refilling the receptor solution at each time point.

### NUMBER OF REPLICATES

The test is often conducted with a group of 6 or 12 cells per test run. The results from 6 diffusion cells dosed with a specific product are routinely sufficient to characterize the performance (release rate) of that product using that specific IVRT method. In instances when two products are compared, the results from 6 cells of a test product are often compared with the results from 6 cells of a reference product during the first stage of data analysis. See *Data Reporting* for more details on the use of additional replicates in instances when a second stage of testing is performed in a comparative IVRT study.

### MEMBRANE TEMPERATURE

The test is conducted at 32 ± 1° for products applied to the skin (measured at the surface of the membrane, when possible, or inferred based upon the temperature of the receptor solution for immersion cells or VDC Model A). The test is conducted at 37 ± 1° for products intended for internal application (e.g., rectal and vaginal products).

During the entire test, the nominal system conditions, like the temperature of the receptor solution, should be maintained so that the temperature at the membrane remains within specified parameters (e.g., 32 ± 1°) for the duration of the IVRT. The temperature control qualification is described under *Equipment*.

### DATA REPORTING

For each cell, the amount of drug released (typically in µg/cm$^2$) at each sampling time ($t_1$, $t_2$, etc.) is determined, and the cumulative amount released is plotted versus $\sqrt{t}$. The slope of the resulting line is a measure of the rate of drug release.

For each cell, the individual amount of drug released is plotted versus the square root of time. The slope of the resulting line is the rate of drug release.

IVRT is a useful tool during semisolid product development to assess whether there may be differences in the arrangement of matter within the semisolid product matrix of compositionally identical (or similar) test and reference products, which may alter their rates of drug release, and that may have the potential to alter product performance in clinical use. When test and reference products exhibit equivalent drug release rates based upon a validated IVRT method, it can mitigate the risk of potential differences in product performance. Therefore, evidence from an IVRT can support a demonstration of bioequivalence, along with other evidence that collectively mitigates the risk of a difference in product performance between a reference product and a prospective generic (test) product.

IVRT is commonly used to assess the sameness of a drug product after postapproval changes. Because common testing artifacts, such as air bubbles and membrane defects, yield measurements that are not normally distributed, a nonparametric statistical technique is used to evaluate the test results. The Mann-Whitney *U* test is used to calculate the 90% confidence interval for the ratio of the slopes between the test and the reference batches. This is illustrated by the following example in which the initial drug product batch is referred to as the reference batch (*R*) and the changed or subsequent batch is referred to as the test batch (*T*). The individual amounts of drug released from *R* are plotted versus the square root of time, and the resulting slopes are determined. Those are the reference slopes. The process is repeated for the test batch (*T*).

The *T*/*R* slope ratios are calculated for each test-to-reference combination of all pairs of *T*/*R* slopes. This procedure is facilitated with a table where the values for the slopes for *T* are listed down the left side of the table and the slopes for *R* are listed across the top of the table. The *T*/*R* slope ratios are then determined. See *Table 1*.

**Table 1. Comparison of Test Slope (TS) and Reference Slope (RS) Ratios**

| | RS1 | RS2 | RS3 | RS4 | RS5 | RS6 |
|---|---|---|---|---|---|---|
| TS1 | TS1/RS1 | TS1/RS2 | TS1/RS3 | TS1/RS4 | TS1/RS5 | TS1/RS6 |
| TS2 | TS2/RS1 | TS2/RS2 | TS2/RS3 | TS2/RS4 | TS2/RS5 | TS2/RS6 |
| TS3 | TS3/RS1 | TS3/RS2 | TS3/RS3 | TS3/RS4 | TS3/RS5 | TS3/RS6 |
| TS4 | TS4/RS1 | TS4/RS2 | TS4/RS3 | TS4/RS4 | TS4/RS5 | TS4/RS6 |
| TS5 | TS5/RS1 | TS5/RS2 | TS5/RS3 | TS5/RS4 | TS5/RS5 | TS5/RS6 |
| TS6 | TS6/RS1 | TS6/RS2 | TS6/RS3 | TS6/RS4 | TS6/RS5 | TS6/RS6 |

After the *T*/*R* ratios have been calculated, they are ordered from the lowest to the highest. The 8th and 29th *T*/*R* ratios are identified and converted to percent (multiplied by 100). These values represent the 90% confidence interval for the ratio of test to reference release rates. To pass first stage testing, those ratios must be within the range of 75%–133.33%.

If the results do not meet this criterion, 4 additional tests (2 reference and 2 test) of 6 cells each should be performed, resulting in 12 additional slope determinations for each product tested. The *T*/*R* slope ratios for all 18 slopes for each product tested are determined. All 324 individual *T*/*R* slope ratios are ordered from the lowest to the highest. To pass this second stage testing, the 110th and 215th slope ratios, representing the 90% confidence interval, must be within the range of 75%–133.33%.

## IN VITRO PERMEATION TEST (IVPT)

The in vitro permeation test (IVPT) is intended to characterize the rate and extent to which a drug applied on the surface of a biological membrane permeates into and through it, using method parameters aimed to simulate in vivo conditions. IVPT methods can utilize a variety of biological membranes, including excised human skin, which can exhibit natural variations in permeability that are reflective of the variability observed in vivo. This variability can be substantial; it is not uncommon to observe a 10-fold difference in skin permeability for a given compound (in the same formulation) between individuals in the

@2024 USPC

population or between different anatomical regions on the same individual. Experimental variability may also be a result of the physicochemical properties of a molecule. For all products or treatments compared in an experiment, the replicate skin sections used should be sourced from the same donor (or the same set of donors), the same anatomical site (e.g., abdomen, back, etc.), the same source (e.g., elective surgery or cadavers) and manner of preparation (e.g., dermatoming, freezing, etc.) to minimize variability.

An IVPT study can be sensitive and discriminating to differences in the rate and extent to which compounds applied on the skin from different formulations become available in and through it. Notably, unlike an IVRT study, differences in permeation that are observed in an IVPT study comparing a test versus reference product, if any, may correlate with and/or be predictive of differences in bioavailability in vivo. The IVPT is routinely carried out to guide semi-solid topical formulation development.

## IVPT Method Development and Validation

IVPT method development should encompass key aspects that influence the IVPT results (some of these aspects are discussed below), including the bioanalytical methodology used to quantify the amount of the drug in the IVPT study samples. The scope of the IVPT method development is dependent upon the purpose of the study. For example, a bioequivalence study is likely to require a larger number of skin donors in order to adequately power a statistical analysis, compared to a study intended to qualitatively evaluate different formulation prototypes. Further, whereas IVPT studies designed to support a demonstration of bioequivalence generally rely upon assessments of the rate and extent to which drugs permeate the skin based upon receptor solution results, the selection of new chemical entities or formulation prototypes may also employ assessments of tissue distributions. A comprehensive discussion on IVPT method validation is outside of the scope of this chapter.

### Biological Membrane

Dermatomed human skin (split-thickness, typically around 250–500 µm), sourced from cadavers or elective surgery (typically abdominoplasties or breast reductions), is often the most appropriate membrane of choice due to its intrinsic relevance to a human drug product development, as well its ease of handling during experimental procedures. The thickness of the dermatomed skin should be confirmed prior to assembling the membrane in the diffusion cell, as significant variability in thickness may increase the variability of IVPT results. Epidermal preparations (sheets of epidermis that have been separated from the dermis at the dermal-epidermal junction) require technical experience to process, have less structural integrity compared to dermatomed skin, and may tear or lose barrier integrity more easily. However, epidermal preparations are often more consistent in thickness than dermatomed skin, and the magnitude of permeation for some compounds may be greater through epidermal preparations than through dermatomed skin. Therefore, while dermatomed skin is a good choice to evaluate in most cases, in some situations (e.g., when the drug of interest is not feasible to quantify permeating through dermatomed skin) epidermal preparations may be useful to evaluate during IVPT method development.

Dermatomed porcine skin has a relatively similar morphology to human skin and can be used as a secondary option (as a surrogate for human skin) for research and development studies, unless regulatory guidance recommendations specify otherwise. The use of rodent skin (as a surrogate for human skin) is discouraged due to significant dissimilarity to human skin in terms of morphology and stratum corneum structure and thickness, which can make the results difficult to interpret in terms of their relevance to human skin permeation. The use of cultured skin constructs (reconstructed human epidermis) is not ideal as a surrogate for natural excised human skin because the permeability properties of such tissues is currently not representative of excised human skin. The use of any synthetic membrane (including the types developed to emulate a biological membrane) is not appropriate for an IVPT method; the results of tests with any synthetic membrane may not reflect the rate and extent to which a drug permeates into and through skin and may be misleading.

The use of human or porcine full-thickness (non-dermatomed) skin can pose experimental challenges and is generally not recommended. Other membranes such as rectal, vaginal, or corneal epithelial tissue may also be employed, depending on the intended route of administration for the drug product under evaluation. In such circumstances, several parameters of the test method may differ from those used for an IVPT with skin due to specific considerations for modeling the relevant in vivo conditions. For example, the appropriate temperature at which to maintain the membrane may be different.

### Diffusion Cells

Two types of diffusion cells are commonly used for IVPT studies: the vertical diffusion cell (VDC) (see *Figures 1–5*) and the flow-through diffusion cell (FDC) (see *Figures 8–10*). Equipment features (e.g., bubble-free cells or cells with a vent hole) other than the ones depicted below may be suitable once qualified. VDCs are well characterized and can be utilized for both, IVRT and IVPT studies. FDCs are used exclusively for IVPT studies (not IVRT studies) and have the advantage that the sampling is more easily automated, which can make it easier to acquire samples at times when investigators are typically not in the laboratory (e.g., the middle of the night). VDCs and FDCs can both produce excellent results when the IVPT method is appropriately developed, and each type of cell has its advantages.

## Bioanalytical Method

The choice of analytical method should consider the physicochemical properties of the analyte(s) present in the formulation and the actual formulation composition; these factors combined will directly affect the ability of a drug to cross the stratum corneum, therefore impacting drug concentrations in each skin layer and in the receptor solution. Liquid chromatography (LC) coupled with a mass spectrometer (MS) or a tandem mass spectrometer (MS/MS) detector provides excellent sensitivity and selectivity, albeit at the expense of higher complexity in terms of method development/validation, troubleshooting, and higher maintenance costs. LC coupled with an ultraviolet (UV) detector, diode array detector (DAD), or fluorescence detector (FLD) offers lesser technical complexity but is generally less sensitive and can pose selectivity challenges for analytes present in biological samples.

The use of validated bioanalytical methods with multipoint calibration curves is encouraged. The validation of an analytical method for IVPT sample analysis is done separately from the validation of an IVPT method, each of which follow specific procedures not described in this chapter.

## Experimental Design

### DOSE

The thermodynamic activity of the drug(s) present in a formulation will affect the rate and extent of skin permeation. It is prudent to understand the drug(s) solubility in the solvents/excipients of interest, as well as in the formulation prototypes under evaluation.

The finite dose typically ranges from 2–15 mg of formulation per square centimeter of dosing area, with a dose of 5–10 mg/cm$^2$ often used as a starting dose for method development. Ensuring consistency in the dispensing of the formulation (e.g., from the product tube) and uniform dose administration (spreading/coverage) on the skin section placed in the diffusion cell can help minimize experimental variability. The use of positive-displacement pipettes is recommended to ensure dosing precision. For semisolid dosage forms such as ointments, creams, and certain gels that do not flow like a solution, a glass rod or the bottom of a glass vial can be used to evenly spread the formulation within the dosing area.

## RECEPTOR SOLUTION

The receptor solution should ensure sufficient solubility of the drug(s) of interest throughout the length of the study, thus not limiting the rate of diffusion/partitioning of the drug(s) from the skin to the receptor solution. The solubility of the drug in the receptor solution should exceed the highest sample concentration in the IVPT study, ideally by an order of magnitude, if possible. The inclusion of 0.1% (w/v) polyoxyethylene (20) oleyl ether is ideal to enhance the solubility of physiological buffer based (aqueous) receptor solutions for hydrophobic drugs. If additional solubility is needed, small increases in the concentration of polyoxyethylene (20) oleyl ether [e.g., from 0.1% (w/v) to 0.2% (w/v)] is typically adequate for most hydrophobic drugs. Higher concentrations of polyoxyethylene (20) oleyl ether may be evaluated, as needed, but should not exceed 6% because higher concentrations may alter the skin barrier. Other solubility modifiers may also be effective but may not be suitable for studies assessed by a regulatory agency unless the impact of that solubility modifier on the permeability of the skin barrier has been adequately characterized. Other strategies to improve the solubility of the drug in the receptor solution that may have the potential to alter the permeability of the skin (e.g., inclusion of organic solvents and alcohols in the receptor solution) are not prudent and may invalidate the IVPT method. Additionally, labile compounds may require modifications in the receptor solution, including the addition of antioxidants and/or chelating agents (e.g., ethylene diamine tetra acetic acid; EDTA) or the use of acidified water (e.g., pH 4.0) instead of phosphate-buffered saline (PBS). The addition of antibacterial/antimycotic agents [e.g., 0.1% (w/v) sodium azide; 0.01% (w/v) gentamicin sulfate] in the receptor solution is also important to prevent microorganism growth and membrane tissue degradation.

## SYSTEM EQUILIBRATION

The system should be appropriately equilibrated under the predefined experimental conditions prior to the beginning of the IVPT run. No air bubbles should be present in the receptor solution (under the membrane) immediately prior and during the experiment; if appropriate, the receptor solution can be degassed. The system temperature (including the membrane surface temperature and the circulating water bath temperature, if applicable) should be stable and well controlled. Frozen biological membranes should be thawed at ambient temperature prior to assembling on the diffusion cells. Once mounted, the skin sections should be allowed to equilibrate to a physiologically relevant state of hydration and temperature (e.g., for 30 min at a membrane surface temperature of 32°).

## EXPERIMENT LENGTH AND SAMPLING

The test duration should be sufficient to characterize a suitable permeation profile. For IVPT studies that are intended to support a demonstration of bioequivalence, the selected sampling schedule and study duration should be sufficient to characterize the cutaneous pharmacokinetics of the drug, which ideally includes a sufficiently complete flux profile to identify the maximum (peak) flux and a decline in the flux thereafter across multiple subsequent time points. IVPT studies typically range from 12–72 h in length; IVPT bioequivalence studies may require longer periods of time to observe a sufficient decline in the skin flux to adequately characterize the cutaneous pharmacokinetics.

The IVPT method development should support the selection of an appropriate sampling schedule, intended to provide suitable resolution for the flux profile. A study with fewer than 8 nonzero sampling time points may not provide adequate characterization of the flux profile.

## NUMBER OF DONORS AND REPLICATES

Depending on the stage of method development, the number of donors may vary. A study with fewer than 4 donors and 4 replicates per donor per treatment may be difficult to interpret. IVPT bioequivalence studies may require a larger number of donors and replicates to adequately power a statistical analysis. The inclusion of a nondosed control (no formulation) is recommended and may help ensure the skin source(s) and receptor solution are absent of contaminants that may influence the results.

## MEMBRANE TEMPERATURE

The surface of each skin section should be kept constant at 32 ± 1° throughout the length of the study. Temperature fluctuations of the skin surface will affect drug diffusion and may increase experimental variability. The use of a thermoregulated diffusion cell is encouraged to control the temperature of the membrane surface.

## MEMBRANE INTEGRITY

The skin barrier integrity in each diffusion cell should be confirmed prior to dosing by using techniques such as transepidermal water loss (TEWL), electrical impedance/conductance or tritiated water permeation; only skin sections with acceptable barrier integrity results should be dosed. TEWL is often a preferred method because, unlike the other methods, it measures the flux of water through the skin barrier while it is dry and in contact with the air, as it is in the normal in vivo state, and TEWL is relatively rapid and convenient.

## DRUG TISSUE DISTRIBUTION AND MASS BALANCE

Most IVPT experiments report skin flux and the total cumulative amount of drug that has permeated into the receptor solution (or as a percentage of drug from the total applied dose). Depending on the purpose of the study, an evaluation of drug tissue distribution (amounts in the stratum corneum, viable epidermis, and dermis) and total mass balance may provide additional insights.

DOI Ref: xs66s
DocId: GUID-94DCFABD-D687-4F3A-A43B-09CB5D5B0B5E_2_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M5695_02_01

Full mass balance requires more intensive bioanalytical method development to ensure that the drug(s) of interest are efficiently extracted from each sample matrix type, such as cotton swabs used to remove the excess of formulation present on the skin surface at the end of the experiment, tape strips used to remove stratum corneum, and homogenized viable epidermis and dermis.

Epidermis and dermis heat splitting can be accomplished by placing the skin sections (harvested at the end of the IVPT study) on a sheet of aluminum foil and incubating it (dry heat) at 60° for 2–3 min. After this step, the epidermis can be separated (by scraping) from the dermis by using forceps. Because the drug levels in the epidermis are generally higher than the dermis, the splitting should be done carefully to avoid cross contamination, and clean forceps should be used in between samples.

### DATA REPORTING

Depending on the purpose of the study (bioequivalence, formulation development, prototype screening, etc.), data may be reported and assessed using different parameters (endpoints). For example: a bioequivalence study will focus on the cutaneous pharmacokinetic endpoints of maximum flux ($J_{max}$), and total cumulative amount (AMT) of drug permeated. Studies conducted in early stages of drug development, such as those intended to select a new chemical entity (NCE), or to rank different formulation prototypes, may report tissue (epidermis and dermis) concentrations in addition to the parameters (endpoints) above, and may include full mass balance data.

The flux (rate of drug permeation) should be calculated for each time point in units of mass/area/time (e.g., ng/cm$^2$/h) on the *y*-axis versus time in the *x*-axis. The extent of drug permeation should also be reported in units of mass/area (e.g., ng/cm$^2$) in the *y*-axis versus time in the *x*-axis—the slope of this curve can help determine the overall drug flux through the skin at different points in time. Drug levels in the viable epidermis and dermis can be reported as absolute mass amount (e.g., nanograms or micrograms) or concentration (e.g., nanograms or micrograms of drug per milligram of tissue [ng/mg or µg/mg]).

Full mass balance results are generally reported as percentage of drug(s) in each compartment (e.g., stratum corneum, viable epidermis, dermis and receptor solution) relative to the total amount applied at the beginning of the experiment.

## IVRT Versus IVPT

The selection between IVRT or IVPT should be based on the intended objective(s) of the formulation assessment, as described in *Table 2*. Intrinsic experimental differences between the two methodologies are further described in *Table 3*.

**Table 2. Guide for Selecting an Appropriate Test Method (IVRT or IVPT) Depending Upon the Goal**

| Evaluation/Goal | Test |
|---|---|
| Assessment of in vitro/in vivo correlation | IVPT |
| Assessment of the ability of a drug in a formulation to cross the stratum corneum and of the distribution of the drug in the epidermis, dermis, and/or receptor solution | IVPT |
| Selection of a new chemical entity (NCE) for further development as a semisolid formulation | IVPT |
| Comparison of the permeation kinetics of different topical semisolid formulations (different composition of different dosage forms, such as solutions, gels, creams, ointments, etc.) | IVPT |
| Comparison of the rate and extent to which a topically administered drug permeates through the skin and becomes available at or near a site of action from a reference and a test product formulation | IVPT |
| Evaluation of the effect of inactive ingredients on the rate of drug release from the formulation matrix | IVRT |
| Assessment of sameness in the formulation matrix between formulations with the same amount of an active ingredient and the same or similar composition of inactive ingredients | IVRT |
| Comparison of the effect of critical manufacturing/process steps on the microstructure of semisolid formulation | IVRT |
| Compare batch-to-batch variability in drug release rate at the time of manufacture, and during stability | IVRT |

**Table 3. Key Differences Between IVRT and IVPT Methodologies**

| Parameter | IVRT | IVPT |
|---|---|---|
| Membrane | Synthetic (e.g., mixed cellulose esters, nylon, polysulfone, polyethersulfone) | Biological (e.g., ex vivo human epithelial tissue such as skin, rectal or vaginal tissue, corneal tissue, nails, other mucous membranes) |
| Receptor solution | Aqueous and aqueous–organic combination, may include high percentages (≥30%) of alcohols and/or organic solvents (e.g., ethanol, isopropyl alcohol, acetonitrile) | Aqueous, typically phosphate buffered saline; low levels (typically ≤5%) of additives may be added to enhance solubility of hydrophobic compounds (see the IVPT *Receptor Solution* section) |

# EQUIPMENT

## General Recommendations for Equipment Qualification and Requalification

The VDC, immersion cells, and FDC should match the general descriptions provided below and may have design variations of the types shown among specific examples illustrated in *Figures 1–5* for VDCs, *Figures 6* and *7* for immersion cells, or *Figures 8–10* for FDCs. The VDC, immersion cell, and FDC components should be manufactured with inert materials that do not adsorb, absorb, bind, or react with the analyte. The diffusion cell and its components should not alter the amount of diffusing drug that is measured, either by adsorbing, absorbing, binding, or reacting with the drug, or by releasing drug that was adsorbed, absorbed, bound, or reacted with in a previous experiment.

The operating principles and specific test procedures differ among the various equipment; relevant procedures from the manufacturer may be used for installation, operational, and performance qualifications, if available.

However, regardless of what qualification information is provided by a diffusion cell manufacturer, the laboratory performing the test should perform an initial qualification of each diffusion cell. Qualified diffusion cells can be used in numerous experiments, and do not need to be qualified again (i.e., requalified) each time. The condition of the orifices and diffusion cells should be ascertained prior to each test. Certain diffusion cell components such as O-rings or tubing may require re-evaluation and occasional replacement. Automated systems are too varied to be covered in any detail within this chapter; however, they should be requalified routinely (e.g., every 6-12 months) based on the manufacturers' recommendations.

The initial qualification of each diffusion cell should, at minimum, include:

1. Measurements of the diffusional area of the orifices of the donor and receptor compartments between which the membrane is mounted
2. Empirically measured volume of the receptor solution compartment/vessel for each VDC or immersion cell, or the empirically measured outflow tube length for each FDC
3. Stability of the temperature measured at the membrane surface (e.g., 32 ± 1°) across a relevant duration (e.g., 6 h for IVRT or 48 h for IVPT)
4. Rate of stirring or agitation for VDCs or immersion cells, or the flow rate for FDCs, as applicable

In addition to the quantitative assessments described above, qualitative assessments should verify that diffusion cells do not leak, and that the membrane can be mounted securely in the diffusion cell so that there is no bulk flow of a dosage form from the donor compartment to the receptor compartment that circumvents the membrane. Several other considerations relevant to a well-controlled test may be included in the qualification.

1. **Qualification of Orifice Diameter:** The orifice diameter for the donor and receptor compartments can be determined using vernier calipers. The orifice should be inspected for any chips or other damage which may alter the surface area.
2. **Qualification of Volume of Receptor Solution Compartment/Vessel:** In the case of a VDC, the volume of the receptor solution should be empirically determined for each cell, individually, and recorded in a manner that can be uniquely associated with each diffusion cell thereafter, for use in calculations. The volume should be filled in a consistent manner for all diffusion cells (some cells may have a fill line marked on the cell which can be utilized) and the procedure used should consider whether the displacement by a stir bar (or other mechanism) may impact the volume measured such that the measured volume would not be relevant to that diffusion cell if a different size stir bar was used during the test. The nominal volume of the diffusion cells provided by the manufacturer should be used only as a guide.
   For immersion cells, the volume of receptor solution to be filled in the dissolution vessel should be accurately measured with the appropriate volumetric glassware and transferred to the dissolution vessel.
3. **Qualification of Temperature Control:** The temperature of each cell should be equilibrated to provide the target temperature at the membrane, and the initial qualification of the equipment should verify that the temperature can be maintained for the duration of the test when using the relevant equipment and method parameters. Depending on the VDC or FDC equipment design, a measurement of the membrane temperature can often be made conveniently using an infrared thermometer, or using a thermocouple mounted with the membrane; for immersion cells, the temperature at the membrane may be assumed to be the same as the bulk volume of the receptor solution in the dissolution vessel,

Printed by: USP NF
Do Not Distribute

once equilibrated and stabilized. The temperature of each cell should typically remain within ±1° of the target temperature (typically 32° or 37°) during the test.

4. **Qualification of Stirring/Agitation/Flow Rate:** The stirring rate should be verified with a suitable device, such as a photo tachometer. For VDC, stirring rates in the range of 400–600 rpm are common. The stirring rate measured is typically applicable to the specific location where the stirring impeller is (e.g., a specific position in a rack that holds multiple VDC, or a specific stir plate). Stirring rate can be measured using a surrogate stir bar if the stir bar used in the diffusion cell is too small to obtain an accurate measurement. The paddle stirring rate for immersion cells of 50 or 100 rpm is common and should be verified and maintained during the test.
Stirring rates are relevant for VDC, but not necessarily for FDC or immersion cells. In case of FDC, the flow rate of the receptor solution should be set at a specific value and maintained throughout the test. The flow rate (typically expressed in units of milliliters per minute) can be determined by setting the desired flow rate and collecting a sample into a tared vial for a specific duration. A suitable flow rate allows for a sample of sufficient size to ensure an accurate weighing and should not be substantially impacted by normal variability that may arise due to a drop that fails to fall from the tip of the dispensing tube. It is essential that the lengths of all the dispensing tubes are exactly the same, because differences in dispensing tube lengths can alter the void volume and lag time for samples to be dispensed into collection tubes.

## Vertical Diffusion Cell (VDC)

A VDC consists of two compartments (a donor compartment and a receptor compartment with a sampling arm) separated by a membrane and held together by a clamp, screw top, or other means (see *Figures 1–5*). The VDC body (i.e., donor and receptor compartment with associated cell structures like the sampling arm and water jacket, if present) is usually made from borosilicate glass, although different materials may be used to manufacture the body and other parts of the VDC assembly. Other diffusion cells that are similar in design principles and features to those depicted in *Figures 1–3* can generally be used.

The diameters of the orifices of the donor compartment and receptor compartment, which influence the diffusional area for the test, should be sized within ±5% of the specified diameter. The diameter of the donor and receptor compartment orifices may vary for different diffusion cell models. The receptor compartment orifice should be the same size as the donor compartment orifice. The design of the VDC should facilitate proper alignment of the orifices in the donor and receptor compartments. The membrane should be held in a horizontal plane between the donor and receptor compartments. Also, the membrane should be mounted so that it is flat, with no folds or wrinkles. The receptor compartment in each unit of a given model of VDC should be manufactured consistently, with a uniform height and geometry. All the cells (units) of the same VDC model should have the same nominal volume, and the actual volume should be measured and recorded for each individual cell. Care should be taken to minimize the intercell volume variability (e.g., not more than ±5%).

When conducting IVRT or IVPT studies, the VDC units are typically positioned in a stirrer rack (not depicted) that holds multiple VDC units (e.g., in sets of 6 or 7) in the correct orientation, providing magnetic stirring at a calibrated rate.

A magnetic nonstick (e.g., Teflon-coated), inert stir bar or similar stirring/agitation device in the receptor compartment is used as the internal stirring mechanism. The stirring bar or device should provide enough circulation to ensure contents of the receptor compartment are uniform. Samples of the receptor solution are removed at intervals throughout the test, and regardless of whether the entire receptor compartment volume or only an aliquot is sampled, an equivalent volume of stock receptor solution is replaced at each sampling event. The aliquots should be removed from the well-mixed center of the receptor compartment, unless sufficient proof exists that the entire receptor solution volume, including the portion in the sampling arm, are homogeneous and at the same concentration. For most VDC models, it is ideal for the volume of receptor solution in the sampling arm to be sampled and dispensed (repeatedly, a few times) into the well-mixed center of the receptor compartment, to ensure that the entire volume of the receptor compartment is homogeneous.

## General IVRT VDC Equipment Set Up

Observational checks should be performed prior to testing. The donor and receptor compartment orifices should be evaluated for any chips or other damage which may affect the orifice area. Chipped or damaged cells should not be used.

### MEMBRANE MOUNTING AND DOSING

Dosing procedures may be dictated by the requirements of the test method and/or the design of the diffusion cell. In general, two approaches are used: 1) the membrane is mounted and equilibrated in the diffusion cell prior to dosing the cell, or 2) the membrane is mounted and dosed during the assembly of the diffusion cell (e.g., VDC Model A in *Figure 1*), before the membrane comes into contact with the receptor solution. The dosing of the membrane prior to mounting on the diffusion cell in VDC Model A is acceptable because VDC Model A incorporates unique design elements to control the consistency of the dose and its alignment with the diffusion cell components. For all other VDC models, the membrane should be mounted and equilibrated in the diffusion cell prior to dosing the cell.

### DOSING VDC WITH OPEN DONOR COMPARTMENTS

It is conventional to install the membrane and then fill the receptor compartment with receptor solution. Any bubbles present underneath the membrane should be removed by tipping the cell and allowing the bubble to rise through the arm.

The system should be equilibrated, and the temperature should be measured at the membrane. The membrane should be within ±1° of the target temperature (typically 32° or 37°) prior to applying the dosage form. The stirrers should be turned on during the equilibration period.

For specific dosing techniques to apply the product to the membrane, refer to *In Vitro Release Test (IVRT), Experimental Design, Dose*.

### DOSING VDC MODEL A DIFFUSION CELLS

Model A VDC are intended to have the membrane prepared and the dosing performed as part of the assembly of the cell top, which is separate from the cell bottom of the Model A VDC. In this model, the unique design and operation of the Model A VDC, as defined by the manufacturer, should be taken into consideration along with requirements of the test method. This method should not be used with conventional VDC designs like VDC models B and C.

During the preparation and dosing of the membrane in the Model A VDC cell top assembly, the membrane should be placed below the Model A VDC donor compartment's dosage wafer on a flat and firm surface. The dosage form is then applied to the membrane within the dosage wafer. The Model A VDC donor compartment (dosage wafer) is filled to capacity; a small spatula can be used to dispense and spread the dosage form evenly within the dosage wafer and to remove any excess formulation.

The receptor compartment of the Model A VDC should be filled with receptor solution that is equilibrated to the target temperature (typically 32° or 37°) during the preparation and dosing of the membrane in the cell top assembly. The stirrers can be run during this period to speed up temperature stabilization. The receptor solution temperature should be measured and ensured to be within ±1° of the target temperature prior to mounting the cell top assembly. The stirrers can be run to help speed up temperature stabilization.

To start the test, the donor compartment cell top assembly is mounted on the cell bottom assembly of the Model A VDC so that the membrane is facing the receptor compartment, and the membrane separates the dosage form from the receptor solution. After assembly of the Model A cell top and bottom, the fully assembled cell should be checked to ensure that no bubbles are present underneath the membrane, and that the membrane has not slipped out of position whereby the dosage form might flow directly into the receptor compartment, circumventing the membrane.

### SAMPLING VDC (GENERAL PROCEDURE FOR ALL MODELS OF VDC)

VDC are typically sampled one of two ways for IVRT, either withdrawal and replacement, or displacement. Cells which use withdrawal and replacement will typically only have one arm leading to the receptor compartment. Cells which are sampled by displacement will have two arms leading to the receptor compartment. For cells sampled by different methods it is recommended to refer to the manufacturer's documentation.

### SAMPLING BY WITHDRAWAL AND REPLACEMENT

The receptor solution volume in the arm of many VDC may not mix adequately with the volume of receptor solution in the stirred receptor compartment. To ensure that the entire volume of the receptor compartment is homogeneous, it is ideal for the volume of receptor solution in the sampling arm to be sampled (drawn out) from the arm and re-dispensed into the well-mixed center of the receptor compartment multiple times prior to collecting a sample of the receptor solution for analysis. A precise volume of the sample should be withdrawn from the well-mixed center of the receptor compartment, typically using a precise syringe or pipette. Typical sample amounts are 200 to 500 µL. The same amount of receptor solution is then replaced through the same arm. Care should be taken to ensure that a bubble is not introduced during the sampling withdrawal and replacement process. If a bubble is present, it should be removed by tipping the cell and guiding the bubble up the arm. Depending upon the test method, the stirring may continue throughout the sampling procedure, or prior to the sample time point, the stirring may be stopped and then resumed shortly after the volume of receptor solution is replaced.

### DISPLACEMENT SAMPLING

Cells with two sampling arms are often sampled by displacement. Prior to the sample time point, all stirring is stopped. The replacement receptor solution is slowly added to the receptor compartment to prevent mixing. The receptor solution displaces the sample out the other sampling arm for collection. Once the sample is collected the stirring is resumed. Typically, a rinse volume is required in the process for displacement sampling to ensure that the current sample does not contain remnants of a previous sample. This is especially important for automated systems.

## General IVPT VDC Equipment Set Up

Observational checks should be performed prior to testing. The donor and receptor compartment orifices should be evaluated for any chips or other damage which may affect the orifice area. Chipped or damaged cells should not be used.

Receptor solution can either be preheated or allowed to equilibrate to temperature in the receptor compartments of the diffusion cells.

Skin should be cut to the appropriate size for the diffusion cell (larger than the diffusional area of the orifice) to ensure that the orifice is completely covered.

Ideally, the skin should be gently stretched to ensure that it is flat (with no folds or wrinkles) when mounted upon the diffusion cell with the stratum corneum of the skin facing toward the air. An inert support membrane (i.e., a synthetic membrane validated for use with an IVRT method for the same drug product) may be used beneath the skin, as appropriate, as long as it does not impede the diffusion of the drug from the skin to the receptor solution. The donor compartment should then be installed on top of the skin ensuring that the skin is mounted securely in the diffusion cell. The receptor compartment may be filled with receptor solution either before or after mounting of the skin. Any bubbles underneath the skin should be removed by tipping the cell and guiding the bubble up the sampling arm. The thermoregulatory mechanism of the VDC system should then be utilized to equilibrate the skin to the target temperature.

Once the hydration and temperature of the skin has equilibrated (i.e., after 30 min) the skin surface temperature should be measured. The skin surface temperature should be within ±1° of the target temperature (32°) prior to applying the dosage form. The temperature of the receptor solution, or the circulating water bath, or the set point of a dry heat system, or any other component of the system should not be assumed to be the same as the skin surface temperature. Instead, the skin surface

temperature should be directly measured (with an infrared thermometer or a thermocouple), and the thermoregulatory mechanism of the VDC system should be adjusted as needed to produce the target temperature of 32° at the skin surface. The stirrers can be run during the duration of the equilibration to speed up temperature stabilization.

For specific dosing techniques to apply the product to the membrane, refer to *In Vitro Permeation Test, Experimental Design, Dose*.

One approach to sampling involves draining the receptor compartment of all the receptor solution and refilling it completely with fresh receptor solution. Removal of the entire receptor solution volume and full volume replacement of the receptor solution at each time point may provide optimal solubility sink conditions. Although the entire receptor solution volume is sampled, an aliquot is typically used for analysis. Another approach to sampling involves the removal of only a partial amount (i.e., an aliquot) of the entire receptor solution volume, leaving behind a partial volume of the receptor solution at each sampling. This approach can allow the concentration of a compound to increase above a quantification limit during time periods of low flux. However, the sampling of relatively small aliquots of the receptor solution for an IVPT study may introduce anomalous measurements of apparently negative flux in certain regions of the IVPT study and produce flux profiles that are difficult to interpret. Therefore, when sampling partial volumes, it is prudent to maximize the volume of the sample aliquot, in order to minimize the potential for apparent negative flux results.

## VDC Qualification

VDC systems should generally match the description of the equipment described in this chapter. Other designs can be used with sufficient scientific justification so long as they consist of a donor compartment separated from a receptor compartment by a membrane.

VDCs should be individually qualified and uniquely identifiable either by a manufacturer issued serial number or other means. The orifice area for the donor and receptor compartments can be determined using vernier calipers. Receptor compartment volume should be determined with all components (e.g., stir bars) in place. The receptor compartment volume should be determined (gravimetrically or volumetrically) to a precision of 0.01 mL. The nominal receptor compartment volume (e.g., 7 mL) should never be used in place of an accurately determined VDC volume (e.g., 6.89 mL). Using the nominal volume fails to account for variations of the receptor compartment volume due to manufacturing which could affect the accuracy and precision of test results.

## VDC Preventative Maintenance Procedure and Requalification

All VDC systems should be properly maintained and requalified on a regular basis (as described previously). The relevant VDC systems (heating/thermoregulation, water bath and circulation tubes/manifolds, magnetic impeller/stirring, mechanical sampling, etc.) and other components of the VDC system should be kept clean and their operation should be evaluated to ensure that each diffusion cell can maintain the skin surface temperature within the target range (32 ± 1°), maintain the stirring speed within the specified range, and support the performance of the test within the specifications of the test method.

Any stirring device that is not stirring properly with the receptor solution present should be repaired or replaced. Since direct measurement of the stirring device used for testing is not always feasible, the stirring system (e.g., the rotating magnetic impeller) can be evaluated with a surrogate. For example, if stirring within a VDC is done with a 5 mm stir bar, the VDC can be temporarily removed, and a 25 mm stir bar can be placed in the cell block which can be measured to determine the stirring speed.

Sampling devices, such as pipettes, syringes, or automated systems should be evaluated to ensure that they are withdrawing and replacing sample volumes of the receptor solution with sufficient accuracy and precision.

Requalification of automated systems should be performed (e.g., every 6–12 months) based on considerations including the extent of equipment usage, the risk tolerance of the laboratory performing the test, and manufacturer's recommendations. Requalification should also be performed if the system is relocated or undergoes a major repair. In situations where a new VDC unit is incorporated into a previously qualified VDC system (with a set of specific VDC units), the elements of VDC qualification relevant to the new VDC unit should be performed, and the elements of VDC qualification relevant to the (previously qualified) VDC system should be requalified, as relevant (e.g., this may include a requalification of the skin surface temperature control for the new/replacement VDC introduced into the previously qualified VDC system).

## Immersion Cells

For immersion cells, USP *Apparatus 2* should be qualified according to the procedure described in *Dissolution* ⟨711⟩.

The immersion cell system consists of the following components:

- immersion cell which is an inert housing that holds a membrane and donor compartment.
- a smaller version of USP *Apparatus 2* (see ⟨711⟩) with vessel volumes that vary from 50–200 mL; however, 150- or 200-mL vessels are typically used.

An example immersion cell configuration can be seen in *Figure 6* and *Figure 7*.

The components of the immersion cell are listed in *Figure 6*. Formulation is placed in the sample compartment and sealed to prevent leaks by the membrane, washer, and retaining ring. The diameters of the orifices of the donor compartment, which define the dosage delivery surface area for the test, should be sized within ±5% of the specified diameter. The membrane should be held horizontal and faced up toward the paddle. Also, the membrane should be mounted so that it is flat, not wrinkled from overtightening the retaining ring. Donor compartments range from holding 300 mg to 4 g of the formulation; some models are adjustable.

The immersion cell can be used with a smaller version of USP *Apparatus 2* (see ⟨711⟩) with vessel volumes that vary from 50–200 mL; however, the 150- or 200-mL vessels are more commonly used. A flat-bottom variation of the 150- or 200-mL vessel

DocId: GUID-94DCFABD-D687-4F3A-A43B-09CB5D5B0B5E_2_en-US
Document Type: GENERAL CHAPTER
DOI: https://doi.org/10.31003/USPNF_M5695_02_01
@2024 USPC

should be used to avoid the issue of dead space under the cell and standardize the orientation of the immersion cell in the vessel. Flat bottom vessels with a small peak at the base, to keep the immersion cell centered, may also be used.

Use of the 150- or 200-mL vessel with USP *Apparatus 2* requires the following modifications:

- holders for the small-volume vessels (e.g., 200 mL vessels instead of standard 900-mL vessels)
- adapter plate to position the small-volume vessel in the center of the spindle
- smaller size shaft/paddle [2/3 cm (1/4 in)] to fit in the small-volume vessels

## General IVRT Immersion Cell Equipment Set Up

Immersion cell sample compartment volume should be set to a constant volume (compartment volume can be adjusted using an adjustment tool). Alignment of the retaining ring over the sample compartment is ensured using an alignment tool for the specific surface area of the immersion cell.

Observational checks should be performed prior to testing. The donor and receptor compartment orifices should be evaluated for any damage which may affect the orifice area. Damaged cells should not be used.

Before loading the cells and placing the receptor solution in the vessel, set the paddle height, which is 10 ± 2 mm above the surface of the membrane. All other operational parameters, such as level, vibration, wobble, etc., should be set at the same conditions defined for USP *Apparatus 2*. The small-volume condition is qualified by first using the standard *Apparatus 2* setup and *Performance Verification Test, Apparatus 1 and 2* (see ⟨711⟩).

Fill the reservoir dosage area with the sample under test. Ensure that the reservoir is filled to the top to minimize the possibility of air bubble formation between the surface of the sample and the membrane. A uniform surface can be obtained with the aid of a spatula. The typical quantity of sample is between 300 mg and 4 g, depending on the type of immersion cell used. Using forceps or tweezers, remove the membrane from the soaking receptor solution and place it over the top of the sample compartment by rolling it onto the surface to avoid entrapment of air. Ensure that the membrane is free of wrinkles. Assemble the immersion cell components as specified by the device manufacturer. Carefully place the completed assembly into the bottom of the dissolution vessel with the membrane facing up. The appropriate preheated receptor solution may be preloaded in the vessel or can be added after immersion of the immersion cell to start the test.

At the end of the test period, dismantle the cell and examine the contents for anything unusual that could explain any anomalous data (e.g., leaks, bubbles, etc.).

## Immersion Cell Qualification

Immersion cells should match the description of one of the instruments listed in this chapter. Other designs can be used with sufficient scientific justification so long as they consist of a donor compartment separated from a receptor compartment by a membrane.

At a minimum, the orifice area and donor compartments volume must be certified. Additional dimensions should also be certified when possible. Due to the uniformity in manufacturing immersion cells, individual identification of the cells and components is recommended, but not required.

Orifice area for the donor and receptor compartments can be determined using vernier calipers. Volume of the donor compartment can be calculated using the donor compartment diameter and height.

A known volume of receptor solution should be transferred to the vessel when testing by suitably accurate method or device.

Immersion cells should only be used on suitably qualified dissolution apparatus.

Requalification should be performed every 6–12 months, based on equipment usage, risk tolerance, and manufacturers recommendation. Requalification should also be performed if the system is relocated or undergoes a major repair.

## Flow-Through Diffusion Cell (FDC) for IVPT

The components of the FDC are displayed in *Figures 8–10*. The skin is placed above the receptor compartment and kept in place by the donor compartment and a clamping mechanism. The skin should be held in a horizontal plane between the donor and receptor compartments. The donor and receptor compartments should be made out of an inert material. The surface area of the orifices of the donor compartment, which define the dosage delivery surface area for the test, should be sized within ±5% of the nominal value.

The FDC is connected to a pump which provides a constant or pulsation flow of receptor solution that passes through the receptor compartment, into a sample line then collected by a sample vial. Typically, the receptor compartment within the cell holds relatively small volumes (≤0.5 mL) as sink conditions are controlled, in part, by the flow rate of the pump. Flow rates in the range of 2–200 µL/min are common, however some methods may have flow rates in the thousands-of-microliters-per-minute range (i.e., in the milliliter-per-minute range), and the appropriate flow rate for each IVPT method may need to be optimized during method development depending upon the solubility of the drug in the receptor solution, the permeation rates during relevant sampling durations, and the limit of quantification of the receptor sample solution analysis method. The cells are typically placed on the arm of a fraction collector which will align the sample lines with vials or test tubes for each sample point. The FDC is heated to allow the membrane to be maintained at appropriate temperature.

## General IVPT FDC Equipment Set Up

Observational checks should be performed prior to testing. The donor and receptor compartment orifices should be evaluated for any damage which may affect the orifice area. Damaged cells should not be used.

Ideally, the skin should be gently stretched to ensure that it is flat (with no folds or wrinkles) when mounted upon the diffusion cell with the stratum corneum facing the air. An inert support membrane (e.g., a synthetic membrane validated for use with

@2024 USPC

an IVRT method for the same drug product) may be used beneath the skin, as appropriate, as long as it does not impede the diffusion of the drug from the skin to the receptor solution. The donor compartment should then be installed on top of the skin ensuring that the skin is mounted securely in the diffusion cell. The receptor compartment may be filled with receptor solution either before or after mounting of the skin. Any bubbles underneath the skin should be removed by tipping the cell and/or facilitating the removal of the bubble via the outflowing receptor solution. The thermoregulatory mechanism of the FDC system should then be utilized to equilibrate the skin to the target skin surface temperature of 32°.

The FDC is connected to a pump and inflow as well as outflow tubing. When all the FDC for testing are connected to pumps, air bubbles may need to be purged from the receptor compartments. A typical method is the cells are tipped upward, with the outflow sample line raised, while the pump is run at a high speed which facilitates the removal of the air bubble from under the skin via the outflowing receptor solution. The pump can be stopped after all air has been purged from the receptor compartment. The cell should be lowered to the testing position and allowed to equilibrate.

Once the hydration and temperature of the skin has equilibrated (e.g., after 30 min) the skin surface temperature should be measured. The skin surface temperature should be within ±1° of the target temperature (32°) prior to applying the dosage form. The temperature of the receptor solution, or the circulating water bath, or the set point of a dry heat system, or any other component of the system should not be assumed to be the same as the skin surface temperature. Instead, the skin surface temperature should be directly measured (with an infrared thermometer or a thermocouple), and the thermoregulatory mechanism of the FDC system should be adjusted as needed to produce the target temperature of 32° at the skin surface.

Collection vials or test tubes should be weighed when empty to determine the exact volume of sample present after collection has completed.

For specific dosing techniques to apply the product to the skin, refer to the *In Vitro Permeation Test, Experimental Design, Dose*.

Set the pump to the flow rate to be used for testing and align the outflow sample tubes (which should all be the same length) with the first set of vials or test tubes.

After samples have been collected, the vials or test tubes should be weighed to determine the exact volume of receptor solution collected. This volume should be used when determining the total amount of drug present in each sample.

## FDC Qualification

FDC systems should generally match the description of the equipment described in this chapter. Other designs can be used with sufficient scientific justification so long as they consist of a donor compartment separated from a receptor compartment by the skin.

FDCs should be individually qualified and uniquely identifiable either by a manufacturer issued serial number or other means. The orifice area for the donor and receptor compartments can be determined using vernier calipers. It may be appropriate to qualify the lengths of (inert) tubing for each of the flow-through diffusion cells, and their associated dead volumes, to accurately calculate the lag time before a sample elutes through the tubing and is collected.

The flow rate of the pump should be qualified for the rate used during testing. For flow rates in the microliters-per-minute range, it is recommended to extend the sampling time to reduce the effects of droplets adhering to the sample line. If an automated system is used it should be ensured that the sample lines are properly aligned over the vials.

Skin surface temperature should be measured using an IR thermometer. The temperature of the heating block must be set higher than the desired membrane temperature (e.g., 33° for a 32° skin surface temperature).

## FDC Preventative Maintenance Procedure and Requalification

All FDC systems should be properly maintained and requalified on a regular basis (as described previously). The relevant FDC systems (heating and thermoregulation, pumps, tubes, mechanical sampling systems, etc.) and other components of the FDC system should be kept clean and their operation should be evaluated to ensure that each diffusion cell can maintain the skin surface temperature within the target range of 32 ± 1°, maintain the flow rate within the specified range, and support the performance of the test within the specifications of the test method.

The pump should be evaluated to ensure it is working properly. If a peristaltic pump is used, the tubing should be unclamped once the test has completed to prevent unnecessary wear on the tubing, which may cause variation in the flow rate. Peristaltic pump tubing should be replaced at regular intervals to ensure the flow rate remains consistent across all the cells. For automated sampling systems, sample tube alignment should also be checked to ensure that all samples are entirely collected into the vials or test tubes, without leakage, failure to capture samples, or sample loss for other reasons.

Requalification of automated systems should be performed (e.g., every 6–12 months) based on considerations including the extent of equipment usage, the risk tolerance of the laboratory performing the test, and manufacturer's recommendations. Requalification should also be performed if the system is relocated or undergoes a major repair. In situations where a new FDC unit is incorporated into a previously qualified FDC system (with a set of specific FDC units), the elements of FDC qualification relevant to the new FDC unit should be performed, and the elements of FDC qualification relevant to the (previously qualified) FDC system should be requalified, as relevant (e.g., this may include a requalification of the skin surface temperature control for the new/replacement FDC introduced into the previously qualified FDC system).▲ (USP 1-Dec-2023)

## 1. INTRODUCTION

The purpose of this general chapter is to provide a general overview of fundamental principles, instrumentation and application of inductively coupled plasma optical emission spectroscopy (ICP–OES) and inductively coupled plasma mass spectrometry (ICP–MS). It is the companion chapter to *Plasma Spectrochemistry* ⟨730⟩. A glossary of terms is located at the end of this general chapter.

## 2. SAMPLE PREPARATION

Sample preparation is critical to the success of plasma-based analysis and is the first step in performing any analysis via ICP–OES or ICP–MS. Plasma-based techniques are heavily dependent on sample transport into the plasma, and because ICP–OES and ICP–MS share the same sample introduction system, the means by which samples are prepared may be applicable to either technique. The most conventional means by which samples are introduced into the plasma is via solution nebulization. If solution nebulization is employed, solid samples must be dissolved in order to be presented into the plasma for analysis. These samples may be dissolved in any appropriate solvent. There is a strong preference for the use of aqueous or dilute nitric acid solutions, because there are minimal interferences with these solvents compared to other solvent choices. Hydrogen peroxide, hydrochloric acid, sulfuric acid, perchloric acid, combinations of acids, or various concentrations of acids can all be used to dissolve the sample for analysis. Dilute hydrofluoric acid can be used, but great care must be taken when using this acid to ensure the safety of the analyst, and to protect the components of the sample introduction system, specifically: peristaltic pump tubing, the nebulizer, spray chamber, and inner torch tube should be manufactured from hydrofluoric acid-tolerant materials. Proper safety procedures must be followed to protect the analyst, as well. Additionally, alternative means of dissolving the sample can be employed. These include, but are not limited to: the use of dilute bases, straight or diluted organic solvents, combinations of acids or bases, and combinations of organic solvents, or any solvent that is compatible with the instrumentation.

When samples are introduced into the plasma via solution nebulization, it is important to consider the potential matrix effects and interferences that might arise from the solvent. The use of an appropriate internal standard and/or matching the standard matrix with samples should be applied for ICP–OES and ICP–MS analyses in cases where accuracy and precision are not adequate. The use of an internal standard should be considered the rule, rather than the exception, in the case of ICP–MS analyses. In either event, the selection of an appropriate internal standard should consider the analyte in question, ionization energy, wavelengths or masses, and the nature of the sample matrix.

Where a sample is found not to be soluble in any acceptable solvent, a variety of digestion techniques can be employed. These include hot-plate digestion and microwave-assisted digestions, including open-vessel and closed-vessel approaches. The decision regarding the type of digestion technique to use depends on the nature of the sample being digested, as well as on the analytes of interest.

Use acids, bases, and hydrogen peroxide of ultra-high purity, especially when ICP–MS is employed. Deionized water must be at least 18 MΩ. Check diluents for interferences before they are used in an analysis. Because it is not always possible to obtain organic solvents that are free of metals, use organic solvents of the highest quality possible with regard to metal contaminants. Open-vessel digestion is generally not recommended for the analysis of volatile metals, e.g., selenium and mercury. The suitability of a digestion technique, whether open-vessel or closed-vessel, should be supported by spike recovery experiments in order to verify that, within an acceptable tolerance, volatile metals have not been lost during sample preparation. Additionally, it may be necessary to extract the analyte(s) of interest, should a sample not completely dissolve. In such an instance, the validity of the extract must be demonstrated by means of spike and recovery studies.

It is important to consider the selection of the type, material of construction, pretreatment, and cleaning of analytical lab ware used in ICP–OES and ICP–MS analyses. The material must be inert and, depending on the specific application, resistant to caustics, acids, and/or organic solvents. For some analyses, diligence must be exercised to prevent the absorption of analytes onto the surface of a vessel, particularly in ultra-trace analyses. Contamination of the sample solutions from metal and ions present in the container can lead to inaccurate results.

The use of lab ware that is not certified to meet Class A tolerances for volumetric flasks is acceptable if the linearity, accuracy, and precision of the method have been experimentally demonstrated to be suitable for the purpose at hand.

## 3. SAMPLE INTRODUCTION

There are two ways to introduce the sample into the nebulizer: by means of a peristaltic pump, and by self-aspiration. The peristaltic pump is preferred and serves to ensure that the flow rate of sample and standard solution to the nebulizer is the same irrespective of sample viscosity. The speed setting of the peristaltic pump should remain constant throughout an analysis during the time period when readings are being taken by the instrument. In some cases, where a peristaltic pump is not required, self-aspiration can be used.

The purpose of a nebulizer is to generate very small droplets of the sample, with the goal of generating a fine aerosol mist. A wide variety of nebulizer types is available, including pneumatic (concentric and cross-flow), grid, and ultrasonic nebulizers. Micronebulizers, high-efficiency nebulizers, direct-injection high-efficiency nebulizers, and flow-injection nebulizers are also available. The selection of the nebulizer for a given analysis should consider the sample matrix, analyte, and desired sensitivity. Some nebulizers are better suited for use with viscous solutions or those containing a high concentration of dissolved solids, whereas others are better suited for use with organic solutions.

Note that the self-aspiration of a fluid is due to the Bernoulli, or Venturi, effect. Not all types of nebulizers will support self-aspiration. The use of a concentric nebulizer, for example, is required for self-aspiration of a solution.

Once a sample leaves the nebulizer as an aerosol, it enters the spray chamber, which is designed to permit only the smallest droplets of sample solution into the plasma; as a result, typically only 1%–2% of the sample aerosol reaches the ICP, although some special-purpose nebulizers have been designed that permit virtually all of the sample aerosol to enter the ICP.

As with nebulizers, there is more than one type of spray chamber available for use with ICP–OES or ICP–MS. Examples include the Scott double-pass spray chamber, as well as cyclonic spray chambers of various configurations. The spray chamber must be compatible with the sample and solvent and must equilibrate and wash out in as short a time as possible. When a spray chamber is selected, the nature of the sample matrix, the nebulizer, the desired sensitivity, and the analyte should all be considered. Gas and liquid chromatography systems can be interfaced with ICP–OES and ICP–MS for molecular speciation, ionic speciation, or other modes of separation chemistry, based on elemental emission or mass spectrometry.

Ultimately, the selection of sample introduction hardware should be demonstrated experimentally to provide sufficient specificity, sensitivity, linearity, accuracy, and precision for the analysis at hand.

In addition to solution nebulization, it is possible to analyze solid samples directly via laser ablation (LA). In such instances, the sample enters the torch as a solid aerosol. LA–ICP–OES and LA–ICP–MS are better suited for qualitative analyses of pharmaceutical compounds because of the difficulty in obtaining appropriate standards. Nonetheless, quantitative analyses can be performed if it can be demonstrated, through appropriate method validation, that the available standards are adequate (*1*).

## 4. STANDARD PREPARATION

Single- or multi-element standard solutions, whose concentrations are traceable to primary reference standards, such as those of the National Institute of Standards and Technology (NIST), can be purchased for use in the preparation of working standard solutions. Alternatively, standard solutions of elements can be accurately prepared from standard materials, as appropriate, and their concentrations can be determined independently. Working standard solutions, especially those used for ultra-trace analyses, may have limited shelf life, depending on the analyte in question, the type of storage container, the solution's concentration, and the storage conditions. As a general rule, working standard solutions with concentrations less than 10 ppm (w/v) should be retained for NMT 24 h unless stability is demonstrated experimentally. The selection of the standard matrix is of fundamental importance in the preparation of element standard solutions. Spike recovery experiments should be conducted with specific sample matrices in order to determine the accuracy of the method. If sample matrix effects cause excessive inaccuracies, standards, blanks, and sample solutions should be matrix matched, if possible, in order to minimize matrix interferences.

In cases where matrix matching is not possible, an appropriate internal standard or the method of standard additions should be used for ICP–OES or ICP–MS. The method of standard additions may be necessary, even with the use of matrix-matched solutions and internal standards. In any event, the selection of an appropriate internal standard should consider the analytes in question, their ionization and excitation energies, their chemical behavior, their wavelengths or masses, and the nature of the sample matrix. Ultimately, the selection of an internal standard should be demonstrated experimentally to provide sufficient specificity, sensitivity, linearity, accuracy, and precision of the analysis at hand.

The method of standard additions involves adding a known concentration of the analyte element to the sample at no fewer than two concentration levels plus an unspiked sample preparation. The instrument response is plotted against the concentration of the added analyte element, and a linear regression line is drawn through the data points. The absolute value of the *x*-intercept multiplied by any dilution factor is the concentration of the analyte in the sample.

Optimization of the ICP–OES or ICP–MS method is also highly dependent on the plasma parameters and means of sample introduction. Forward power, gas flow rates, and torch position may all be optimized to provide the best signal. Selection of wavelengths or isotopes must be carefully considered. The presence of dissolved carbon at concentrations of a small percentage in aqueous solutions enhances ionization of selenium and arsenic in an inductively coupled argon plasma. This phenomenon frequently results in a positive bias for ICP–OES and ICP–MS selenium and arsenic quantification measurements, which can be

remedied by using the method of standard additions or by adding a small percentage of carbon, such as analytically pure glacial acetic acid, to the linearity standards.

## 5. INDUCTIVELY COUPLED PLASMA (ICP)

The components that make up the ICP excitation source include the argon gas supply, torch, radio frequency (RF) induction coil, impedance-matching unit, and RF generator. Argon gas is almost universally used in the ICP. The plasma torch consists of three concentric tubes designated as the inner, the intermediate, and the outer tube. The intermediate and outer tubes are almost universally made of quartz. The inner tube can be made of quartz or alumina if the analysis is conducted with solutions containing hydrofluoric acid. The nebulizer gas flow carries the aerosol of the sample solution into and through the inner tube of the torch and into the plasma. The intermediate tube carries the intermediate (sometimes referred to as the auxiliary) gas. The intermediate gas flow helps to lift the plasma off the inner and intermediate tubes to prevent their melting and the deposition of carbon and salts on the inner tube. The outer tube carries the outer (sometimes referred to as the plasma or coolant) gas, which is used to form and sustain the toroidal plasma. The tangential flow of the coolant gas through the torch constricts the plasma and prevents the ICP from expanding to fill the outer tube, keeping the torch from melting.

An RF induction coil, also called the load coil, surrounds the torch and produces an oscillating magnetic field, which in turn sets up an oscillating current in the ions and electrons produced from the argon. The impedance-matching unit serves to efficiently couple the RF energy from the generator to the load coil. The unit can be of either the active or the passive type. An active matching unit adjusts the impedance of the RF power by means of a capacitive network, whereas the passive type adjusts the impedance directly through the generator circuitry. Within the load coil of the RF generator, the energy transfer between the coil and the argon creates a self-sustaining plasma. Collisions of the ions and electrons liberated from the argon ionize and excite the analyte atoms in the high-temperature plasma. The plasma operates at temperatures of 6,000–10,000 K, so most covalent bonds and analyte-to-analyte interactions are eliminated.

## 6. INDUCTIVELY COUPLED PLASMA OPTICAL EMISSION SPECTROSCOPY (ICP–OES)

The ICP can use either an optical or a mass spectral detection system. In the former case, ICP–OES, analyte detection is achieved at an emission wavelength of the analyte in question. Because of differences in technology, a wide variety of ICP–OES systems are available, each with different capabilities as well as different advantages and disadvantages. Simultaneous-detection systems are capable of analyzing multiple elements at the same time, thereby shortening analysis time and improving background detection and correction. Sequential systems move from one wavelength to the next (sometimes referred to as slewing) to perform analyses, and often provide a larger number of analytical lines from which to choose.

Modern instruments typically use array detectors as detection devices. Array detectors, including charge-coupled devices and charge-injection devices, have detectors assembled on a chip, making it possible to combine the advantages of both simultaneous and sequential systems. These types of detection devices are used in the most powerful spectrometers, providing rapid analysis and a wide selection of analytical lines. Some instruments may use photomultiplier tubes (PMT's) for detection. PMT's are best-suited for simultaneous analyses; however, the use of PMT's is quickly waning, and array detectors are more commonly found.

The ICP can be viewed in either axial or radial (also called lateral) mode. The torch is usually positioned horizontally in axially viewed plasmas and is viewed end on, whereas it is positioned vertically in radially viewed plasmas and is viewed from the side. Axial viewing of the plasma can provide higher signal-to-noise ratios (better detection limits and precision); however, it also incurs greater matrix and spectral interferences. Axial plasmas normally require the use of a shear gas, which effectively removes the coldest part of the plasma to help reduce self-absorption. Methods validated on an instrument with a radial configuration may not be completely transferable to an instrument with an axial configuration, and vice versa.

Additionally, dual-view instrument systems are available, making it possible for the analyst to take advantage of either torch configuration. The selection of the optimal torch configuration will depend on the sample matrix, the analyte in question, the analytical wavelength(s) used, the cost of instrumentation, the required sensitivity, and the type of instrumentation available in a given laboratory.

Regardless of torch configuration or detector technology, ICP–OES is a technique that provides a qualitative and/or quantitative measurement of the optical emission from excited atoms or ions at specific wavelengths. These measurements are then used to determine the analyte concentration in a given sample. Upon excitation, an atom or atomic ion emits an array of different frequencies of light that are characteristic of the distinct energy transition allowed for that element. The intensity of the light is generally proportional to the analyte concentration. It is necessary to correct for the background emission from the plasma. Sample concentration measurements are usually determined from a working curve of known standards over the concentration range of interest. It is, however, possible to perform a single-point calibration under certain circumstances, such as limit tests, if the method has been validated for sufficient specificity, sensitivity, linearity, accuracy, precision, ruggedness, and robustness.

Because there are distinct transitions between atomic energy levels, and because the atoms in the ICP are rather dilute, emission lines have narrow bandwidths. However, because the emission spectra from the ICP contain many lines, and because "wings" of these lines overlap to produce a nearly continuous background on top of the continuum that arises from the recombination of argon ions with electrons, a high-resolution spectrometer is required in ICP–OES.

The decision regarding which spectral line to measure should include an evaluation of potential spectral interferences. All atoms in a sample are excited simultaneously; however, the presence of multiple elements in some samples can lead to spectral overlap. Spectral interference can also be caused by background emission from the sample or plasma. Modern ICPs usually have background correction available, and a number of background correction techniques can be applied. Simple background correction typically involves measuring the background emission intensity at a baseline level away from the main peak and subtracting this value from the total signal being measured. Mathematical modeling to subtract the interfering signal as a

@2024 USPC

background correction can also be performed with certain types of ICP–OES spectrometers. One simple way to avoid spectral interferences is to select an analytical line that is free of interferences, if possible.

The selection of the analytical spectral line is critical to the success of the ICP–OES analysis, regardless of torch configuration or detector type. Though some wavelengths are preferred, the final choice must be made in the context of the sample matrix, the type of instrument being used or the sensitivity required. Analysts might choose to start with the wavelengths recommended by the manufacturer of their particular instrument and select alternative wavelengths based on manufacturer recommendations or published wavelength tables (*2, 3, 4, 5, 6*). Ultimately, the selection of analytical wavelengths should be demonstrated experimentally to provide sufficient specificity, sensitivity, linearity, accuracy, and precision of the analysis at hand.

Forward power, gas flow rates, viewing height, and torch position can all be optimized to provide the best signal. However, it must also be kept in mind that these same variables can influence matrix and spectral interferences.

The analysis of the Group I elements can pose some challenges. When atomic ions are formed from elements in this group, they assume a noble gas electron configuration, with correspondingly high excitation energy. Because the first excited state of these ions is extremely high, few are excited, so emission intensity is correspondingly low. This situation can be improved by reducing the fractional ionization that can in turn be achieved by using lower forward power settings in combination with adjusted viewing height or nebulizer gas flow, or by adding an ionization suppression agent to the samples and standards.

When organic solvents are used, it is often necessary to use a higher forward power setting, higher intermediate and outer gas flows, and a lower nebulizer gas flow than would be employed for aqueous solutions, as well as a reduction in the nebulizer gas flow. It could be necessary to reduce the peristaltic pump speed, and alter the selection of the spray chamber. When using organic solvents, it could be necessary to bleed small amounts of oxygen into the torch to prevent carbon buildup in the torch.

### 6.1 Calibration

The wavelength accuracy for ICP–OES detection must comply with the manufacturer's applicable operating procedures. Because of the inherent differences among the types of instruments available, there is no general system suitability procedure that can be employed. Calibration routines recommended by the instrument manufacturer for a given ICP–OES instrument should be followed.

### 6.2 Standardization

The instrument must be standardized for quantitation at time of use. Because ICP–OES is a technique generally considered to be linear over a range of 6–8 orders of magnitude, it is not always necessary to continually demonstrate linearity by the use of a standard curve composed of multiple standards. Once a method has been developed and is in routine use, it is possible to calibrate with a blank and a single standard. One-point standardizations are suitable for conducting limit tests, as well as other analyses, on production materials and final products if the method has been rigorously validated for sufficient specificity, sensitivity, linearity, accuracy, precision, ruggedness, and robustness. The use of single-point standardization is also acceptable for qualitative ICP–OES analyses, where the purpose of the experiment is to confirm the presence or absence of elements without the requirement of an accurate quantitation.

An appropriate blank solution and standards that bracket the expected range of the sample concentrations should be assayed and the detector response plotted as a function of analyte concentration, as in the case where the concentration of a known component is being determined within a specified tolerance. The plot of the analyte concentration against the known concentrations of components is usually performed automatically by the instrument.

It is not always possible to employ a bracketing standard when an analysis is performed at or near the detection limit. This lack of a bracketing standard is acceptable for analyses conducted to demonstrate the absence or removal of elements below a specified limit. The number and concentrations of standard solutions used should be based on the purpose of the quantitation, the analyte in question, the desired sensitivity, and the sample matrix. Regression analysis of the standard plot should be employed to evaluate the linearity of detector response, and individual monographs may establish other criteria.

### 6.3 Procedure

It is important to follow the procedure for the instrument parameters, as directed in the individual monograph. The specification of definitive parameters in a monograph does not preclude the use of other suitable operating conditions, and adjustments of operating conditions may be necessary. Because of differences in manufacturers' equipment configurations, the manufacturer's suggested default conditions could be used and modified as needed. Alternative conditions must be supported by suitable validation data, and the conditions in the monograph will take precedence for official purposes. Data collected from a single sample introduction are treated as a single result. This result might be the average of data collected from replicate sequential readings from a single solution introduction of the appropriate standard or sample solution. Sample concentrations are calculated versus the working curve generated by plotting the detector response versus the concentration of the analyte in the standard solutions, which is often calculation directly by the instrument.

## 7. INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY (ICP–MS)

When using the ICP–MS, analytes are detected directly at their atomic masses. Because these masses must be charged to be detected in ICP–MS, the method relies on the ability of the plasma source to both atomize and ionize sample constituents. As is the case with ICP–OES, a wide variety of ICP–MS instrumentation systems are available.

The systems most commonly in use are quadrupole-based systems. Additionally, high-resolution sector field instruments and time of flight-based instruments are available, as are multiple quadrupole systems. Regardless of instrument design or configuration, ICP–MS provides both a qualitative and a quantitative measurement of the components of the sample.

@2024 USPC

Ions are generated from the analyte atoms by the plasma, and ions are then extracted from the atmospheric-pressure plasma through a sampling cone into a lower-pressure zone, ordinarily held at a pressure near 1 Torr. In this extraction process, the sampled plasma gases, including the analyte species, form a supersonic beam, which dictates many of the properties of the resulting analyte ions. A skimmer cone, located behind the sampling cone, "skims" the supersonic beam of ions as they emerge from the sampling cone. Behind the skimmer cone is a lower-pressure zone, often held in milliTorr ranges. Lastly, the skimmed ions pass a third-stage orifice to enter a zone held near microTorr pressures, where they encounter ion optics and are passed into the mass spectrometer. The pressure differences aid in moving the ions along and into the mass spectrometer, which separates the ions according to their mass-to-charge (m/z) ratios. The ICP–MS has a mass range up to 240 atomic mass units.

Depending on the equipment configuration, analyte adducts can form with diluents, with argon, or with their decomposition products. Also formed are oxides and multiply-charged analyte ions, which can increase the complexity of the resulting mass spectra. Interferences can be minimized by appropriate optimization of operational parameters, including gas flows (central, intermediate, and outer gas flow rates), sample-solution flow, RF power, extraction-lens voltage, etc., or by the use of collision or reaction cells, or cool plasma operation, if available on a given instrument. Unless a laboratory is generating or examining isotopes that do not naturally occur, a list of naturally occurring isotopes will provide the analyst with acceptable isotopes for analytical purposes. Isotopic patterns also serve as an aid to element identification and confirmation. Additionally, tables of commonly found interferences and polyatomic isobaric interferences and correction factors can be used, and are often pre-programmed into an instrument.

ICP–MS generally offers considerably better detection limits than ICP–OES, largely because of the extremely low background noise that it generates. This ability is a major advantage of ICP–MS for determination of very low analyte concentrations or when elimination of matrix interferences is required. In the latter case, some interferences can be avoided simply by additional dilution of the sample solution. In some applications, analytes can be detected below the parts per trillion (ppt) level using ICP–MS. As a general rule, ICP–MS as a technique requires that samples contain significantly less total dissolved solids than does ICP–OES.

The selection of the analytical mass to use is critical to the success of the ICP–MS analysis, regardless of instrument design. Though some masses are often considered to be the primary ones, because of their high natural abundance, an alternative mass for a given element is often used to avoid spectral overlaps (isobaric interferences). Selection of an analytical mass must always be considered in the context of the sample matrix, the type of instrument being used, and the concentrations to be measured. Analysts could choose to start with masses recommended by the manufacturer of their particular instrument and select alternate masses based on manufacturer's recommendations or published tables of naturally occurring isotopes (*7*).

Optimization of the ICP–MS method is also highly dependent on the plasma parameters and means of sample introduction. Forward power, gas flow rates, and torch position may all be optimized to provide the best signal. When organic solvents are used, it is often necessary to use a higher forward power setting and a lower nebulizer flow rate than would be used for aqueous solutions. Additionally, when organic solvents are used, it could be necessary to introduce small amounts of oxygen into the central or intermediate gas to prevent carbon buildup in the torch or on the sampler cone orifice. The use of a platinum-tipped sampling or skimmer cone may also be required in order to reduce cone degradation with some organic solvents.

## 7.1 Calibration

The mass spectral accuracy for ICP–MS detection must be in accordance with the applicable operating procedures. Because of the inherent differences between the types of instruments available, there is no general system suitability procedure that can be employed. Analysts should refer to the tests recommended by the instrument manufacturer for a given ICP–MS instrument.

## 7.2 Standardization

The instrument must be standardized for quantification at the time of use. Because the response (signal vs. concentration) of ICP–MS is generally considered to be linear over a range of 6–8 orders of magnitude, it is not always necessary to continually demonstrate linearity by the use of a working curve. Once a method has been developed and is in routine use, it is common practice to calibrate with a blank and a single standard. One-point standardizations are suitable for conducting limit tests on production materials and final products, provided that the method has been rigorously validated for sufficient specificity, sensitivity, linearity, accuracy, precision, ruggedness, and robustness. An appropriate blank solution and standards that bracket the expected range of the sample concentrations should be assayed and the detector response plotted as a function of analyte concentration, which are normally performed by the instrument. The number and concentration of standard solutions used should be based on the analyte in question, the expected concentrations, and the sample matrix, and should be left to the discretion of the analyst.

The method of standard additions should be employed in situations where matrix interferences are expected or suspected. This method involves adding a known concentration of the analyte element to the sample solution at no fewer than two concentration levels. The instrument response is plotted against the concentration of the added analyte element, and a linear regression line is drawn through the data points. The absolute value of the *x*-intercept multiplied by any dilution factor is the concentration of the analyte in the sample. In many instances, the instrument will perform this calculation automatically after being programmed to use the method of standard additions.

## 7.3 Procedure

Follow the procedure for the detection mode and instrument parameters for ICP–MS, as directed in the individual monograph. The specification of definitive parameters in a monograph does not preclude the use of other suitable operating conditions, and adjustments of operating conditions may be necessary. Alternative conditions must be supported by suitable validation data, and the conditions in the monograph will take precedence for official purposes. Because of differences in manufacturers' equipment configurations, the analyst could begin with the manufacturer's suggested default conditions and

https://nhathuoc.org.uk/

modify them as needed. Data collected from a single sample introduction are treated as a single result. Data collected from replicate sequential readings from a single introduction of the appropriate standard or sample solutions are averaged as a single result. Sample concentrations are calculated versus the working curve generated by plotting the detector response versus the concentration of the analyte in the standard solutions. With modern instruments, this calculation is often performed by the instrument.

## 8. GLOSSARY

**Auxiliary gas:** See *Intermediate (or auxiliary) gas.*

**Axial viewing:** A configuration of the plasma for AES in which the plasma is directed toward the spectrometer optical path, also called "end-on viewing."

**Central (or nebulizer) gas:** One of three argon gas flows in an ICP torch. The central gas is used to help create a fine mist of the sample solution when solution nebulization is employed. This fine mist is then directed through the central tube of the torch and into the plasma.

**Collision cell:** A design feature of some ICP–MS instruments. Collision cells are used to reduce interferences from argon species or polyatomic ions and facilitate the analysis of elements that might be affected by those interferences.

**Cool plasma:** Plasma conditions used for ICP–MS that result in a plasma that is cooler than that normally used for an analysis. This condition is achieved by using a lower forward power setting and higher central-gas flow rate, and is used to help reduce isotopic interferences caused by argon and some polyatomic ions.

**Coolant gas:** See *Outer (or coolant or plasma) gas.*

**Forward power:** The number of watts used to ignite and sustain the plasma during an analysis. Forward power requirements may vary, depending on sample matrix and analyte.

**Intermediate (or auxiliary) gas:** Gas used to "lift" the plasma off the surface of the torch, thereby preventing melting of the intermediate tube and the formation of carbon and salt deposits on the inner tube.

**Internal standard:** An element added to or present in the same concentration in blanks, standards, and samples to act as an intensity reference for the analysis. An internal standard should be used for ICP–AES work and must always be used for quantitative ICP–MS analyses.

**Lateral viewing:** See *Radial viewing.*

***m*:** The ion mass of interest.

**Multiply-charged ions:** Atoms that, when subjected to the high-ionization temperature of the ICP, can form doubly or triply charged ions ($X^{++}$, $X^{+++}$, etc.). When detected by MS, the apparent mass of these ions will be ½ or ⅓ that of the atomic mass.

**Nebulizer:** Used to form a consistent sample aerosol that mixes with the argon gas, which is subsequently sent into the ICP.

**Outer (or coolant or plasma) gas:** The main gas supply for the plasma.

**Plasma gas:** See *Outer (or coolant or plasma) gas.*

**Radial viewing:** A configuration of the plasma for AES in which the plasma is viewed orthogonal to the spectrometer optic path. Also called "side-on viewing." See also *Lateral viewing.*

**Reaction cell:** Similar to *Collision cell,* but operating on a different principle. Designed to reduce or eliminate spectral interferences. Used in ICP–MS.

**Sampling cone:** A metal cone (usually nickel-, aluminum-, or platinum-tipped) with a small opening, through which ionized sample material flows after leaving the plasma in ICP–MS.

**Sequential:** A type of detector configuration for AES or MS in which discrete emission lines or isotopic peaks are observed by scanning or hopping across the spectral range by means of a monochromator or scanning mass spectrometer.

**Simultaneous:** A type of detector configuration for AES or MS in which all selected emission lines or isotopic peaks are observed at the same time by using a polychromator or simultaneous mass spectrometer, offering increased analysis speed for analyses of multi-element samples.

**Skimmer cone:** A metal cone through which ionized sample flows after leaving the sampling cone and before entering the high-vacuum region of an ICP–MS.

**Standard additions:** A method used to determine the actual analyte concentration in a sample when viscosity or matrix effects might cause erroneous results.

**Torch:** A series of three concentric tubes, usually manufactured from quartz, in which the ICP is formed.

## 1. INTRODUCTION

This general chapter provides information regarding the theory and acceptable practices for the consistent analysis and interpretation of X-ray fluorescence spectroscopic data. X-ray fluorescence (XRF) spectrometry is an instrumental technique based on the measurement of characteristic X-ray photons caused by the excitation of atomic inner-shell electrons by a primary X-ray source. The XRF technique can be used for both qualitative and quantitative analysis of liquids, powders, and solid materials. Although some vendors supply radioactive isotope-based source instruments, nearly all modern instruments use an X-ray tube as the source.

## 2. PRINCIPLES OF X-RAY FLUORESCENCE SPECTROMETRY

The X-rays produced by an X-ray tube include characteristic lines corresponding to the anode material, and a continuum also known as Bremsstrahlung radiation. Both types of X-rays can be used to excite atoms in a specimen and thus induce X-rays. The intensity of both of these types can be adjusted by the voltage and current settings of the X-ray generator. These parameters can be adjusted to optimize the flux of X-ray photons for each element of interest. Further adjustments, such as the addition of filters in the primary beam, can be used to remove undesirable and potentially interfering tube spectral lines. Secondary targets may be used to produce an excitation X-ray beam that differs from the primary X-ray tube spectrum, with the aim of achieving optimum excitation conditions. Numerous instrument designs with different geometrical configurations, for example, secondary filters and polarization, are used to optimize X-ray detection and reduce background contributions.

Although many variations exist, XRF instrumentation can be divided into two categories: wavelength-dispersive XRF (WDXRF) and energy-dispersive XRF (EDXRF) instruments. The main distinguishing factor between these two technologies is the method used to separate the spectrum emitted by all atoms in the sample according to X-ray photon energy.

The *energy* (or the *wavelength*) of the X-ray photon is characteristic of a given electron transition in an atom, and is therefore *qualitative* in nature. The *intensity* of the emitted radiation is indicative of the number of atoms in the sample, and therefore constitutes the *quantitative* nature of the technique.

# 3. PHYSICS OF X-RAY EXCITATION AND EMISSION

## 3.1 Ionization and the Photo-Electric Effect

The emission of characteristic X-ray radiation results from an electron transition between two inner shells of an atom, after ionization. After, for example, the ejection of an electron from the K-shell, the atom is ionized and the ion is left in a high-energy state, $E_1$, with $E_1$ being equal to the energy required to remove the K-electron from the shell to a situation where it is at rest (no remaining kinetic energy) at infinite distance from the nucleus. This interaction between electromagnetic radiation (a photon) and an atom resulting in an electron being excited is called the *photo-electric effect*. It is typically the largest contribution to absorption of X-rays. $E_1$ thus corresponds to the binding energy of the electron, which is identical to the energy of the atomic level. The excited state has a very limited life span, and will decay rapidly by a transition of an electron from an outer shell to the vacancy in the inner shell. The atom is still ionized, with an electron vacancy in the other shell. Let the energy state after this transition be represented by $E_2$, corresponding to the binding energy of the electron prior to the transition. The energy difference, $\Delta E$, is represented by

$$\Delta E = E_1 - E_2 \text{ [1]}$$

and can be released in two competing processes: the Auger effect, or the emission of a photon. For XRF, obviously the latter is of interest. The energy of the photon emitted is thus equal to $\Delta E$. The binding energies of the inner electrons are not affected by the chemical state of the atom concerned. The atomic energy levels are unique (characteristic) to the element, thus the energy difference between two given levels is also a characteristic. Therefore, the resulting X-ray photon is called a *characteristic* photon. The energy of the characteristic photons is varying in a systematic way with the atomic number $Z$ of the elements, a fact that can be represented using Moseley's law [*1*]:

$$E_{photon} = k(Z - s)^2 \text{ [2]}$$

where $k$ is a constant for a given series (as defined by the shell with the initial electron vacancy) and $s$ is the screening constant. A fairly complete tabulation of the energies of characteristic radiation can be found in the work by Bearden [*2*]. Assume that the initial vacancy was created in the K-shell. After an electron transition from, for example, the L3-shell, the atom still has an electron vacancy, but in the L3-shell, while a photon with an energy $E$ corresponding to

$$E_{photon} = E_k - E_{L3} \text{ [3]}$$

has escaped the atom. The vacancy in the L3-shell can subsequently be filled by an electron from the M5-shell (assuming that this is a high-atomic-number element). This results in a vacancy in the M5-shell that can then decay further. At the end of this cascade, the ion is back in the neutral state.

## 3.2 Scattering

The most important interaction between X-rays and matter is the photo-electric effect, described above. Two other mechanisms are coherent and incoherent scatter.

### 3.2.1 COHERENT SCATTER

Coherent scatter is elastic scattering of electromagnetic radiation by a free, charged particle. It is also known as Thomson scattering. The electric field of the incident photon accelerates the charged particle. This particle will subsequently emit radiation with the same energy as the incident photon, but travelling in a different direction.

### 3.2.2 INCOHERENT SCATTER

Incoherent scatter of a photon is usually called Compton scatter. Compton scatter is inelastic in nature. Both momentum and energy are conserved in the process. After Compton scattering, the electron has acquired considerable momentum (and is excited from the atom), and a photon with a longer wavelength than the incident photon is emitted (see *Figure 1*). The conservation of energy and of momentum leads to a simple relationship between the scattering angle $\Phi$ and the wavelength difference $\Delta\lambda$ between the incident and the Compton scattered photon:

$$\Delta\lambda = 0.00243 \cdot (1 - \cos\Phi) \text{ [4]}$$

*Equation [4]* calculates the wavelength shift in nm. The peaks of Compton scattered radiation are typically broader than those corresponding to characteristic radiation or coherently scattered radiation. The reason is that most X-ray fluorescence

spectrometers do not have a collimated incident beam. The incident angle on the specimen can thus vary significantly. This contributes to wide variation in total scattering angles $\Phi$, leading to variation in $\Delta\lambda$.

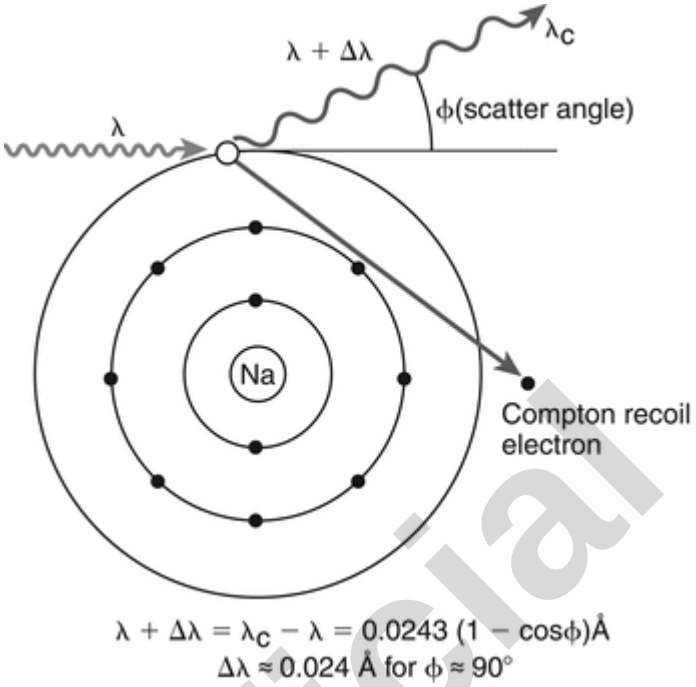

Figure 1. Compton scattering of an X-ray photon; $\Phi$ is the scattering angle (from Willis and Duncan [*3*] with permission).

## 3.3 Conversion between Energy and Wavelength

Photons exhibit a wave-particle duality [*4*]. The energy, *E,* of the "particle" and the wavelength $\lambda$ of the "wave" are related through Planck's constant, *h*:

$$E = \frac{hc}{\lambda} \text{ [5]}$$

where *E* is the photon energy; *h* is Planck's constant; and *c* is the speed of light in vacuum. By substituting these values in *Equation [5]*, and expressing photon energy *E* in keV and wavelength $\lambda$ in nm, the following is obtained:

$$E = \frac{1.24}{\lambda} \text{ [6]}$$

This allows quick and easy conversion between energy and wavelength scales. Note that *shorter* wavelengths correspond to *higher* energies.

Commonly, textbooks designed around WDXRF will use wavelength units for the characteristic radiation. On the other hand, when dealing with EDXRF, the scale of choice is an energy scale with keV as the unit. Photon energy can be converted to photon wavelength and vice versa using *Equation [6]*. The *frequency* of the electromagnetic radiation (which can be calculated using $c/\lambda$ or from $E/h$) is not used when relating to XRF analysis.

## 3.4 The Electromagnetic Spectrum

The X-ray range is typically the spectral range between 0.01 and 10 nm, and it spans 4 orders of magnitude. In practice, however, the range of X-rays commonly analyzed varies from about 0.04 to 1 nm.

The X-ray region of the electromagnetic spectrum can also be expressed in terms of the characteristic radiation of the elements. Most wavelength-dispersive X-ray spectrometers can be equipped to analyze characteristic lines between about 0.04 and 4.4 nm. This allows analysis of all elements in the periodic table from carbon upwards ($Z = 6$). With dedicated analyzers, the elemental range can be extended to include beryllium, although issues with limited specificity and sensitivity severely limit the practical applications for the quantitative analysis of beryllium.

## 3.5 Selection Rules

The transitions in the process described above are governed by quantum-mechanical selection rules. XRF radiation is observed with reasonable probability only from those transitions where

$$\Delta j = -1, 0, +1$$

https://pharmacopeia.cn/v29240/

and

$$\Delta l = -1 \text{ or } +1$$

where *j* and *l* are the usual quantum numbers. The correspondence between shell designations (K, L, M…) and the quantum numbers *n*, *l*, and *m* is given in *Table 1*. This means that in transitions such as K ← L1 and L1 ← M1, both shells with *l* = 0 for initial and final state are forbidden radiative transitions. These transitions, however, can be accompanied by the emission of an Auger electron.

**Table 1. Correspondence between Shell Designations (K, L, M, N) and Quantum Numbers (*n*, *l*, *m*)**

| Shell | Quantum Numbers | | | Number of Orbitals | Subshell Designation | Number of Electrons to Fill Subshell | Total Number of Electrons in Shell |
|---|---|---|---|---|---|---|---|
| | *n* | *l* | *m* | | | | |
| K | 1 | 0 | 0 | 1 | 1s | 2 | 2 |
| L | 2 | 0 | 0 | 1 | 2s | 2 | 8 |
| | 2 | 1 | –1,0,1 | 3 | 2p | 6 | |
| M | 3 | 0 | 0 | 1 | 3s | 2 | 18 |
| | 3 | 1 | 1,0,–1 | 3 | 3p | 6 | |
| | 3 | 2 | –2,–1,0,1,2 | 5 | 3d | 10 | |
| N | 4 | 0 | 0 | 1 | 4s | 2 | 32 |
| | 4 | 1 | 1,0,–1 | 3 | 4p | 6 | |
| | 4 | 2 | –2,–1,0,1,2 | 5 | 4d | 10 | |
| | 4 | 3 | –3,–2,–1,0,1,2,3 | 7 | 4f | 14 | |

After the initial vacancy has been created, the ion is in a highly excited state. After an electron transition, for example, K ← L3, an energy equal to the difference in the binding energies (see *Equation [3]*) between the two shells involved can be released. In the case on hand, this gives rise to the emission of a Kα photon. Photon emission is, however, only one of two competing processes. The other is the emission of an Auger electron. This is the process in which the energy is transferred to another electron, which escapes the ion with a certain kinetic energy $E_{Kin}$. The kinetic energy can be calculated in much the same fashion as the photon energy, using the energy levels from the shells involved. If the energy released from the K ← L3 transition is transferred to an L1 electron, the kinetic energy can be calculated from

$$E_{Kin} = E_{Auger} = E_K - E_{L1} - E_{L3} \text{ [7]}$$

The kinetic energy of the Auger electron is characteristic because it is made up of characteristic quantities. The vacancies created after the emission of an Auger electron can subsequently decay, either by other Auger electrons or by photons.

## 3.6 Fluorescence Yield

The fluorescence yield (symbol $\omega$) is defined as the probability that a vacancy is filled through a radiative transition. For the K-shell this is simply

$$\omega_K = \frac{l_K}{n_K} \text{ [8]}$$

where $I_k$ is the total number of K-shell X-ray photons and $n_k$ is the number of vacancies created in the K-shell. For the L-shell and M-shell, a similar definition applies for each of the subshells, but the number of primary vacancies needs to be corrected for the cascade effects and the occurrence of Coster-Kronig transitions [*5*]. These are nonradiative transitions between subshells having the same principal quantum number. Data regarding values for fluorescence yields can be found in the work by Bambynek et al. [*5*] and Hubbell et al. [*6*].

## 3.7 Counting Statistical Error

The *counting statistical error* (CSE) is the uncertainty in the measurement of the number of photons, which is subject to a Poisson distribution. The distribution of the number of photons can be approximated by a normal distribution, because the number of photons counted is usually sufficiently large. The standard deviation $\sigma_N$ of an intensity measurement of *N* counts is given by the square root of the number of counts:

$$\sigma_N = \sqrt{N} \text{ [9]}$$

Official

DocId: GUID-D67910D6-321A-4250-A903-CE77DF1721D8_2_en-US
DOI: https://doi.org/10.31003/USPNF_M8986_02_01
@2024 USPC

Most measurements in XRF are now expressed as an intensity, *I*, which is simply the ratio of the number of photons counted divided by the measuring time, *t*. The counting statistical error on a measured intensity can be calculated using

$$\sigma_I = \sqrt{\frac{I}{t}} \text{ [10]}$$

This indicates that the counting statistical error on an intensity measurement becomes smaller with longer measurement times. Measuring longer on an XRF instrument (under otherwise constant conditions of measurement) reduces the relative uncertainty on the measurement. This is generally applicable until the resulting CSE becomes comparable to the *overall instrument error*. For high-end instrumentation, the order of magnitude of this overall instrument error is about 0.1% or better. Performing measurements with a CSE significantly lower than the overall instrumental error will not lead to more precise results. The CSE thus imposes a theoretical lower limit to the precision of an X-ray measurement. The contribution of the instrumental errors is added to the CSE to obtain the total error on the measurement.

The *intensity* of a photon beam is calculated from the number of photons collected divided by the time taken for the measurement, expressed in counts per second (cps) or kilocounts per second (kcps).

## 3.8 Detection Limit

The lower limit of detection (LLD) is defined as the concentration that will yield a positive intensity above background intensity with a given confidence level. For analysis near the detection limit, the intensity of the peak will be comparable to the intensity of the background. For example, a net signal that is 3 times larger than the CSE of the background will satisfy this criterion with 99.7% confidence. This intensity can then be converted to a concentration using the sensitivity, *S*, of the spectrometer for the analyte considered:

$$LLD = \frac{k \times CSE}{S} \text{ [11]}$$

where *k* is a factor depending upon the confidence level chosen, *S* is the sensitivity (expressed as net intensity per unit concentration), and *CSE* is the counting statistical error of the determination. Substituting *Equation [10]* where $\sigma_I$ is the CSE of the intensity of the background yields

$$LLD = \frac{k}{S}\sqrt{\frac{I_B}{t}} \text{ [12]}$$

where $I_B$ is the intensity of the background radiation at the analytical line considered. The LLD can be improved by the following:

- Increasing the sensitivity, *S*, of the spectrometer
- Decreasing the intensity of the background, $I_B$
- Increasing the measurement time, *t*.

The third method, increasing the measurement time, seems to be an especially easy way to improve detection limits, but it is limited because long counting times can make the method impractical. Hence, for a given spectrometer configuration, any increase in the sensitivity results in a similar increase of the background intensity. Quadrupling the sensitivity also leads to a 4-fold higher background intensity and an improvement of the LLD by a factor of 2.

## 3.9 Nomenclature of X-Ray Emission Lines

There are different nomenclatures in use involving the designation of the X-ray emission lines. The International Union of Pure and Applied Chemistry (IUPAC) published a systematic notation for X-ray emission lines and absorption edges, based on the energy-level designation. In practice and in many publications, Siegbahn's notation is still dominant. For the most important characteristic lines, the correspondence between Siegbahn and the IUPAC notation is given in *Table 2*.

**Table 2. Correspondence between Siegbahn and IUPAC Notation for the Most Important Characteristic Lines**

| K-series | | M-series | | L-series | |
|---|---|---|---|---|---|
| **Siegbahn** | **IUPAC** | **Siegbahn** | **IUPAC** | **Siegbahn** | **IUPAC** |
| $K\alpha_{1,2}$ or Kα | $K–L_{2,3}$ | $L\alpha_1$ | $L_3–M_5$ | $M\alpha_{1,2}$ | $M_5–N_{6,7}$ |
| $K\alpha_1$ | $K–L_3$ | $L\alpha_2$ | $L_3–M_4$ | Mβ | $M_4–N_6$ |

# 4. SAMPLE PREPARATION

With XRF it is possible to analyze most materials, irrespective of their physical state—whether they are liquids, powders, or solids—with little or no additional sample preparation. A significant advantage is the sample-size capacity: the XRF technique can accommodate large sample masses (usually in the gram weight range), thereby minimizing analytical sampling errors. This enhances the degree to which the sample presented to the spectrometer is representative of the bulk material submitted for analysis. A primary concern is that the final sample surface is flat when it is placed into the measuring position.

Measurements can be performed in a variety of environmental conditions including air, nitrogen, helium, and vacuum. Most X-ray spectrometers typically use vacuum as the medium of analysis, with the exception of some bench-top instruments. Liquid samples are incompatible with vacuum environments, so helium, air, or nitrogen at near-ambient pressure is used. Air and nitrogen readily absorb low-energy X-rays; therefore, their use is generally limited to the analysis of high-energy X-rays. Liquid and powder samples are commonly analyzed in helium, as this significantly lowers the absorption of the characteristic radiation from the specimen, compared with the effects of air or nitrogen.

## 4.1 Liquid Samples

Liquid samples need to be placed into disposable sample cups before being introduced to the spectrometer. The sample cup should be constructed with an appropriate supporting film known to be free of contaminant elements. Suitable films, such as polyester or polypropylene, may have a thickness as low as 1.5 µm. It is also important that the disposable cup is an appropriate size so that it is not viewed by the spectrometer; this ensures that the signals measured are coming from the sample only, and not from the sample cup.

Furthermore, it is important to understand the relationships among the sample matrix, elements of interest, and concept of infinite thickness. In general, when analyzing samples composed of low-atomic-number elements (e.g., organic matrices), it is important to use a thicker sample than when analyzing for the same elements in a heavier (e.g., metallic) matrix. This ensures that the intensity of the X-rays produced (and detected) is only dependent upon the specimen's composition and not also on the quantity of mass analyzed. The thickness at which the intensities are no longer dependent upon the thickness of the specimen presented to the spectrometer is called the *critical thickness* (also known as *infinite thickness*). The critical thickness depends upon the energies of the emission lines considered, the sample matrix, and—to a lesser degree—also on the excitation conditions. In many cases, it may not be possible to obtain infinitely thick samples because of lack of sufficient material or because the critical thickness may exceed sample cup depth; the latter can happen when analyzing liquids that are mainly composed of water or organic compounds. In these cases, correction procedures are applicable. In many cases, a simple modification to the analytical procedure—ensuring that all samples analyzed are of *constant* mass—is sufficient to avoid problems relating to non-infinite thickness.

An additional consideration is variation of the density between samples and standards. The analysis of samples that do not satisfy the requirement of critical thickness will be further complicated by limitations imposed by the geometry of the instrument. The X-rays incident on the sample and the X-rays emitted from the sample form a complex shape in three dimensions that is essentially a cone. The geometry is referred to as a *wedge*. This geometry limits the usefulness of traditional matrix correction because these conventional methods assume a uniform X-ray sampling volume, as opposed to a cone. In most cases, the difference between a cone-shaped geometry and the simpler geometry model is insignificant. This effect is more pronounced when measuring heavy elements in light matrix samples (such as organics). In these cases, it can have severe effects on the calculated concentrations if it is not considered. However, it is possible to include a geometric model of the wedge with a matrix correction technique referred to as the *wedge effect correction* [*7*].

An alternative solution is to have an infinitely thin layer of sample, thereby removing any possible sample interference (matrix effects), as well as the geometrical effect described above. This is not always practical, and in practice it can be difficult to prepare reproducible samples and standards.

## 4.2 Powder Samples

To ensure infinite sample thickness, loose powder samples may be simply weighed and placed directly into a disposable sample cup as described above. For reasons described below, it is often advantageous to lightly pack the powder, using constant pressure and a clean tool. Variations in sample compaction due to manual pressing can be compensated for by using the Compton corrections, which can account for small variations in sample thickness and/or density. These powders can also be ground to a finer particle size (if required) and then pressed to produce a solid pellet.

Preferably, all non-homogenous solid samples, such as coated tablets, should be ground using a grinding device. Similarly, any homogenous and flat sample that has too small an area to cover the instrument optical aperture should also be ground. For softer materials, a pestle and mortar may be sufficient, and for other materials swing mills, ball mills, and/or cryogenic grinding mills may be required. The analyst should ensure that the grinding means do not contribute traces of the analyte elements; this can be ascertained easily by grinding/milling pure compounds and comparing the spectra. By convention, the maximum powder (particle) size should be 50 µm or less. It is, however, more important to have a consistent particle size for both standards and samples. This ensures the homogeneity of the sample and provides an accurate representation of the entire sample, not just the near-surface layer. It is then possible to load a sample into a disposable sample cup, or to press the sample into a pellet. The disadvantage of pressing a sample into a pellet is that it may be necessary to blend a binder (e.g., wax or cellulose) into the sample. The use of such a material must be considered as a possible source of contamination. A number of different binders are available to improve the mechanical properties of the pellet. An advantage of pressing a sample is that it removes air voids, which can absorb X-rays, and thus after pressing, the measurements typically show enhanced light element reproducibility.

Furthermore, it is possible to directly measure a pressed pellet without a supporting film. It is important to note that supporting films can result in signal attenuation, depending upon the element of interest. This effect is commonly seen with

lighter elements such as sodium (Na), magnesium (Mg), and aluminum (Al). The other key advantage is that the pellet ensures a flat surface that is available for reproducible excitation from all angles. In addition, pelletized samples can be measured in vacuum conditions, and this reduces any photon absorption by air or any other gas such as helium (He). Some materials such as lactose and cellulose are self-binding, thus there are no deleterious considerations when preparing a pellet except for the additional time spent on sample preparation. It is important to note that standards and samples must be treated the same from sample preparation through analysis.

Because the majority of pharmaceutical materials have an organic matrix, it is recommended to use a quantity of material corresponding to a thickness of about 1.5 cm. This can be used for both liquids and loose powder samples (provided all samples and standards have a similar matrix composition). Furthermore, any minor sample thickness variations can be compensated for by Compton ratio corrections.

## 5. INSTRUMENTATION

All spectrometers include a source (e.g., X-ray tube), some kind of source filtration mechanism, a sample chamber, and a detector. In addition, wavelength-dispersive systems have a set of collimators and an analyzing crystal. These components, and a few optional items, are discussed below and are further divided according to type of instrument. A diagram of a wavelength-dispersive spectrometer is shown in *Figure 2*. An energy-dispersive spectrometer is simpler in that the collimators and the crystal shown in *Figure 2* are not present, and the detector is pointed directly at the sample.

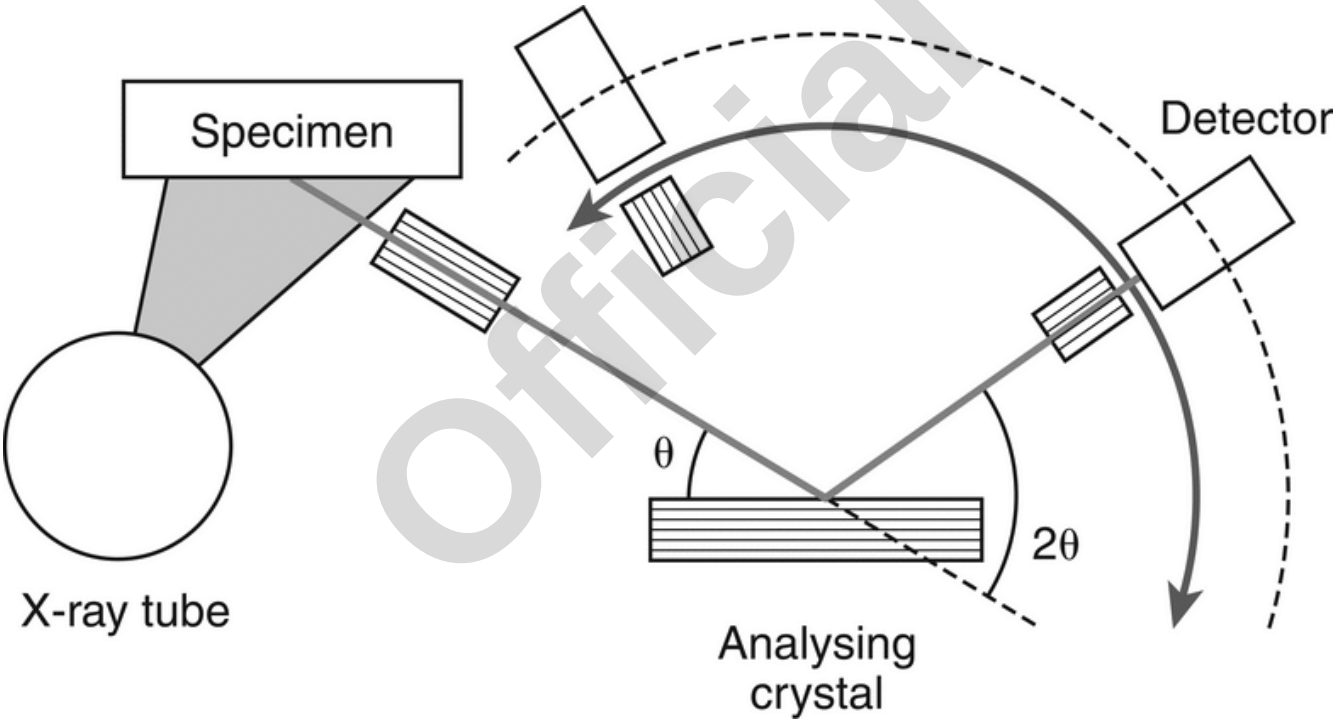

Figure 2. Schematic diagram of a wavelength-dispersive XRF spectrometer, indicating the main components.

### 5.1 X-Ray Tube

The two most important components of an X-ray tube are the filament (used as a cathode) and the anode. The filament is the source of electrons, which are accelerated to the anode material by a strong electric field between filament and anode. Upon impact with the anode, the electrons can gradually lose their kinetic energy, generating heat and a continuous spectrum of X-ray radiation in the process. Alternatively, when the electrons ionize atoms from the anode, the resulting vacancy can decay by emitting characteristic X-ray radiation. The total spectrum of an X-ray tube thus consists of the characteristic lines of the anode element (which is discrete in nature) superimposed on a continuum. Note that the continuum radiation, scattered by the specimen, is the main source of the background observed in XRF analysis.

### 5.2 Primary Beam Filter

Most X-ray spectrometers are equipped with one or more programmable beam filters. These filters are thin metal foils (typically between 50 and 1,000 microns in thickness) that are mounted on a mechanical device that can move a particular filter in the path of the primary beam. The main purpose of the primary beam is to eliminate the characteristic lines of the X-ray tube anode. If for example a rhodium anode tube is used, a significant part of the incident rhodium X-rays will be scattered by the sample. The fraction that is coherently scattered cannot be distinguished from rhodium lines that are created by atoms in the sample. In such a case, to allow for analysis of rhodium in the sample, the primary beam filter is used to prevent

DOI: https://doi.org/10.31003/USPNF_M8986_02_01

characteristic lines from the X-ray tube from reaching the sample. Another application of beam filters is the reduction of background in certain energy ranges. The lower limit of detection can be improved in cases where the background intensity is significant. However, the use of primary beam filters also leads to a degradation of sensitivity, and care must be taken to achieve optimum setup conditions.

## 5.3 Wavelength-Dispersive X-Ray Fluorescence Spectrometry

### 5.3.1 PRINCIPLE OF OPERATION—BRAGG'S LAW

As the name implies, the wavelength-dispersive spectrometers employ an X-ray *monochromatizing* strategy, using *Bragg's Law of Diffraction*, to split the X-ray spectrum into its individual components (or rather, narrow energy bands):

$$n\lambda = 2d\sin\theta \text{ [13]}$$

where $n$ is the order of reflection; $\lambda$ is the wavelength of the photons considered; $d$ is the spacing of the crystallographic planes, and $\theta$ is the angle of incidence (and reflection) with respect to the crystal's plane. In the vast majority of applications, the first order ($n = 1$) is used. For diffraction of photons with wavelength $\lambda$ to occur, the angle $\theta$ must be selected such that the product of $2d\sin\theta$ equals $\lambda$. Bragg's Law can be viewed as the requirement for positive interference of X-ray photons. Consider a monochromatic and parallel beam of X-rays of a specific wavelength $\lambda$ with electrical vectors of equal amplitude in phase along any point of the direction of propagation. This beam is incident on a crystal at an angle $\theta$. The beam is scattered in all directions. However, constructive interference only occurs in those directions for which the phase relationship is conserved. This happens at an angle $\theta$ for incident rays 1 and 2 (see *Figure 3*), for which the path difference $AB + BC$ is equal to an integer number of wavelengths $\lambda$. The integer $n$ refers to the order of the diffraction. The most intense diffraction peaks—and thus the highest measured intensity—can be obtained when $n = 1$ (first order). Higher-order diffractions with $n = 2$, 3, or 4 do occur, but the efficiency is low.

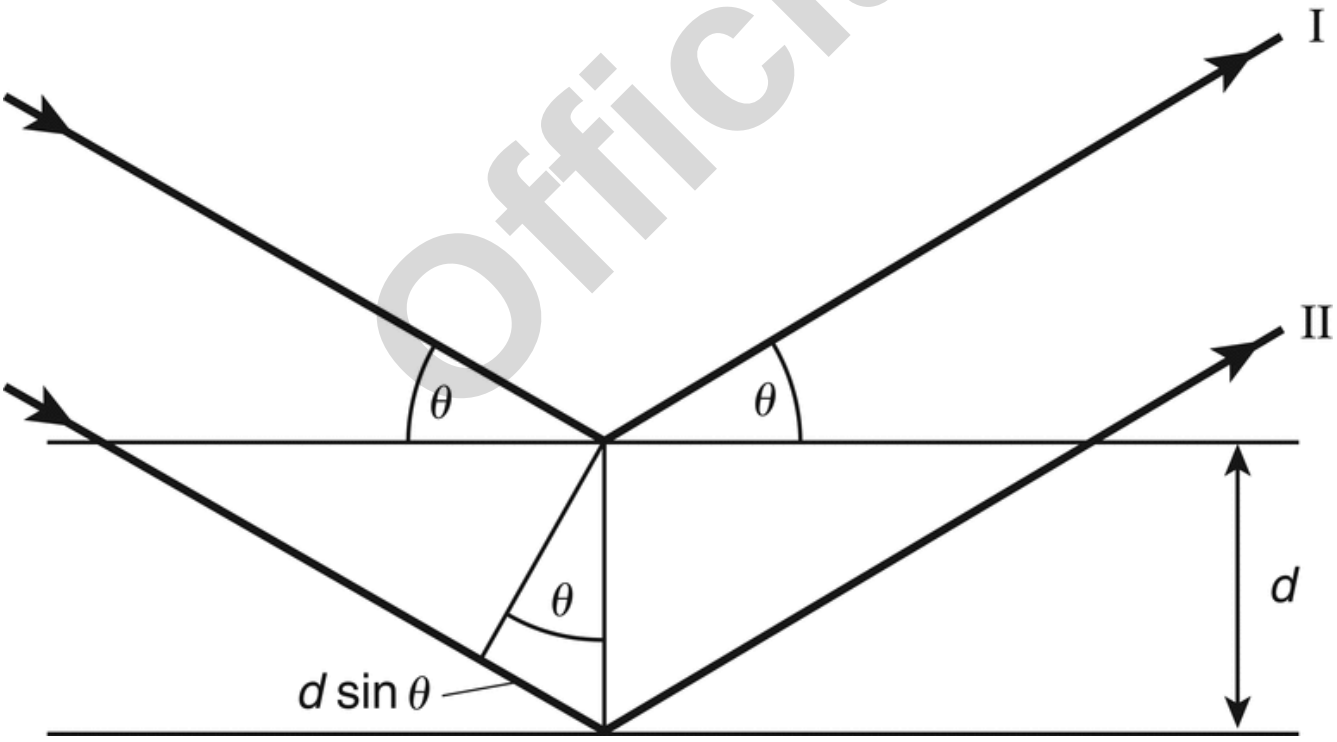

Figure 3. Geometry involving Bragg's law.

### 5.3.2 DISPERSION

The *dispersion* of a WDXRF instrument can be calculated by differentiating *Equation [13]* as follows:

$$\frac{d\theta}{d\lambda} = \frac{n}{2d\cos\theta} \text{ [14]}$$

Dispersion is a measure of the angular separation between peaks corresponding to two different wavelengths. A larger value for the dispersion indicates a larger angular separation, thus a smaller (potential) overlap between photons of slightly different wavelengths. Decreasing the $2d$ spacing is an obvious way to improve on angular dispersion; the $2d$ spacing is, however, determined by the crystal used. For most of the wavelength range, there are at least two crystals available; the one with the

DOI Ref: 1h4ow
DocId: GUID-D67910D6-321A-4250-A903-CE77DF1721D8_2_en-US
@2024 USPC
DOI: https://doi.org/10.31003/USPNF_M8986_02_01

smaller spacing offers the better angular separation, but typically this involves a loss of intensity. Well-defined crystals with known *2d* spacing are used as monochromators. A list of commonly used crystals appears in *Table 3*.

**Table 3. Commonly Used Monochromators in WDXRF**

| Crystal | Name | Reflection Plane | *2d* Spacing (nm) | Element Range |
|---|---|---|---|---|
| LiF(220) | Lithium fluoride | (220) | 0.2848 | V-U |
| LiF(200) | Lithium fluoride | (200) | 0.4028 | K-U |
| Ge | Germanium | (111) | 0.6532 | P, S, Cl |
| PE or PET | Pentaerythritol | (002) | 0.8742 | Cl-Al |
| TlAP | Thallium acid phthalate | (1010) | 2.575 | Mg-O |
| | Layered synthetic microstructure | | 3–12 | Mg-Be |

*Dispersion* only describes the *angular separation* between two peaks; it does not describe the width of the peak, which is typically referred to as resolution (in other forms of spectrometry) and is calculated from the full width of the peak at half height. The actual resolution from the detector system has no discernible influence on peak separation.

The choice of crystal and angle of the detector relative to the crystal determine which elemental X-ray lines may enter the detector. The main task of the detectors in WDXRF is reduced to counting photons with a known energy, as the use of the monochromator crystal thus separates the selection of the wavelength of the photons from the actual counting.

### 5.3.3 DETECTORS FOR WDXRF

**Gas-filled detectors:** Gas-filled detectors consist of a cylindrical volume filled with a noble gas such as argon (Ar) or krypton (Kr), and a wire running through the center of the detector (see *Figure 4*).

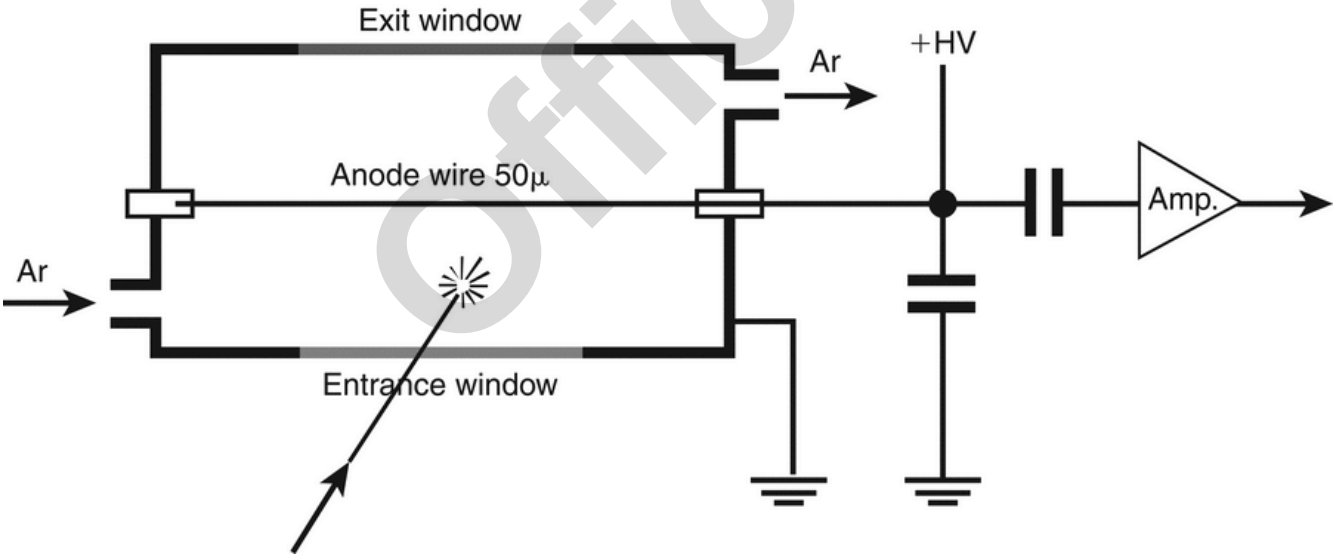

Figure 4. Schematic diagram of a flow counter.

An incoming photon (represented by its energy $h\nu$) can remove an outer (valence) electron of one of the inert gas atoms. For an argon-filled detector:

$$Ar \xrightarrow{h\nu} Ar^{+} + e^{-} \text{ [15]}$$

The energy required for the ionization, $e_i$, depends on the element; for argon (Ar), about 26 eV is required to create an ion-electron pair. The total number of such primary ionizations, $n_p$, caused per incident photon with energy, $E$, can then be calculated using

$$n_p = \frac{E}{e_i} \text{ [16]}$$

The electric field between the wire and the outer body will cause the electrons to accelerate toward the anode wire. The positive ions, on the other hand, will migrate toward the housing. The resulting electric field gives rise to a cascade of ionization events. The result of this cascade effect is as follows: for each of the individual electrons originally created by the incident photon,

DOI: https://doi.org/10.31003/USPNF_M8986_02_01

many more electrons are finally collected at the anode wire (this is called the *gas amplification factor* and is typically around $10^4$ to $10^6$), creating a voltage drop that is then processed by the counting electronics.

The entrance window should absorb as few of the incoming photons as possible, because any photons absorbed into the window are lost from the counting circuit, thus reducing the sensitivity. Large windows with low attenuation for long wavelengths can be made from stretched polymers, such as polyethylene or polyester, coated with a conductive material at the interior of the counter to provide for a homogeneous electric field. Such thin windows need a mechanical support to withstand the pressure difference caused by the vacuum in the spectrometer chamber. The collimator is usually preferred as a support because it will also reduce the amount of radiation that is scattered from the crystal or the multilayer.

On the other hand, the polymer windows have small pinholes. These pinholes allow the counting gas to gradually leak away. Such detectors would have only a very short lifetime before the counting gas leaked away or became so contaminated that it would effectively render the detector useless. To compensate for the leaks, a constant flow of counting gas is used, the excess of which is vented away out of the spectrometer chamber; such detectors are therefore called *flow proportional counters* (or gas flow detectors). Only a fraction of this flow is leaking into the spectrometer chamber, whereas the remainder is leaving the detector through a tube and is vented into the atmosphere. It is essential for the overall stability of the spectrometer that the pressure and temperature of the gas are kept constant. Hence, most instruments are equipped with a gas-density stabilizer.

Gas flow proportional counters are the preferred counters for the detection of X-rays with very long wavelengths in wavelength-dispersive spectrometers. The counting efficiency of the gas-filled detectors is determined by the absorption in the entrance window and the capture efficiency (absorption of the incident radiation) of the counting gas for the wavelengths of interest. The capture efficiency depends on the path length available within the detector, the composition of the counting gas, and its pressure. The absorption properties of the window determine the efficiency of the detector at the long wavelengths, whereas the absorption properties of the gas determine the efficiency at the shorter wavelengths. Considering the typical dimensions, the nature of the gas, and the pressure, the absorption of the gas as function of the wavelength of the incident photon can be calculated. Around wavelengths of 0.2–0.3 nm, about half of the incident photons are not absorbed, reflecting a low efficiency. This is the main reason why sequential WDXRF instrumentation is equipped with more than one detector.

**Scintillation counter:** WDXRF instruments are generally fitted with a scintillation counter for the detection of shorter wavelengths for which the gas proportional counter is less efficient. The operation of the scintillation counter is based on two distinct stages: a scintillation crystal and a photo-multiplier tube (see *Figure 5*).

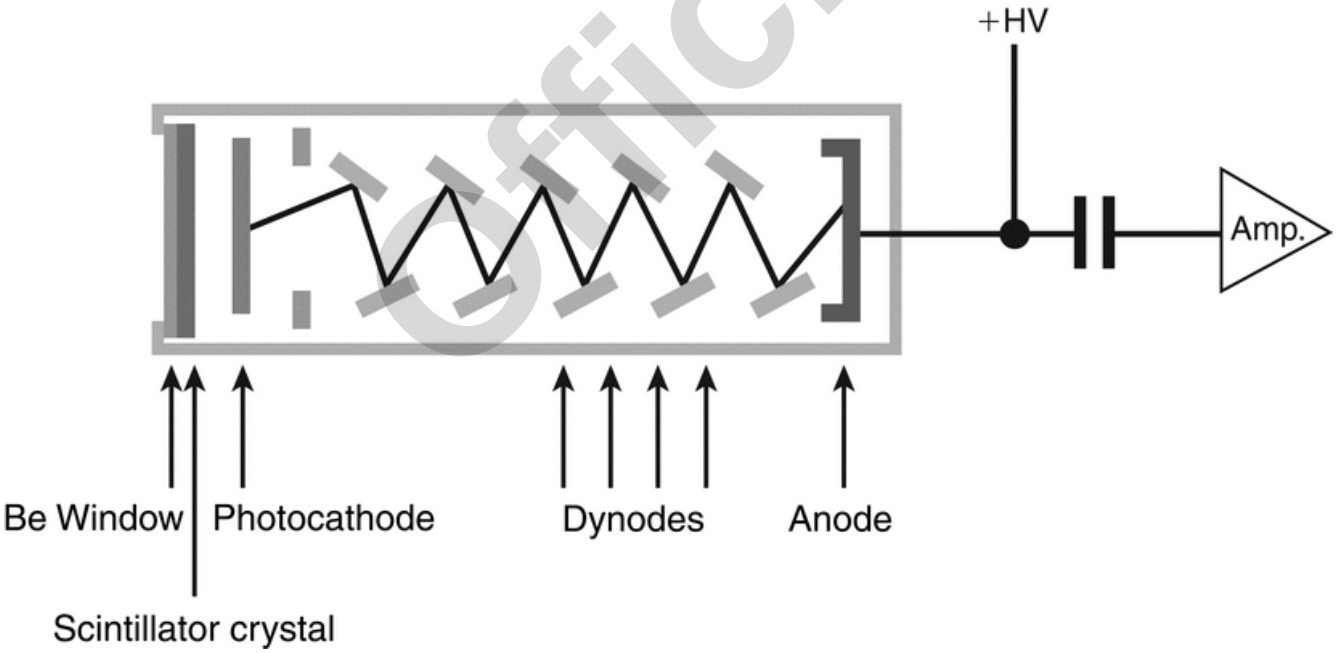

Figure 5. Schematic diagram of a scintillation counter.

In the first stage, the incoming photon is absorbed by a “scintillator crystal”. A scintillator is a material that emits light when it is excited by ionizing radiation, such as X-rays. Many different scintillator materials exist, with different properties regarding radiation hardness, operating temperature range, decay times, optical properties, and other properties. The most commonly used scintillator material in WDXRF instruments is a sodium iodide (NaI) crystal, doped with thallium (Tl). The scintillating crystal is optically coupled to a “photo-multiplier”, which consists of a photo-cathode and a series of dynodes. In the second stage, upon impact by a photon, the photo-cathode releases free electrons. These are then accelerated toward a series of dynodes. At each dynode, the impact of the electrons generates more electrons. If 10 dynodes are used, the total amplification provided is about a factor of $10^6$.

The counting efficiency of the scintillation counter is largely determined by the thickness of the sodium iodide thallium [NaI(Tl)] crystal. The counting efficiency for a 3-mm-thick crystal is better than 99% for wavelengths of 0.05 nm and longer. This allows the detection of high-energy photons such as Sn Kα with high efficiency.

The production of light photons is higher in the scintillation detector than the number of electron-ion pairs created in a flow counter; this should lead to a better resolution. However, this advantage is cancelled out by the low yield of photo-electrons

https://pharmacopeia.com/
Printed on: Fri Jan 05 2024 06:37:18 AM(EST)
Printed by: USP NF
Do Not Distribute

by the photo-cathode, where less than 1 electron is freed for every 10 incident light photons. Compared to the gas-filled counters, the resolution of a scintillation counter is worse.

The use of the WDXRF technique (typically with power in the kW range) for organic matrix sample analysis is limited because heat generated by the X-rays may be sufficient to induce significant specimen alteration, such as browning or burning of the sample surface. Furthermore, even if the sample is measured for a very short time by WDXRF, the heat imparted to the sample surface may induce the loss of volatile elements [e.g., mercury (Hg) and selenium (Se)]. The WDXRF technique is, however, perfectly suited to measure inorganic materials that can withstand elevated temperatures. Examples of common inorganic materials that are suitable for WDXRF measurement are calcium carbonate ($CaCO_3$) and sodium chloride (NaCl).

## 5.4 Energy-Dispersive X-Ray Fluorescence Spectrometry

### 5.4.1 PRINCIPLE OF OPERATION

The energy-dispersive XRF technique typically involves simultaneous detection of photons of different energies that are emitted by the atoms in the sample. The detector determines both the photon's energy and the intensity, which is the number of photons per unit of time. To provide adequate resolution for distinguishing between characteristic lines and overlapping lines from other elements, most EDXRF instruments are equipped with a high-resolution detector and a multi-channel analyzer (MCA). The MCA essentially provides a histogram representation of the spectrum. High-end instruments use sophisticated calculation (deconvolution) algorithms to identify the peaks (i.e., to establish the presence of certain elements) and to obtain intensity data from the histogram. EDXRF is theoretically a simultaneous technique because it measures the complete spectrum in a single counting phase. However, significant improvements in performance can be achieved by measuring the sample using two or more different excitation conditions, each optimized for a certain energy range.

Compared to WDXRF, the design of an EDXRF spectrometer is much simpler because it lacks a high-precision goniometer and the associated collimators. The positioning of the detector relative to the sample is very simple; the most obvious requirement is that there should not be a direct path between the anode of the X-ray tube through the entrance window of the detector onto the active body. Distances between the X-ray tube window and specimen, and between the specimen and detector entrance window, can be small, in the order of 1–2 cm. Furthermore, as only limited collimation is required, the angle of acceptance of the photons from the specimen can be quite large. Low-power X-ray tubes with ratings up to 50 W are used. Because of the inherent simplicity of their design, wide variation of systems with varying capabilities exists. A typical spectrum on an energy-dispersive spectrometer is shown in *Figure 6*. The energy on the horizontal axis increases from left to right. The peak shape is nearly perfect Gaussian.

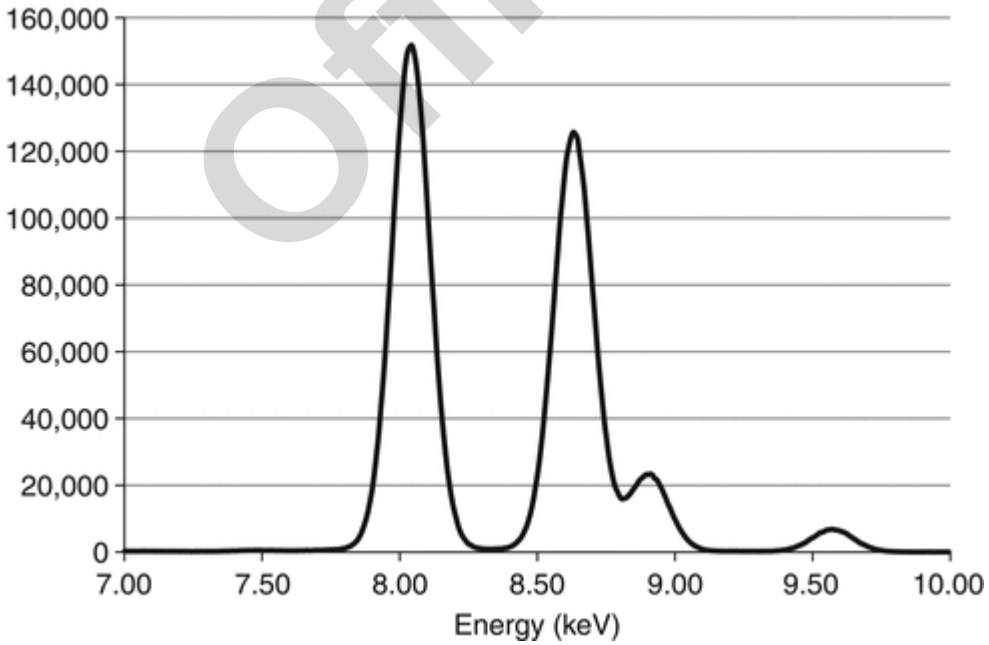

Figure 6. Energy-dispersive spectrum of a brass specimen. From left, the peaks are due to Cu Kα, Zn Kα, Cu Kβ, and Zn Kβ. The horizontal axis is energy and the vertical axis is in counts per channel. This spectrum was recorded at 75,000 cps with 50 kV and an Ag primary filter to reduce the background. The full width at half maximum (FWHM) is about 165 eV at the Cu Kα peak.

### 5.4.2 DETECTORS

The resolution of the detector system determines both the peak width (expressed as FWHM) and the peak separation. Systems may be equipped with gas-filled, solid-state, or semi-conductor detectors. The three most common solid-state detectors used are the following:

- Liquid nitrogen-cooled silicon-lithium drifted Si(Li)

Official

https://pharmacopeia.com/
Printed on: Fri Jan 05 2024 06:37:18 AM(EST)
Printed by: USP NF
Do Not Distribute

- Liquid nitrogen-cooled germanium detectors, such as the LeGe and HPGe
- Detectors based on intrinsic silicon, such as the PIN (positive, intrinsic, and negative) detector and the SDD (silicon drift detector).

The first two types of detectors allow for high photon-capture efficiency but require relatively bulky, well-insulated containers (Dewar) for the liquid nitrogen. These detectors are generally rather large, which improves sensitivity, and thick, which improves capture efficiency for high-energy photons. They are typically found on floor-standing equipment. Bench-top systems are equipped with detectors that are based on intrinsic silicon. These types of detectors do not require cooling to temperatures as low as the other two categories; temperatures between –25° and –15° are acceptable. Peltier-cooling or electro-thermal cooling is sufficient to reach those temperatures. The detectors are smaller and thinner than their bulk siblings. Older equipment might still be using so-called PIN detectors, but all of the newer equipment tends to be equipped with an SDD. The SDDs have much better resolution and can be used at much higher intensities than the PIN detectors, which are typically limited to about 220 eV at Mn Kα. The SDDs combined with state-of-the-art electronics have a resolution (expressed as FWHM) of better than 145 eV at Mn Kα. This is comparable to liquid nitrogen-cooled semi-conductor detectors. A word of caution is required as the resolution worsens with increasing count rate or intensity. Most manufacturers therefore specify resolution at an impractical, low count rate of 1,000 or 2,000 cps.

## 5.5 Polarized X-Ray Spectrometry

### 5.5.1 PRINCIPLE OF OPERATION

The most elaborate EDXRF spectrometers use polarization or a secondary target to modify the spectral distribution of the X-ray source; the aim is to reduce, or ideally eliminate, the intensity of the continuum background. This effort is a logical consequence of *Equation [3]*. Due to the fact that the major component of the background is scattered tube radiation, one method of preventing radiation from the X-ray tube from reaching the detector system is the use of polarized radiation. These systems have applications in the analysis of, for example, residues of palladium (Pd) catalyst in some pharmaceutical ingredients.

### 5.5.2 POLARIZED RADIATION AND POLARIZING TARGET

The orientation of the electric field vector, *E*, of the photons generated in an X-ray tube is random but always perpendicular to the direction of propagation. Using a Cartesian coordinate system, with the *z*-direction coinciding with the direction of propagation, the two components of the electric field vector in the *x*-direction (denoted by $E_x$) and *y*-direction ($E_y$) are identical and obey the following relationship:

$$E_x^2 = E_y^2 = \frac{1}{2}E^2 \quad [17]$$

The component along the axis of propagation, $E_z$ is zero; this is because electromagnetic radiation is a transverse wave. After *coherent scattering* in the *yz* plane, the field vector of photons traveling in the *y* direction, $E_y$, is also reduced to zero. This beam of photons, all with their electric field vector parallel to the *x*-direction, is directed at the sample and interacts in the usual way. The photons cause ionizations and can be scattered, but they cannot be scattered in the direction along the *x*-axis, because the electric field vector cannot have a component parallel to the direction of propagation. If the detector is now placed somewhere along the *x*-direction (still in the same frame of reference), the background is significantly reduced because the main contribution (i.e., scatter from the incident radiation) is absent. The process is inefficient because there is no active polarization; it is entirely achieved by suppressing one component of the electromagnetic wave, thereby significantly reducing its intensity. Therefore, high-power X-ray tubes are used.

### 5.5.3 SECONDARY TARGETS

The use of secondary targets in energy-dispersive spectrometry has been widespread for high-power instrumentation. The aim is to reduce the background, thus improving the lower limit of detection. When *electrons* decelerate, they generate Bremsstrahlung of a continuous nature; however, photons do not generate Bremsstrahlung. The principle behind an instrument equipped with secondary targets is to use a classic X-ray tube to provide a beam of X-rays (including the troublesome continuum) and direct it at a secondary target, which is typically a metal. The radiation emanating from the secondary target will consist of the very intense characteristic radiation corresponding to the nature of the target and scattered continuum. The intensity of the scattered background is relatively low, especially when the target material is a metal of medium-to-high atomic number. There is no additional continuum created by the incident photons, but a tiny contribution to background radiation is created by the high-energy photo-electrons. The radiation from the secondary target is directed at the sample for excitation purposes. The spectrum from the sample is composed of the characteristic lines from the elements present, the scattered characteristic radiation from the secondary target, and the concomitantly scattered continuum from the tube. The latter contribution is very weak because it has been subjected to two scattering events, one at the secondary target and another one at the sample. If the instrument is equipped with a selection of secondary targets, then significant improvements in the lower limit of detection can be obtained. The two-step process requires a higher-power X-ray tube to get the same flux at the sample when compared to direct excitation, so it is generally not incorporated into bench-top instrumentation. Currently, secondary targets are often used in combination with polarization targets. This combination is straightforward, because both types of targets can use the same geometrical arrangement.

### 5.6 Total Reflection X-Ray Fluorescence Spectrometry

Another variety, *total reflection X-ray fluorescence* (TXRF, also sometimes abbreviated to TRXRF), specializes in the analysis of infinitely thin and extremely homogenous samples derived from liquids. Typically, TXRF instrumentation employs an X-ray source, which is directed at the sample under a very small angle with respect to the surface. The detector is typically placed above the sample at a 90° angle. The TXRF technique commonly uses internal standards (mixed into the unknowns) and geometrical relationships to determine elemental concentrations.

## 6. QUALITATIVE XRF ANALYSIS

This section applies to both WDXRF and EDXRF.

### 6.1 X-Ray Spectra

Qualitative analysis by means of X-ray fluorescence is relatively simple because the characteristic line spectra of the elements are simple and are not affected by chemical bonding; i.e., these spectra are truly elemental. For qualitative (and quantitative) analysis, the main lines are those from the K- and L-series. The K-lines result from electron transitions after one of the K-electrons has been expelled. Due to quantum mechanical selection rules, not all transitions are allowed. Transitions from the L-shell to the K-shell are limited to transitions involving L2 and L3, as radiative transitions between the L1-shell and K-shell are forbidden. These transitions are the most probable, leading to the most dominant line in the spectra. For most elements, the energy difference between the L2-shell and L3-shell is rather small (in the order of a few eV), so the emitted lines are typically not separated and simply considered a doublet. Radiative transitions from M- and N-shells to the K-shell are also occurring. These give rise to a more complex part of the K-spectrum. In practice, however, only the $K\beta_{1,3}$ doublet (resulting from transitions between M3 and K and M2 and K) is of importance. The relative intensity between the Kα and the Kβ varies from 1 in 1,000 for sodium (Na) to 1 in 6 for plutonium (Pu), with the Kα always being the most intense line of the series.

The Kα-line is generated by an electron transition from an electron in the L3 shell, following the removal of a K-shell electron. The Kα-line is the most dominant line in an element's series. The K electrons of an element, however, have the highest binding energy of all electrons in the atom, and thus are only excited by high-energy incident photons. This is generally not a problem for the low- and middle-atomic number elements, but excitation of the K-lines of elements with atomic numbers above 50, for example, might not be possible, as the excitation potential is higher than the maximum operational voltage on most X-ray tubes.

Whereas the K-line spectra are typically limited to two lines only, the situation for the L-series spectra is more complicated. For lead (Pb), a total of 46 L-lines are listed in Bearden [*2*]. Many of these are weak, or are doublets. For qualitative analysis, not all of these lines are to be considered. In all cases, it is important to realize that if the Kβ is visible, then the Kα must be visible too and must have a higher intensity.

### 6.2 Qualitative Analysis

Qualitative analysis typically consists of a few simple steps. After the spectra have been collected, the background is subtracted. This background subtraction can be done in a separate step, or it can be done in conjunction with a peak search algorithm. A fraction of these photons propagate in the direction of the analyzing crystal (WDXRF) or directly to the detector (EDXRF). Next, a peak search is performed, and finally, these peaks are identified, i.e., each is attributed to a particular element. Efficient algorithms for qualitative analysis look for the presence of each element, rather than trying to identify each peak. This is different from X-ray diffraction, where each peak is checked for a match with a phase. In this method, the peak search is performed first. Then, for each element, the presence of the $K\alpha_{1,2}$-doublet is verified. If this line is found in the spectrum, then the weaker lines of the same series ($K\beta_{1,3}$ and $K\beta_2$) are investigated. Note that all characteristic lines in the same series should appear, except in cases where the intensity of a weaker line is similar to the intensity of the background. For elements with higher atomic numbers where the K-lines are not excited (or not detected due to limitations in detection hardware) the process starts with the L-line spectra. The intensity ratios of, for example, Kα to Kβ are listed in several databases [*8*,*9*]. The tabulated ratios are for the "isolated" atom; they reflect the intensities as obtained from an atom without any matrix effects. These ratios can be corrected quite easily for matrix effects, even in the case of overlapping lines. Only elements that are present at trace levels (with intensities comparable to the standard deviation of the background intensity) are usually deemed "not present". Note that, in principle, line interference between elements is not much of a problem in qualitative analysis; this is due to the fact that in qualitative analysis, many more data points that cover alternative lines are available. Hence, establishing the presence of elements is not impacted as much as one would suspect. Also, in energy-dispersive spectrometry, where the line overlap is most severe, adequate corrections can be performed because the peak shape is rather well known.

## 7. QUANTITATIVE XRF ANALYSIS

### 7.1 Selection of Analytical Line

The characteristic emission spectra of most elements contain several lines. The choice of an analytical line for a given element is largely dependent on three factors: the concentration of the element in the sample, the potentially interfering lines, and the excitation capabilities of the spectrometer. In most cases, the Kα emission line of an element is preferred. When the excitation of the K-lines is not possible due to limitations of the tube and/or generator, the use of L-lines, with their lower energy, is necessary. Use of the Lα-line (when the Kα-line is not excited) does not involve much of a detriment because for those elements,

DOI: https://doi.org/10.31003/USPNF_M8986_02_01
@2024 USPC

the intensity of the L-lines is quite high. Also, the detection efficiency of the L-line photons is then much higher than that of the high-energy K-lines of the same element. For elements with high atomic numbers (i.e., Z larger than about 72), the Lβ offers a very good alternative to the Lα and these lines have comparable sensitivities.

In general, on a typical WDXRF instrument, all elements with atomic numbers up to 56 are measured on their Kα-line. For elements with higher atomic numbers, the Lα-line is used. For EDXRF spectrometers equipped with SDD-using generators (and tubes) with a maximum voltage of at least 30 kV, K-lines are available to measure for elements up through about Z = 47; the L-line spectra are used for all elements with higher atomic numbers. The exact point at which the switch over occurs between the K-line and the L-line spectra depends on factors such as the application and the anode material of the X-ray tube used.

Quantification procedures are carried out using routine spectroscopic techniques involving the measurement of blanks and standards of varying elemental concentrations. The measured intensities are then corrected for background and for line overlap, if required. In a number of cases, a straightforward linear relationship between the intensity of the analyte and its concentration can be established. This is especially the case with low concentrations in a constant matrix. In the more general case, however, corrections for matrix effects are required. Matrix effects are not the limiting factor in the precision of the final analysis, but they must be accounted for in order to obtain an accurate measurement.

## 7.2 Matrix Correction Techniques

### 7.2.1 ORIGIN OF MATRIX EFFECTS

XRF is typically applied to condensed samples, without resorting to dissolution of the sample in an abundance of acids or other solvents. Thus, the samples remain concentrated, in contrast to many other techniques. Because of this, the XRF technique is prone to matrix effects, in that the relationship between the intensity of a particular analyte and its concentration is generally not as simple and straightforward as with diluted specimens. With the latter, this relationship between concentration and intensity is often expressed as a straight line. However, the presence of other elements at high concentrations can cause deviations of this straight-line relationship. The physics of X-ray emission and detection is well understood and relatively simple for bulk materials, and this provides a solid theoretical basis for a mathematical description of matrix effects. Matrix effects can thus be described accurately and correctly using a variety of mathematical techniques, and several methods have been developed to address them. Two main matrix effects can be distinguished and are discussed below—absorption and enhancement.

**Absorption:** Absorption as a matrix effect occurs when the matrix elements and the analyte element have different absorption properties for the characteristic radiation of the analyte. If the mass attenuation coefficient of one or more of the matrix elements is larger than the mass attenuation coefficient of the analyte, the matrix will absorb more of the analyte radiation than expected and the measured intensity of the analyte will be lower. This results in a concave calibration curve. If, on the other hand, the absorption of the matrix elements is lower, a higher intensity of the analyte will be measured and a convex calibration curve will be observed. Absorption as a matrix effect can be large, reducing the intensity by as much as 100% (and more) or "increasing" it by as much as 10%, depending upon the analyte and matrix elements. The magnitude of the absorption effect depends on the wavelength of the analytical line considered and the composition of the specimen. In a given specimen, the absorption effect can be significant for the characteristic line of one analyte and rather insignificant for another. The absorption effect can also differ significantly for the same analyte when measured on two different characteristic lines.

The three processes that cause absorption are the photo-electric effect, the coherent scatter, and the incoherent scatter. In general terms, photons with a given energy will be absorbed more with increasing atomic number of the absorbing element. Also, the absorption by a given element decreases in a steady, smooth manner when the photon energy increases. However, when the photon energy exceeds the binding energy of electrons in an inner shell, the photo-electric effect (see *3.1 Ionization and the Photo-Electric Effect*) causes an increase in absorption. This leads to discontinuities in the absorption curve at energies corresponding to the binding energy of the electron levels. These discontinuities are called absorption edges; the energy at which the absorption edge occurs is equal to the binding energy of the electron shell concerned.

**Enhancement:** *Enhancement* as a matrix effect is the process whereby the characteristic radiation of matrix elements is absorbed by atoms of the analyte, subsequently causing characteristic radiation of the analyte. The intensity of the analyte is thus enhanced, which leads to concave calibration curves. For a given analyte, all characteristic lines from the same series are enhanced to the same degree. This is because the root cause of the enhancement is the photo-electric absorption of radiation from matrix elements. The effect of enhancement is typically smaller than that of absorption. It is most pronounced in alloys of the first-row transition elements, where it can reach 25%. In many other applications, the enhancement effect is smaller, but is still important enough to warrant consideration and correction.

### 7.2.2 FUNDAMENTAL PARAMETER METHODS

The physical processes involved in absorption and excitation in XRF are well understood and easy to model mathematically. All entities required are listed in a variety of tables and databases. The calculations were previously tedious and time consuming, but with the current computing power available, the calculation effort is no longer an obstacle. Fundamental parameter methods are based on the underlying physical processes governing X-ray fluorescence, including the specifics of the instrument's geometry, the anode material of the X-ray tube, the voltage on the tube, and the composition of the specimen. The derivation of the equations is beyond the scope of this chapter, but is addressed by Criss and Birks [*10*] and Shiraiwa and Fujino [*11*].

### 7.2.3 COMPTON CORRECTION

The use of Compton scattered radiation as a means to correct for matrix effects (as well as for variations in sample preparation) has been described by Reynolds [*12*] and Taylor and Andermann [*13*]. The Compton correction is based on the fact that the intensity of incoherent (or Compton) scatter is inversely related to the mass attenuation coefficient of the sample. In practice, a

high-energy characteristic line from the tube anode is used. Measuring the intensity of the Compton scattered tube line thus reveals information about the absorption properties at the wavelength of the Compton scattered line. At first glance this seems to be of limited use, but in the field of X-rays, values of the mass attenuation coefficients for the same sample at different energies/wavelengths are proportional. This relationship, and the fact that absorption is the major source of matrix effects, explains why the Compton correction is a powerful correction method in a variety of matrices.
