19.3.2.3 Parameters Controlling Absorption The absorption of a chemical into the skin is a function of the nature of the molecule, the behavior of the vehicle, and the status of the skin. Three major variables account for differences in the rate of absorption or flux of different topical chemicals or of the same molecule in different vehicles: the concentration of the molecule in the vehicle, the partition coefficient of chemical between the stratum corneum and the vehicle, and the diffusion coefficient of molecule in the stratum corneum.

The rate of diffusion is proportional to the concentration of molecule in the vehicle. The relationship is linear only at low molecular concentrations and only applies to soluble molecule in the vehicle. The latter factor may explain the variable therapeutic effects of different formulations of the same drug molecule. The partition coefficient is a measure of the molecule's ability to escape from the vehicle and is defined as the equilibrium solubility of molecule in the surface of the stratum corneum relative to its solubility in the vehicle. Increased lipid solubility favors penetration of molecule through the skin by increasing the solubility in the relatively lipophilic stratum corneum. The diffusion coefficient indicates the extent to which the matrix of the barrier restricts the mobility of the molecule. Increases in molecular size of the molecule will increase frictional resistance and decrease the diffusion coefficient (Bronaugh, 1998); molecules over 1000Da usually will not be absorbed easily into normal adult skin.

Finally, intact stratum corneum is an excellent barrier, but in disease states that compromise the skin barrier, the resistance to absorption is rapidly lost and absorption can be facilitated. Such compromised skin can be humanly simulated by using either a dermatome or tape stripping the skin site in question.

19.3.3 Distribution

Once the chemical gains access to the body, it is carried by the bloodstream and distributed to the different organs. The preferential organ of deposition is determined by a variety of factors: the two most important are blood flow to the organ and the affinity of the chemical for that organ. Affinity is governed by two general characteristics. First, the product may be designed to have a specific affinity for a specific molecular entity in a target cell. For example, an anticholinesterase insecticide will tend to accumulate in the cells that have the highest concentration of cholinesterase. Second, the product may have a nonspecific or general chemical attraction for a specific cell type. The more highly lipophilic a chemical is, the more likely it is to distribute and remain in

adipose tissue. Blood flow will also have a major impact on distribution, as chemicals will be distributed more readily to those organs that are more highly perfused. A highly lipophilic chemical may first be deposited in the brain due to the fact that it is richly perfused and then be distributed to body fat with time.

Once a material is absorbed, distribution of a compound in most early toxicology studies is usually of limited interest. This is unfortunate, as it is the preferential distribution of the drug to the therapeutic target that is desired. Some factors which can serve to alter distribution are listed in Section 19.3.3.

For most drugs, the rate of disposition or loss from the biological system is independent of rate and input, once the agent is absorbed. Disposition is defined as what happens to the active molecule after it reaches a site in the blood circulation where concentration measurements can be made (the systemic circulations, generally). Although disposition processes may be independent of input, the inverse is not necessarily true because disposition can markedly affect the extent of availability. Agents absorbed from the stomach and the intestine must first pass through the liver before reaching the general circulation (Figure 19.1). Thus, if a compound is metabolized in the liver or excreted in bile, some of the active molecule absorbed from the GI tract will be inactivated by hepatic processes before it can reach the systemic circulation and be distributed to its sites of action. If the metabolizing or biliary excreting capacity of the liver is great, the effect on the extent of availability will be substantial. Thus, if the hepatic blood clearance for the chemical is large, relative to hepatic blood flow, the extent of availability for this chemical will be low when it is given by a route that yields first-pass metabolic effects.

Likewise, metabolism is generally of only limited concern in most acute studies. There are some special cases, however, in which metabolic considerations must be factored in seeking to understand differences between routes and the effects which may be seen.

The first special case is parenteral routes, where the systemic circulation presents a peak level of the moiety of interest to the body at one time, tempered only by the results of a single pass through the liver.

The second special case arises from inhalation exposures. Because of the arrangements of the circulatory system, inhaled compounds enter the full range of systemic circulation without any "first-pass" metabolism by the liver. Keberle et al. (1971) and O'Reilly (1972) have published reviews of absorption, distribution, and metabolism that are relevant.

19.3.3.1 Protein Binding The degree to which a drug binds to plasma proteins will highly influence its distribution. Albumin, the most prominent of the many proteins found in mammalian plasma, carries both positive and negative charges with which a polar compound can associate by electrostatic attraction. As with all such reactions, it can be

described by the following equations. The more avidly bound the material, the less will be distributed to surrounding fluids as part of a solution and only that portion that is free in solution will be available for diffusion into the tissues.

$$\frac{\text{Dose}}{C_0} = V_D$$

19.3.3.2 Water Solubility The solubility of a chemical has a direct bearing on its distribution. Recall that only molecules that are in solution will be available for absorption.

As mentioned earlier, only that portion that is free in solution will be available for diffusion into the tissues. Hence, the more material that is in solution, the more that will be available for diffusion.

19.3.3.3 Volume of Distribution If one takes the dose administered (milligrams) and divides it by the plasma concentration of the test material (milligram per milliliter), the result is a volume number:

$$\frac{\text{Dose}}{\text{Concentration}} = \text{Volume}$$

One can take this process a step further and extrapolate back from a plasma time curve to the y axis. This is theoretically the plasma concentration (C_0) that would occur if, upon being administered, the material is instantly distributed throughout the body. The volume number obtained with the preceding equation becomes

where V_D represents the apparent volume of distribution, a proportionality constant that reflects the relation of the concentration of a xenobiotic in plasma to the total amount of the entity in the body. Materials that are avidly bound to plasma proteins will have a high volume of distribution, while materials that are avidly taken by the tissues (e.g., deposit fat) will have a low volume of distribution. V_D is a parameter that is simple to calculate yet gives one important information about the distribution of the chemical under investigation.

The available volumes and masses for distribution vary from species to species, as summarized in Tables 19.3 and 19.4.

19.3.4 Metabolism/Biotransformation

Metabolism describes the process by which chemicals are changed by the body. In fact, very few foreign chemicals that come to enter the body are excreted unchanged. Most are chemically modified. In general, metabolism results in chemicals that are more polar and water-soluble, and more easily excreted (La Du et al., 1972). Examples of more common metabolic conversions are shown in Table 19.5. In general, a vast majority of lipophilic chemicals are first oxidized via the CYP-dependent mixed function oxidase system

TABLE 19.3 Volume and Half-Life of Body Water in Selected Species

Species	Sex	Exchangeable Body Water	
		(% of Body Weight)	Half-Life (Days)
Mouse	F	58.5	1.13

TABLE 19.5 Summary of Prominent Phase I Biotransformation Reactions

Reaction	Enzyme	Location	Example/Comments
Hydrolysis	Carboxylesterase	Ubiquitous	Vinyl acetate to acetate and acetaldehyde
	Peptidase	Blood, lysosomes	Amino-, carboxy-, and endopeptidase which cleave peptides at specific amino acid linkages
Reductions	Epoxide hydratase	Microsomes, cytosol	Conversion of styrene-7,8-epoxide to styrene-7,8-glycol
	Azo and nitro reduction	Gut microflora	Sequential conversion of nitrobenzene to aniline
	Carbonyl reductase	Cytosol	Conversion of haloperidol to reduced haloperidol (a secondary alcohol)
	Disulfide reduction	Cytosol	Glutathione-dependent reduction of disulfiram to diethyldithiocarbamate
	Sulfoxide reduction	Cytosol	Thioredoxin-dependent reduction of sulindac to sulindac sulfide
	Quinone reduction	Cytosol, microsomes	DT-diaphorase reduction of menadione to hydroquinone
Oxidation	Reductive dehalogenation	Microsomes	Conversion of pentabromoethane to tetrabromoethane (releasing free bromide ion)
	Alcohol dehydrogenase	Cytosol	Conversion of ethanol to acetaldehyde (DAD/DADH-dependent reversible reaction)
	Aldehyde dehydrogenase	Mitochondria/cytosol	Conversion of acetaldehyde to acetate
	Aldehyde oxidase	Liver cytosol	FAD-dependent metalloenzyme, oxidation of benzaldehyde to benzoic acid
	Xanthine oxidase	Cytosol	Oxidation of purine derivative, conversion of allopurinol to alloxanthine
	Monoamine oxidase	Mitochondria	FAD-dependent oxidative deamination of monoamines, for example, primaquine
	Diamine oxidase	Cytosol	Pyridoxal-dependent, copper-containing enzyme. Conversion of allylamine to acrolein
	Prostaglandin oxidase	Microsomes	Cooxidation reaction can activate chemicals in tissues low in cytochrome P450, for example, nephrotoxicity of acetaminophen, oxidation of phenylbutazone
	Flavin-containing monooxygenase	Microsomes	FAD-dependent oxidation of nucleophilic nitrogen, sulfur, and phosphorus heteroatoms, for example, conversion of nicotine to nicotine 1'-N-oxide, cimetidine to cimetidine S-oxide
	Cytochrome P450	Microsomes	

of the liver. This is the process classically called phase I metabolism. CYP exists as a family of isozymes (the *CYP* gene superfamily) with varying but overlapping substrate affinities and varying responses to different inducing agents. For a review of the molecular biology of the *CYP* gene superfamily, the reader is referred to Meyer (1994). Induction is the process whereby exposure to a chemical leads to increased activity of the mitochondrial mixed-function oxidase (MMFO) system due to an increase in the amount of the *CYP* isozyme. The isoenzymes induced by a variety of chemicals are given in Table 19.6, and example compounds which inhibit specific CYPs are presented in Table 19.6. In a practical sense, a drug can induce its own metabolism. Hence, repeated dosing with a chemical may lead to lower blood levels at the end, for example, of a 13-week study than at the beginning. There could also be alterations in the spectrum of metabolites produced, such that an agent could become more, or less, toxic with repeated dosing depending on the nature of the metabolites. It is not unusual during a subchronic or chronic toxicity test for tolerance to occur. There may be signs of toxicity early in the study, but even

with continued daily dosing, the signs abate. This phenomenon, particularly in rodents, is frequently due to microsomal induction, whereby the chemical has induced its own metabolism, and more rapid clearance of the parent chemical occurs. It should be noted that the P450 system is not the only drug-metabolizing system. As Table 19.7 summarizes, there are at least five major metabolic systems in mammals.

After the drug has been metabolically oxidized, it can be further metabolized. In fact, it is possible for the metabolites to also be substrates of the MMFO or the other metabolic systems shown in Table 19.7 and thus be further metabolized themselves.

The route of metabolic activation of the classic carcinogen benzo[*a*]pyrene is due to such a mechanism. The biology of these reactive intermediates has been extensively studied. Glutathione is among the most common organic intracellular chemicals in all mammalian species, being present at a concentration of up to 10mM, and glutathione *S*-transferase is very active. Glutathione is a tripeptide (glutamine–cysteine–glycine). The sulfhydryl group of cysteine is the business end of the molecule where the reaction with the nucleophilic reactive intermediate takes place. After that, the glutathione conjugate is further metabolized to a cysteinyl-acetyl moiety. These moieties are called mercapturic acids and are generally found in the urine. The relative predominance of mercapturic acid over other metabolites may be considered a rough indication of how “reactive” the intermediates may have been. Teleologically, it is tempting to speculate that it is a very well-designed protective mechanism. So long as intracellular glutathione concentrations remain above a critical level, the destructive actions of active metabolites can be held in check. Thus, a small dose of a chemical (bromobenzene is a good example) may cause no liver damage, while a large dose may. This is also a good example of one of the aspects of TKs versus PKs where a high dose of a chemical can become toxic due to saturation of a detoxification pathway.

The glutathione *S*-transferase pathway is sometimes in biochemical competition with the epoxide hydratase pathway in that both deactivate intermediates of the MMFO system.

TABLE 19.7 A Comparison of the Key *In Vitro* Drug-Metabolizing Experimental Systems (Liver Microsomes), Liver Postmitochondrial Supernatant (S9), Liver Cytosol, and Hepatocytes and Their Contents of Major Drug-Metabolizing Enzymes

<i>In vitro</i> System	P450	MAO	UGT	ST	GST
Microsomes	+	–	+ ^a	–	+ ^b
S9	+	–	+ ^a	+ ^a	+
Cytosol	–	–	– ^a	+ ^a	+ ^c
Hepatocytes	+	+	+	+	+

GST, glutathione *S*-transferase; MAO, monoamine oxidase; P450, cytochrome P450 isoforms; ST, sulfotransferase; UGT, UDP-glucuronosyltransferase.
^aActivity of this drug-metabolizing enzyme requires the addition of specific cofactors, for instance, UDP-glucuronic acid (UDPGA) for UGT activity and 3'-phosphoadenosine 5'-phosphosulfate (PAPS) for ST activity.
^bMembrane-bound GST but not the soluble GST is found in the microsomes.
^cSoluble GST but not membrane-bound GST is found in the cytosol.

Epoxide hydratase is a microsomal enzyme that acts specifically to deactivate epoxide intermediates by the addition of water across the C—O bond to form a diol. As a very broad generality, the glutathione *S*-transferase pathway tends to be more prominent in rodents, while the epoxide hydratase pathway tends to be more dominant in nonrodents.

The hydroxyl- or diol-containing metabolites of the MMFO can be further metabolized by so-called “phase II” (synthetic) metabolism whereby they are conjugated to/from glucuronides and/or sulfates (so-called “ethereal sulfates”). Amines can also be substrates. The net effect of phase II reactions is to create a more polar molecule that is more water-soluble and therefore readily excretable. While there are species differences, glucuronides are actively transported and excreted in the bile into the GI tract. Sulfates are excreted more predominantly in the urine. Both glucuronides and sulfates, however, can be found in both the urine and the feces. Like the MMFO pathway, glutathione *S*-transferase, UDP-glucuronyl transferase, and epoxide hydratase are inducible; that is, treatment with exogenous chemicals will increase the amount of enzyme proteins present.

Outside of the MMFO-mediated (phase I) reactions, there are a few other major reactions that are worthy of note. The two major ones involve ester hydrolysis and alcohol and aldehyde dehydrogenases. All mammalian species have an extensive ability to hydrolyze the ester bond. The products of the reactions then can go on to be further metabolized. In the pharmaceutical industry, this property has been utilized to synthesize prodrugs, that is, chemicals that have desirable pharmaceutical properties (generally increased water solubility) and are not converted to their active moiety until hydrolyzed in the body.

The activity of alcohol dehydrogenase is one with which we should all be familiar. It oxidizes alcohols to aldehydes. The aldehydes produced by this reaction can go on to be further metabolized to a carboxylic acid, if they are not sterically hindered. Side chain constituents of aromatic compounds can also be substrates for this reaction sequence, producing side chain carboxylates. The oxidation of alcohols to aldehydes can also be a form of metabolic activation as aldehydes can have potent physiological actions. Fortunately, aldehyde dehydrogenase has a very high activity when compared to alcohol dehydrogenase so that the aldehydes do not accumulate. Inhibition of aldehyde dehydrogenase by disulfiram (Antabuse) leads to the accumulation of acetaldehyde, causing nausea, dizziness, and flushing. Like disulfiram, some pesticides contain dithiocarbamates and have the potential of causing this type of reaction.

Hopefully, this brief description of the major metabolic pathways has given one some appreciation of the richness of the processes. The different sites of oxidation, the possibility of additional oxidative metabolism of metabolites, and the differences in phase II reactions all lead to a multiplicity of possible metabolites. Over 100 different metabolites of the human

pharmaceutical chlorpromazine have been isolated and identified. When analyzed by high-performance liquid chromatography (HPLC), for example, the parent chemical and the different (detectable) metabolites will form a pattern of different peaks. This is referred to as the metabolic fingerprint or profile of a chemical. Different species may have different profiles. Ideally, in doing a risk assessment, one would like to know the similarity between the metabolic pattern in animals used in the toxicology studies and that produced by human beings. This is only infrequently available for most nonpharmaceutical products; pesticides, for example, are rarely given intentionally to human subjects for the purposes of such a metabolic study. The technology now exists, however, to address this potential problem. Cell lines with human CYP have been developed that can provide some indication of the similarities between human metabolism of a chemical and that of experimental animals. At least they may be able to assist in identifying the major oxidative metabolite(s). For nonpharmaceutical products, it may be an unusual circumstance that would require one to identify potential human metabolites as part of a marketing application; however, it may be useful for one to know that the technology exists to do so.

The processes of metabolic conversion are frequently involved in the mechanisms of toxicity and carcinogenicity.

19.3.4.1 Metabolic Activation As mentioned, most non-nutritive chemicals pass through the GI tract by passive absorption and then enter the mesenteric circulation. The venous circulation from the mesentery flows through the portal vein into the liver. The metabolic action of the liver literally sits between the GI tract and the general systemic circulation. Thus, even chemicals that may be highly absorbed from the GI tract could appear only sparingly in systemic circulation if they are highly metabolized by the liver. The combination of absorption from the GI tract and intestinal and hepatic metabolism leads to what is called the first-pass effect. An extension of this is the fact that the gut floras contain glucuronidases, which can cleave glucuronides of chemicals and/or metabolites that are then available to be reabsorbed. This process is called enterohepatic circulation.

19.3.4.2 Induction of P450 Metabolism and Isoenzymes When organisms are exposed to certain xenobiotics, their ability to metabolize a variety of chemicals is increased. This phenomenon can produce either a transitory reduction in the toxicity of a drug or an increase (if the metabolite is the more toxic species). However, this may not be the case with compounds that require metabolic activation. The exact toxicological outcome of such increased metabolism is dependent on the specific xenobiotic and its specific metabolic pathway. Since the outcome of a xenobiotic exposure can depend on the balance between those reactions that

represent detoxification and those that represent activation, increases in metabolic capacity may at times produce unpredictable results.

The ability of different drugs to differentially inhibit and/or induce individual CYP isoenzymes has become critical in assessing the potential safety of drug molecules. Table 19.8 presents an overview of some of what we have come to know about differential metabolism by P450 isoenzymes. Draper et al. (1998) had published on the use of human liver microsomes for determining the levels of activity or inhibition a drug has on the formation of 6 β -hydroxytestosterone as a model for CYP3A activity (i) and chlorzoxazone for CYP2E1 activity (ii). If, for example, a chemical under study competitively inhibits the metabolism of these model substrates in these systems, then it is a substrate for that human isozyme. Using these more recently available *in vitro* systems, it is much easier to perform cross-species comparisons with regard to biotransformation. It is now easier to determine how similar the routes of metabolism are in the experimental animals with

comparison to those in man without having to administer the chemical to human subjects. Human and animal microsomal preparations may be used as models to identify patterns of metabolites *in vitro*, allowing for better selection of model species for safety studies, and competition for or inhibition of activation of specific isoenzymes can be evaluated to identify potential problems of DDI in patients (Levy et al., 2000).

19.3.4.3 Species Differences Species differences in metabolism are among the principal reasons that there are species differences in toxicity. Differences between species in CYP isozyme content and amounts are one of the most common reasons for differences in metabolism. For example, Monostory et al. (1997) published a paper comparing the metabolism of panomifene (a tamoxifen analog) in four different species. These data serve to address that the rates of metabolism in the nonhuman species were most rapid in the dog and slowest in the mouse. Thus, one should not *a priori* make any assumptions about which species will have the

more rapid metabolism. Of the seven metabolites, only one was produced in all four species. Both the rat and the dog produced the two metabolites (M5 and M6) produced by human microsomes. So how does one decide which species best represents man? One needs to consider the chemical structure of the metabolites and the rates at which they are produced. In this particular case, M5 and M6 were relatively minor metabolites in the dog, which produced three other metabolites in larger proportion. The rat produced the same metabolites at a higher proportion, with fewer other metabolites than the dog. Thus, in this particular instance, the rat, rather than the dog, was a better model. Likewise, Table 19.9 offers a comparison of excretion patterns between three species for a simple inorganic compound. Table 19.10 presents a summary of interspecies differences between species in drug metabolism and PKs, and Table 19.11 presents differences in total liver concentrations of CYP enzymes in each of six mammalian species.

A more thorough review on species differences in PKs has been presented by Smith (1991), Gad and Chengelis (1998), and Gad (2015).

TABLE 19.9 Differences in the Disposition of 2,4-Dichlorophenoxyacetic Acid

Species	Sex	Urine	Feces
Rat	M	31.2	2.7
	F	16.5	1.1
Mouse	M	12.7	2.8
	F	26.8	6.7
Hamster	M	4.9	2.5
	F	33.9	14.5

Note: All animals dosed orally with radiolabeled 2,4-D, 200 mg kg⁻¹. Results are expressed as percentage of ¹⁴C dose recovered. Urine was collected for 8 h and feces for 24 h.

TABLE 19.10 “General Rules” on Interspecies Differences in DMPK

Species	DMPK Characteristics
Human	Polymorphisms (e.g., CYP 2C9, CYP 2C19, CYP 2D6, NAT1, NAT2)
Dog	Low acetylation, high capacity for deacetylation. Different absorption due to higher pH in gastrointestinal tract than in humans (consider use of synthetic gastric fluid to mimic human situation)
Rat	Often gender differences which are not observed in other species Abundant tetrahydrofolate (protects, e.g., against methanol ocular damage)
Rabbit	Low sulfation
(Mini)Pig	Low sulfation Gastrointestinal conditions similar to humans
Cat	Low glucuronidation High sulfation

TABLE 19.11 Total Liver Content of CYP Enzymes in Humans, Monkeys, Pigs, and Dogs

Species	Total Liver Content of CYP (nmol/mg Protein)	Reference
Humans	0.29 ± 0.06 (n = 12)	Stevens et al. (1993),
	0.307 ± 0.16 (n = 18)	Shimada et al. (1997)
Rhesus monkeys	0.95 ± 0.08 (n = 6)	Stevens et al. (1993)
Cynomolgus monkeys	1.03 ± 0.11 (n = 5)	Shimada et al. (1997)

19.3.4.4 Sex-Related Differences in Rodents Not only are there differences in absorption, distribution, and metabolism between species but also there may be differences between sexes within a species (Mugfor and Kidderis, 1998).

Griffin et al. (1997), for example, had demonstrated sex-related differences in the metabolism of 2,4-dichlorophenoxyacetic acid (2,4-D) (Table 19.9). They noted that while there were differences between sexes, they tended to be quantitative (rates), not qualitative (metabolites). Differences between species were greater than sex-related differences. With regard to sex-related differences, it is noteworthy that males do not always have the higher rates, as Griffin et al. have shown; in hamsters, the females metabolize 2,4-D more rapidly than males. In general, male rats tend to have higher activity than female rats, especially with regard to CYP-dependent activity.

In the case of 2,4-D, the only urinary metabolite is 2,4-D-glucuronide, but the half-life of 2,4-D was 138 min in males and 382 min in females.

19.3.5 Excretion

Excretion encompasses the process by which chemicals or their metabolites are transported out of the body. There are three possible major routes of excretion and a handful of minor ones. The major routes of excretion for chemicals, and in particular their metabolites, are the following:

19.3.5.1 Urine The kidneys filter the entire cardiac output multiple times each day and thus provide a large opportunity for the removal of chemicals from the bloodstream.

How much of a xenobiotic is actually excreted is dependent on three factors or processes:

1. The glomerular membrane has pores of 70–80 Å, and under the positive hydrostatic conditions in the glomerulus, all molecules smaller than about 20 000 Da are filtered. Proteins and protein-bound compounds thus remain in the plasma, and about 20% of the non-bound entity is carried with 20% of the plasma water into the glomerular filtrate.
2. As the glomerular filtrate contains many important body constituents (e.g., glucose), there are specific active uptake processes for them. Also, lipid-soluble chemicals diffuse back from the tubule into the blood, especially as the urine becomes more concentrated because of water reabsorption. The pH of the urine is generally lower than that of the plasma, and therefore, pH partitioning tends to increase the reabsorption of weak acids. The pH of the urine can be altered appreciably by treatment with ammonium chloride (decreases pH) or sodium carbonate (increases pH); the buffered plasma shows little change.
3. Xenobiotics may be secreted actively into the renal tubule against a concentration gradient by anion and cation carrier processes. These processes are saturable and of relatively low specificity; many basic or acidic compounds and their metabolites (especially conjugation products) are removed by them. As the dissociation rate for the chemical–albumin complex is rapid, it is possible for highly protein-bound compounds to be almost completely cleared at a single passage through the kidney.

19.3.5.2 Feces The most important mechanism allowing circulating foreign compounds to enter the gut is in the bile. The biological aspects of this mechanism have been reviewed and certain pertinent points have emerged. The bile may be regarded as a complementary pathway to the urine, with small molecules being eliminated by the kidney and large molecules in the bile. Thus, the bile becomes the principal excretory route for many drug conjugates. Species differences exist in the molecular weight requirement for significant biliary excretion, which has been estimated as 325 ± 50 in the rat, 440 ± 50 in the guinea pig, and 475 ± 50 in the rabbit. In the rat, small molecules (<350 Da) are not eliminated in the bile or large molecules (>450 Da) in the urine, even if the principal excretory mechanism is blocked by ligation of the renal pedicles or bile duct, respectively (Wang and Reuning, 1994). Compounds of intermediate molecular weight (350–450 Da) are excreted by both routes, and ligation of one pathway results in increased use of the other.

Foreign compounds may also enter the gut by direct diffusion or secretion across the gut wall, elimination in the saliva, pH partitioning of bases into the low pH of the stomach, and elimination in the pancreatic juice.

19.3.5.3 Expired Air Volatile compounds or metabolites can be extensively excreted by passage across pulmonary membranes into the airspace of the lungs and then expulsion from the lungs in expired air.

Minor routes for excretion can include tears, saliva, sweat, exfoliated keratinocytes, hair, and nasal discharge. These are of concern or significance only in rare cases. Accordingly, quantitation of excretion typically requires collection of urine and feces (and occasionally expired air) over a period of time.

19.4 PHARMACOKINETICS

The interplay of absorption, distribution, metabolism, and excretion processes results in changes in the concentration of the test chemical in different organs with time (Shargel and Yu, 1999; Roberts and Renwick, 2014). With regard to the practical concerns of monitoring human exposure, the organ of interest is the blood. Blood is generally considered the central compartment. Determining the concentration of the chemical in plasma gives one an assessment of exposure. Mathematical formulas are used to quantitatively describe this exposure (Bauer, 2001).

19.5 LABORATORY METHODS

The actual means by which PK information is collected is through the conduct of one or more of specific studies, employing a wide range of available analytical techniques. Administered therapeutic molecules can be identified and quantified in relevant samples collected in accordance with carefully designed and executed protocols. While it is most common to use either rats or mice as the rodent species in all cases, for small molecules, nonrodent species (dog, monkey, or minipig) are most commonly selected based on the compatibility of their metabolism of the molecule of interest to that of humans. There has been a lot of work on the capabilities of these species in recent years (Dalgaard, 2015)—see Table 19.8.

19.5.1 Analytical Methods

There are three broad categories of analytical techniques now available—instrumental (cold chemical), radiolabeled, and immunological. Each of these has advantages and disadvantages. Only an overview of these techniques will be given here—detailed explanations are beyond the scope of this text. These methodologies are all directed at being able to identify and/or quantify a chemical (and/or its metabolites) in various biological matrices.

19.5.1.1 Instrumental Methods These bioanalytical methods are also sometimes called cold chemistry methods (Crooks et al., 2014). These generally start from a place of

isolating the compound or compounds of interest, for which the workhorse methodology is HPLC. A wide variety of specialized columns are used to achieve desired separation. At the end of the column, where separation of molecular entities has been achieved, the outflow of the column can be directed to any of a wide variety of detection instruments, including various forms of detectors intrinsic to the HPLC. In general, all of the cold chemistry methodologies have less sensitivity (higher detection limits) than radiochemical or immunological methods.

Mass spectrometry (MS); nuclear magnetic resonance (NMR) spectroscopy; electron spin resonance (ESR) spectroscopy; ultraviolet, infrared, and visible spectrophotometry; and mass spectroscopy are all well-established detection methodologies.

19.5.1.2 Radiochemical Methods The massive expansion of our understanding of TKs since the late 1970s is to a large degree a reflection of the wide use of radioactive isotopes as tracers of chemical and biological processes. Appropriately radiolabeled test compounds are commonly used in TK studies, providing a simple means of following the administered dose in the body. This is particularly important when specific analytical methods are unavailable or too insensitive. The use of total radioactivity measurements allows an estimation of the total exposure to drug-related material and facilitates the achievement of material balance and the routes of excretion.

The most commonly used radionuclides in drug metabolism and disposition studies are carbon-14 (¹⁴C) and tritium (³H), both of which are referred to as beta emitters. Since these beta-emitting isotopes have relatively long half-lives,

their radioactive decay during an experiment is insignificant. Additionally, they provide sufficient emission energy for measurement and are relatively safe to use, as indicated by the data in Table 19.12. Although individual beta particles can have any energy up to the maximum, E_{max} , the basic quantity in determining the energy imparted to tissues by beta emitters is the average energy, E_{β} . The range is the maximum thickness the beta particles can penetrate. Beta particles present virtually no hazard when they originate outside the body (Shapiro, 1981).

During the synthesis of radiolabeled compounds, the label is usually introduced as part of the molecular skeleton in a metabolically stable and, with tritium, nonexchangeable position. The *in vivo* stability of ¹⁴C labels is often reflected by the extent of [¹⁴C] carbon dioxide formation. The biological stability of ³H labels can be estimated by the extent of tritiated water formation. The tritiated water concentration (dpm mL⁻¹) in urine samples collected during a designated time interval after dosing, assumedly after equilibrium is reached between urine and the body water pool, is determined. This value is extrapolated from the midpoint of the collection interval to zero time, based on the known half-life of tritiated water in the given species. The percentage of the radioactive dose that is transformed to tritiated water (% ³H₂O) can be calculated using the following equation:

Values for the exchangeable body water content as well as the half-life of tritiated water in some mammalian species that can be applied to the preceding equation were shown earlier in Table 19.13. If the molecule is likely to or is known to fragment into two major portions, it may be desirable to monitor both fragments by differential labeling (³H and ¹⁴C).

$$\text{Percent } ^3\text{H}_2\text{O} = \frac{^3\text{H}_2\text{O concentration at zero time} \times \text{exchangeable body water volume}}{\text{Radioactivity dose}} \times 100\%$$

The chemical and radiochemical purity of the labeled compound must be ascertained prior to use. In practice, a value of 95% or greater is usually acceptable. The desired

TABLE 19.12 Properties of Primary Radioisotopes Employed in PKs

Property	³ H	⁵¹ Cr	¹⁴ C	¹²⁵ I
Half-life (year)	12.3	27.8 (days)	5730	13 (days)
Maximum beta energy (MeV)	0.0186	0.752	0.156	2.150
Average beta energy (MeV)	0.006	0.049		
Range in air (mm)	6	300		
Range in unit density material (mm)	0.0052	0.29		

specific activity of the administered radioactive compound depends on the dose to be used as well as the species studied. Doses of ¹⁴C on the order of 5 μCi kg⁻¹ for the dog and 20 μCi kg⁻¹ for the rat have been found adequate in most studies, while doses of ³H are usually two to three times higher owing to lower counting efficiency of this isotope.

Liquid scintillation counting is the most popular technique for the detection and measurement of radioactivity. In order to count a liquid specimen such as plasma, urine, or digested blood or tissues directly in a liquid scintillation spectrometer, an aliquot of the specimen is first mixed with a liquid scintillant. Aliquots of blood, feces, or tissue homogenates are air-dried on ash-free filter papers and combusted in a sample oxidizer provided with an appropriate absorption medium and a liquid scintillant prior to counting. The liquid scintillant plays the role of an energy transducer, converting energy from

TABLE 19.13 Selected Factors that May Affect Chemical Distribution to Various Tissues

Factors relating to the chemical and its administration
Degree of binding of chemical to plasma proteins (i.e., agent affinity for proteins) and tissues
Chelation to calcium, which is deposited in growing bones and teeth (e.g., tetracyclines in young children)
Whether the chemical distributes evenly throughout the body (one-compartment model) or differentially between different compartments (two- or more compartment model)
Ability of chemical to cross the blood–brain barrier
Diffusion of chemical into the tissues or organs and degree of binding to receptors that are and are not responsible for the drug's beneficial effects
Quantity of chemical given
Route of administration/exposure
Partition coefficients (nonpolar chemicals are distributed more readily to fat tissues than polar chemicals)
Interactions with other chemicals that may occupy receptors and prevent the drug from attaching to the receptor, inhibit active transport, or otherwise interfere with a drug's activity
Molecular weight of the chemical
Factors relating to the test subject
Body size
Fat content (e.g., obesity affects the distribution of drugs that are highly soluble in fats)
Permeability of membranes
Active transport for chemicals carried across cell membranes by active processes
Amount of proteins in blood, especially albumin pathology or altered homeostasis that affects any of the other factors (e.g., cardiac failure and renal failure)
The presence of competitive binding substances (e.g., specific receptor sites in tissues bind drugs)
pH of blood and body tissues
pH of urine ^a
Blood flow to various tissues or organs (e.g., well-perfused organs usually tend to accumulate more chemicals than less well-perfused organs)

^aThe pH of urine is usually more important than the pH of blood.

nuclear decay into light. The light generates electrical signal pulses which are analyzed according to their timing and amplitude and are subsequently recorded as a count rate, for example, counts per minute (cpm). Based on the counting efficiency of the radionuclide used, the count rate is then converted to the rate of disintegration, for example, disintegrations per minute (dpm), which is a representation of the amount of radioactivity present in the sample.

19.5.1.3 Immunoassay Methods Radioimmunoassay (RIA) allows measurement of biologically active materials which are not detectable by traditional cold chemistry techniques. RIAs can be used to measure molecules that cannot be radio-labeled to detectable levels *in vivo*. They also are used for

molecules unable to fix complement when bound to antibodies, or they can be used to identify cross-reacting antigens that compete and bind with the antibody. These are discussed further in Section 19.11.

19.6 SAMPLING METHODS AND INTERVALS

19.6.1 Blood

Since blood (plasma and serum) is the most easily accessible body compartment, the blood concentration profile is most commonly used to describe the time course of drug disposition in the animal. With the development of sensitive analytical methods that require small volumes (100–200 μL) of blood, ADME data from individual rats can be obtained by serial sample collection. Numerous cannulation techniques have been utilized to facilitate repeated blood collection, but the animal preparation procedures are elaborate and tedious and are incompatible with prolonged sampling periods in studies involving a large number of animals. In contrast, non-cannulation methods such as collection from the tail vein, orbital sinus, or jugular vein are most practical. Significant volumes of blood can be obtained from the intact rat by cardiac puncture, although this method can cause shock to the animal system and subsequent death; therefore, cardiac puncture is usually only a terminal collection method.

Blood collection from the tail vein is a simple and rapid, nonsurgical method which does not require anesthesia. A relatively large number of serial samples can be obtained within a short period of time. However, this method is limited to relatively small sample volumes (~250 μL per sample). Although larger volumes can be obtained by placing the rat in a warming chamber, this procedure could significantly influence the disposition of the test compound and therefore is not recommended for routine studies. Blood collected from the cut tail has been shown to provide valid concentration data for numerous compounds.

The rat is placed in a suitable restrainer with the tail hanging freely. The tail is immersed in a beaker of warm water (37–40°C) for 1–2 min to increase the blood flow and thereby visibility of the vein. Using surgical scissors or a scalpel, the tail is completely transected approximately 5 mm above the tip. The tail is then gently “milked” by sliding the fingers down the tail from its base. It should be noted that excessive “milking” could cause damage to the blood capillaries or increase the white cell count in the blood. A heparinized micropipette of desired capacity (25–250 μL) is held at a 30–45° downward angle in contact with the cut end of the tail. This allows blood to fill the micropipette by capillary action. Application of gentle pressure with a gauze pad for approximately 15 s is sufficient to stop bleeding. A sufficient number of serial blood samples may be obtained to adequately describe the blood level profile of a compound.

If plasma is required, the blood may be centrifuged after sealing one end of the filled micropipette and placing it in a padded centrifuge tube. The volume of plasma is determined by measuring the length of plasma as a fraction of the length of the micropipette, multiplied by the total capacity of the pipette. The tube is then broken at the plasma/red blood cell (RBC) interface and the sample is expelled using a small bulb. If serum is needed, the blood should be collected without using anticoagulants in the sampling tube.

Serial blood samples can also be collected from the orbital sinus, permitting rapid collection of larger (1–3 mL) samples. However, since 2008, there have been initiatives to collect smaller samples from fewer animals in an attempt to reduce animal usage.

Three new approaches for blood sampling for PK/TK analysis have, however, come into consideration for use in rodents to facilitate use of fewer animals.

The first of these is microsampling, by means of a microdialysis or capillary sampling needle. There is minimal trauma to the rodents, and in taking minimal amounts of blood each time (typically $\leq 50 \mu\text{L}$), it does not compromise the rat or the mouse (or hamster). Accordingly, “main study” animals can be used and satellite groups of animals are not required—significantly reducing the number of animals required for a study (particularly for longer duration studies where sampling at multiple time points is required). Furthermore, this provides the advantage that the relationship between safety and exposure can be directly evaluated in the same animals (ICH, 2017).

A variation on this is the use of dried blood spot sampling (DBSS). With liquid plasma samples, a significant amount of each sample collected is lost in adherence to the walls of a series of glass or plastic collection and handling vessels; DBSS collects directly onto a chemically inert medium from a capillary sampling tube or the Cutex[®] collecting device. As long as the molecules to be analyzed are chemically stable under these conditions, again smaller samples (and fewer animals) are required.

The third approach is sparse sampling, where only a small number (usually three) of animals are sampled at each time point, with sampling being rotated between time points (such as the traditional 0.5, 1, 2, 4, 8, and 12 h), so that levels of blood collected from any one animal are sufficient to avoid notable traumatization. Again, either no satellite group of animals or only a smaller such group is required.

19.6.2 Excreta

Excretion samples commonly collected from the rat include urine, feces, bile, and expired air. By using properly designed cages and techniques, the samples can be completely collected so that the mass balance is readily determined. These samples also serve to elucidate the biotransformation characteristics of the compound.

These samples can be easily collected through the use of suitable metabolism cages. Since rodents are coprophagic, the cage must be designed to prevent the animal from ingesting the feces as it is passed. Other main features of the cage should include the ability to effectively separate urine from feces with minimal cross-contamination, a feed and water system that prevents spillage and subsequent contamination of collected samples, and collection containers that can be easily removed without disturbing the animal. Also, the cage should be designed so that it can be easily disassembled for cleaning or autoclaving.

Following dose administration, rats are placed in individual cages. The urine and feces that collect in containers are removed at predetermined intervals. The volume or weight of urine and the weight of feces are measured. After the final collection, the cage is rinsed, normally with ethanol or water, to assure complete recovery of excreta and radioactivity. If the rats are also used for serial blood sampling, it is important that bleeding be performed inside the cage to avoid possible loss of urine or feces.

19.6.3 Bile

The bile is the pathway through which an absorbed compound is excreted in the feces. In order to collect this sample, surgical manipulation of the animal is necessary.

19.6.4 Expired Air

For ^{14}C -labeled chemicals, the tracer carbon may be incorporated *in vivo* into carbon dioxide, a possible metabolic product. Therefore, when the position of the radiolabel indicates the potential for biological instability, a pilot study to collect expired air and monitor its radioactivity content should be conducted prior to initiating a full-scale study. Expired air studies should also be performed in situations where the radiolabel has been postulated to be stable but analyses of urine and feces from the TK study fail to yield complete recovery (mass balance) of the dose.

Following drug administration, the rat is placed in a special metabolism cage. Using a vacuum pump, a constant flow of room air ($\sim 500 \text{ mL min}^{-1}$) is drawn through a drying column containing anhydrous calcium sulfate impregnated with a moisture indicator (cobalt chloride) and is passed into a second column containing Ascarite II[®], where it is rendered carbon dioxide-free. The air is then drawn in through the top of the metabolism cage. Exhaled breath exiting the metabolism cage is passed through a carbon dioxide adsorption tower, where the expired $^{14}\text{CO}_2$ is trapped in a solution such as a mixture of 2-ethoxyethanol and 2-aminoethanol (2 : 1). The trapping solution is collected, replaced with fresh solution, and assayed at designated times postdose so that the total amount of radioactivity expired as labeled carbon dioxide can be determined.

TABLE 19.14 Approximate Volumes of Pertinent Biological Fluids in Adult Laboratory Animals

Fluid	Rat	Mouse	Dog	Rabbit	Monkey
Blood (mL kg ⁻¹)	75	75	70	60	75
Plasma (mL kg ⁻¹)	40	45	40	30	45
Urine (mL kg ⁻¹ day ⁻¹)	60	50	30	60	75
Bile (mL kg ⁻¹ day ⁻¹)	90	100	12	120	25

19.6.5 Milk

The study of passage of a xenobiotic into milk serves to assess the potential risk to breastfed infants in the absence of human data. The passage into milk can be estimated as the milk–plasma ratio of drug concentrations at each sampling time or that of the area under the curve (AUC) values. Approximately, 30 rats in their first lactation are used. The litter size is adjusted to about 10 within 1–2 days following parturition. The test compound is administered to the mothers 8–10 days after parturition. The rats are then divided into groups for milk and blood collection at designated times postdose. All sucklings are removed from the mother rats several hours before milking. Oxytocin, 1 IU per rat, is given intramuscularly 10–15 min before each collection of milk to stimulate milk ejection. The usual yield of milk is about 1 mL from each rat. Blood is obtained immediately after milking. In order to minimize the number of animals used, the sucklings can be returned to the mother rat which can then be milked again 8–12 h later.

In all the fluid sampling techniques mentioned earlier, the limitations of availability should be kept in mind. Table 19.14 presents a summary of such availability for the principal model species.

For topical exposures, determining absorption (into the skin and into the systemic circulation) requires a different set of techniques. For determining how much material is left, skin washing is required. There are two components to skin washing in the recovery of chemicals. The first component is the physical rubbing and removal from the skin surface. The second component is the surfactant action of soap and water. However, the addition of soap effects the partitioning. Some compounds may require multiple successive washing with soap and water applications for removal from skin.

Skin tape stripping can be used to determine the concentration of drug in the stratum corneum at the end of a short application period (30 min) and by linear extrapolation predicts the percutaneous absorption of that chemical for longer application periods. The chemical is applied to skin of animals or humans, and after a 30-min skin contact application time, the stratum corneum is blotted and then removed by successive tape applications. The tape strippings are assayed for chemical content. There is a linear relationship between this stratum corneum reservoir content and percutaneous absorption. The major advantages of this method are (i) the elimination of urinary and fecal excretion to determine

TABLE 19.15 Blood Samples Required so that Certain TK Parameters Can Be Obtained and Calculated

Parameter	Blood Sample Required	Information Obtained
C_{\min} (C_{24})	24-h	Accumulation
CT	T -h	Proof of absorption
C_{\max} (C peak)	Several ^a	Rate of absorption
T_{\max} (T peak)	Several ^a	Rate of absorption
AUC	Several ^a	Extent of absorption
$t_{1/2}$	Several ^a	Various
Accumulation ratio	Several after first and repeated doses	Extent of accumulation

^aSeveral samples to define concentration-versus-time profile.

absorption and (ii) the applicability to nonradiolabeled determination of percutaneous absorption, because the skin strippings contain adequate chemical concentrations for nonlabeled assay methodology.

Finally, a complete determination of the distribution and potential departing of a chemical and its metabolites requires some form of measurement or sampling of tissues/organs. Autoradiography provides a nonquantitative means of doing such, but quantitation requires actual collection and sampling of tissues. Table 19.4 provides guidance as to the relative percentage of total body mass that the organs constitute in the common model species.

19.6.5.1 Sampling Interval To be able to perform a valid TK analysis, it is necessary not only to properly collect samples of appropriate biological fluids but also to collect a sufficient number of samples at the current intervals. Both of these variables are determined by the nature of the answers sought. Useful parameters in TK studies are C_{\max} , which is the peak plasma test compound concentration; T_{\max} , which is the time at which the peak plasma test compound concentration occurs; C_{\min} , which is the plasma test compound concentration immediately before the next dose is administered; AUC, which is the area under the plasma test compound concentration-versus-time curve during a dosage interval; and $t_{1/2}$, which is the half-life for the decline of test compound concentrations in plasma. The samples required to obtain these parameters are shown in Table 19.15. C_{\min} requires one blood sample immediately before a dose is given and provides information on accumulation. If there is

no accumulation in plasma, the test compound may not be detected in this sample.

Several C_{\min} samples are required at intervals during the toxicity study to check whether accumulation is occurring. CT is a blood sample taken at a chosen time after dosing and provides proof of absorption as required by the GLP regulations, but little else. C_{\max} requires several blood samples to be taken for its accurate definition, as does T_{\max} : these two parameters provide information on rate of absorption. AUC also requires several blood samples to be taken so that it can be calculated: it provides information on extent of absorption. $t_{1/2}$, the half-life, requires several samples to be taken during the terminal elimination phase of the test compound concentration-versus-time curve: this parameter provides information on various aspects such as any change in the kinetics of the test compound during repeated doses or at different dose levels. Depending on the other parameters obtained, the accumulation ratio can be calculated from C_{\min} , C_{\max} , and/or AUC when these are available after the first dose and after several doses to steady state.

Operational and metabolic considerations generally make urine sampling and assay of limited value for TK purposes.

19.7 STUDY TYPES

Metabolic and PK data from a rodent species and a nonrodent species (usually the dog) used for repeat dose safety assessments (14 days, 28 days, 90 days, or 6 or 9 months) are recommended. If a dose dependency is observed in metabolic and PK or toxicity studies with one species, the same range of doses should be used in metabolic and PK studies with other species. If human metabolism and PK data also are available, this information should be used to help select test species for the full range of toxicity tests and may help to justify using data from a particular species as a human surrogate in safety assessment and risk assessment.

Metabolism and PK studies have greater relevance when conducted in both sexes of young adult animals of the same species and strain used for other toxicity tests with the test substance. The number of animals used in metabolism and PK studies should be sufficient to reliably estimate population variability. This usually means a separate (but parallel) set of groups of animals in rodent studies. A single set of intravenous (IV) and oral dosing results from adult animals, when combined with some *in vitro* kinetic results, may provide an adequate data set for the design and interpretation of short-term, subchronic, and chronic toxicity studies.

Studies in multiple species may clarify what appear to be contradictory findings in toxicity studies (i.e., equal milligram per kilogram body weight doses having less effect in one species than in another). If disposition and metabolite profiles are found to be similar, then differences in responses among species could more reliably be attributed to factors other than

differences in metabolism. Studies of the PKs and metabolism of a substance in neonatal and adolescent animals provide information about any changes in metabolism associated with tissue differentiation and development. Animals with fetuses of known gestational age should be used for determining the disposition of the test substance in the fetus. Dosage is by (to the maximum extent possible) the intended clinical route.

An acute IV study can provide accurate rates of metabolism—without interference from intestinal flora—plus rates of renal and biliary elimination, if urine and bile are collected. This route also avoids the variability in delivered dose associated with oral absorption and ensures that the maximum amount of radiolabel is excreted in the urine or bile for purposes of detection. Once IV data and parameters are available, they can be used with plasma concentrations from limited oral studies to compute intestinal absorption via the ratio of areas under the (plasma and/or urine) curves or via simulations of absorption with GI absorption models.

In single-dose PK studies of oral absorption, the primary concerns are with the rates and extent of absorption and peak plasma or target tissue concentrations of the test substance. If the test vehicle affects gastric emptying, it may be necessary to use both fasted and nonfasted animals for PK studies.

Blood (RBCs, plasma, and serum), urine, and feces are the most commonly collected samples. In addition, a few representative organ and tissue samples should be taken, such as liver, kidney, fat, and suspected target organs. Sampling times should depend on the substance being tested and the route of administration. In general, an equal number of blood samples should be taken in each phase of the concentration-versus-time curve. IV studies usually require much shorter, and more frequent, sampling than is required for oral dosing. Time spacing of samples will depend on the rates of uptake and elimination. In a typical IV study, blood and tissue samples are taken in a “powers of 2” series, that is, samples at 2, 4, 8, 16, and 30 (32) min, 1, 2, 4, 8, and 16 h. Similar coverage could be obtained with only 7 time points by using a “powers of 3” series: 3, 9, and 30 (27) min, 1, 3, 9, and 24 (27) h. Oral dosing studies usually extend to at least 72 h. Such a sampling scheme over 3 days would provide better data coverage for a more thorough evaluation of absorption, elimination, enterohepatic recirculation, and excretion processes.

The number of animals used in metabolism and PK studies should be large enough to reliably estimate population variability. In the case of rats and mice, tissue and/or blood sample size is usually the limiting factor: analysis of the substance may require 1 mL or more of blood, but this is not usually practical or safe to obtain multiple blood samples of this size from one animal and may confound or complicate PK or safety evaluations. As a consequence, a larger number of animals are required (3–4 per time point, 7–9 time points) when small rodents are used. Such an approach has the advantage of allowing limited sampling of critical tissues (e.g., liver, fat) at each time point, an option which is usually unavailable with

large animals. The use of humans and large animals generally permits a collection of multiple (serial) blood samples. For outcrossing populations like humans and large animals, individual differences in the rates of biotransformation are likely to be greater than those of inbred rodent populations; under these circumstances, more samples/sexes/groups may be needed to reliably estimate variability.

Individual metabolism cages are recommended for collecting urine and feces in oral dosing studies. Excreta should be collected for at least five elimination half-lives of the test substance. When urine concentrations will be used to determine elimination rates, sampling times should be less than one elimination half-life (taken directly from the bladder in IV studies); otherwise, samples should be taken at equal time intervals.

The results of the preliminary biotransformation/kinetic study, together with the current regulatory metabolism studies and the 28- and 90-day studies, should allow the selection of a relatively small number of appropriate tissues and/or fluids for monitoring purposes. Satellite groups of animals will provide the material for analysis. Methods must be developed to analyze the nonradioactive test chemical. Obviously, it is important to monitor blood. It is accessible and convenient, and in certain circumstances, sequential sampling from the same animal may be important. The most useful aspect of blood is that the results can be compared with those obtained in man (see succeeding text). It is important, however, not to be constrained by this aspect. The most relevant tissues and body fluids should also be analyzed. These are target organs (if known) and indicator organs, tissues, or fluids, that is, those in which the concentration of pesticide or metabolite is a measure of that in the whole animal. In cases where distribution varies with dose (if shown in the preliminary study), a larger number of organs/tissues would be chosen for monitoring.

Whether the parent drug or metabolite (or both) is chosen for analysis depends on the preliminary study. In principle, analysis for the parent compound should always be carried out; however, there are situations (e.g., rapid metabolism) when this is quite futile and a major retained metabolite should be used. Covalently bound metabolites are addressed in the succeeding text.

Four occasions may be adequate for monitoring:

1. One month (equilibrium between intake of chemical and elimination of metabolites should be established; the time relates to the 28-day preliminary study)
2. Three months (confirmation of results at one month; relates to the 90-day study)
3. One year (coincides with the interim kill)
4. Two years (effects of age; coincides with termination of study)

Consideration should be given to the analysis of moribund animals.

19.7.1 Whole-Body Autoradiography

Autoradiography is the production of an image in a photographic emulsion by the emission from a radioactive element. The term “autoradiography” is preferred to radioautography. Prefixes are added to words to further classify the concept. Therefore, the process is “auto-” radiography for a “self-” radiograph and not a “radio-” autograph or one’s transmitted signature (Waddell, 1972).

Whole-body autoradiography (WBA) has been used with increasing frequency as a means of identifying tissues which concentrate on test substances. This technique allows a small number of animals (5–10) to be used for screening purposes with a minimal investment in manual labor. FDA encourages the use of WBA with IV dosing as a means of screening and selecting tissues of greatest relevance for later oral dosing studies. Animals used for WBA should generally be sacrificed during primary consideration in selecting specific tissues.

The most comprehensive technique currently available for the initial survey of the distribution of a drug is that of WBA. The species of animals used include mice, rats, hamsters, monkeys, pigs, dogs, and ferrets. The most widely used animal has been the mouse, which has the advantages of requiring few isotopes and being easier to section.

The animals are anesthetized and then frozen by immersion at various times after administration of the labeled compound in hexane or acetone cooled with dry ice. Since the freezing in the interior of the animals occurs slowly, large ice crystals form within these tissues; hence, subcellular localization of compounds is not possible.

The selection of times for freezing an animal after injection of a drug must be based on the information available on the rate of elimination of the compound from the animal by metabolism and excretion. In general, a geometric increase in time intervals is most useful. In order to have time intervals for comparison, we routinely have employed freezing times which are approximately multiples of three, namely, 2 min, 6.5 min, 20 min, 1 h, 3 h, 9 h, and 24 h. In certain cases, rapid elimination of the drug by the kidneys must be circumvented by ligation of the renal pedicles to avoid apparent localization from failure of the agent to reach equilibrium.

The animal is frozen into a block of carboxymethyl cellulose ice on the microtome stage. Although the Jung type K microtome has been used, the Leitz model 1300 sledge microtome is more suitable, for its smaller size allows it to be mounted in an ordinary commercial freezer instead of a walk-in freeze room. The microtome stage must be designed for mounting in the vice of the front-end of the stage.

Sections that are from 5 μm to approximately 80 μm thick are taken onto #800 Scotch tape (Minnesota Mining & Manufacturing Company). Before removal from the freezer, the sections must be allowed to dry thoroughly so that no ice remains, which melts and allows movement of the isotope. After drying, if covered to prevent condensation of moisture

on the sections, the sections may be transferred from the freezer to room temperature.

X-ray films which produce the most satisfactory autoradiograms are Kodak industrial type AA and Gevaert Structurix D-7. Both are fine-grained films which have been demonstrated not to produce chemical artifacts. Approximately six times faster, Kodak No-Screen and Kodirex may be used for rapid screening and timing of autoradiograms. However, they occasionally produce artifacts and should not be relied on for interpretation. Some investigators have used photographic emulsions such as Ilford G-5 (10 μm thick, preapplied to glass plates). The increased cost and likelihood of breakage, however, hardly justify the small improvement in resolution for whole-body sections.

Exposure of the photographic emulsion to the radioactivity of the tissue section should be at freezer temperatures to prevent autolysis of the tissue. After exposure of the X-ray film, sections with isotopes which have a long half-life may be placed against fresh X-ray film for additional sets of autoradiograms with either a longer or shorter exposure time. This procedure is useful for revealing relative concentrations of radioactivity for areas that have either very high or very low concentrations after the first exposure. When no further autoradiograms are needed, the section can be stained with histological dyes to verify localizations of radioactivity.

Compounds that fluoresce under ultraviolet light can be visualized in the tissue sections and their locations recorded with color film. Whole-body tissue sections can be used for histochemical localizations for comparison with the autoradiograms. Furthermore, the areas can be removed and extracted, and the extract chromatographed to identify the chemical nature of the radioactivity revealed by the autoradiogram.

Although the whole-body technique will allow localization of an increased concentration of an isotope in a tissue or occasionally a cell type, other techniques must be used for single cells and subcellular localization. A nuclear tract plate is prepared by dipping the plate in a 12% solution of glycerin in absolute ethyl alcohol and allowing it to drain for 10 min in a vertical position before approximating the section to tape. After the emulsion is exposed, soaking in xylene removes the tape but leaves the section attached to the nuclear tract plate. The Ilford G-5 nuclear tract plates with 10 μm emulsions are most satisfactory. The increased resolution gained by the finer-grained Ilford K and L emulsions is warranted only for tissues that are well preserved and relatively free of ice crystal artifacts. Kodak NTB emulsions seem to produce more pressure artifacts than the Ilford plates.

A comparison of various techniques of autoradiography for diffusible compounds clearly demonstrates that no solutions can be used in processing the tissue. These investigators have dried thin sections of liver and uterus at temperatures below -60°C . These freeze-dried sections were dry-mounted

on microscope slides which had been precoated with either Kodak NTB-3 or NTB-10 emulsion. Other techniques which thawed the frozen section, embedded the tissue in paraffin, or dipped the section in liquid emulsion were demonstrated to translocate diffusible compounds. Many other similar attempts have been and are currently being made to localize diffusible compounds by autoradiography at the electron microscope level.

19.7.2 Mass Balance Studies

Another method for evaluating the distribution of drug throughout the body while also assessing clearance rates from the body is the mass balance study. In this study format, the drug (in a radiolabeled form) is administered by the desired route. Excreta (urine and feces, as well as occasionally expired air) are collected over a suitable interval of time after dosing (usually 24–48 h in rodents and up to 72 h in large animals) by placing test animals in special collection chambers or cages.

At the end of this interval, blood is collected, the animal is euthanized, key tissues are collected and weighed, and then the amount of label in each is determined. The rest of the body is separately weighed and processed and residual compound (measured as radioactivity) is determined. It is usually the case that accounting for 85%+ of administered drug is considered acceptable, but 90–95% is desirable. Rodents should yield recovery values of 95%+, while recovery in dogs and monkeys may be more often 85%+.

19.7.2.1 In Vitro Studies *In vitro* measurements employing enzymes, subcellular organelles, isolated cells, and perfused organs may be used to augment the dose–response information available from less-extensive metabolic and PK studies. Because *in vitro* systems are less complex than whole animals, elucidation of a test compound's metabolic pathways and the pathways' kinetic characteristics may be facilitated. Such systems can be used to measure binding, adduct and conjugate formation, transport across cell membranes, enzyme activity, enzyme substrate specificity, and other singular objectives. Biochemical measurements that can be made using *in vitro* systems include intrinsic clearances of enzymes in an organ or tissue, kinetic constants for an enzyme, binding constants, and the affinity of the test compound and its metabolites for the target macromolecules. The activity of a hepatic drug-metabolizing enzyme *in vivo* may be approximated by kinetic constants that are calculated from *in vitro* studies; when a first-order approximation is used, the ratio of V_{max} to K_{m} is equal to the intrinsic clearance of the drug. *In vitro* measurements made using readily accessible tissues and body fluids from animals and man may also be useful in elucidating mechanisms of toxicity.

19.8 ANALYSIS OF DATA

Data from all metabolism and PK studies should be analyzed with the same PK model and results should be expressed in the same units. Concentration units are acceptable if the organ or sample size is reported, but percentage of dose/organ is usually a more meaningful unit. In general, all samples should be analyzed for metabolites that cumulatively represent more than 1% of the dose.

A variety of rate constants and other parameters can be obtained from IV and oral dosing data sets, provided that good coverage of the distribution, elimination, and absorption (oral dose) phase is achieved. Typical parameters calculated to characterize the disposition of a test substance are half-lives of elimination and absorption; area under the concentration-versus-time curve (AUC) for blood (or plasma); total body (renal and metabolic) clearance (CL); volume of distribution (V_d); bioavailability (F); and mean residence time (MRT) and mean absorption time (MAT). Some of these parameters, such as half-lives and elimination rates, are easily computed from one another; the half-life is more easily visualized than the rate constant.

Computation of oral absorption (k_a) and elimination (E) rates is often complicated by the “flip-flop” of the absorption and elimination phases when they differ by less than a factor of 3. Because of these analysis problems, computation of absorption and elimination rates should not be attempted on the basis of oral dosing results alone, and therefore, it is preferable to have both oral and IV PK data in hand when determining oral absorption and elimination rates.

Blood–tissue uptake rates (k_{ji}) can often be approximated from data at early ($t < 10$ min) time points in IV studies, provided that the blood has been washed from the organ (e.g., liver) or the contribution from blood to the tissue residue is subtracted (fat). High accuracy is not usually required since these parameters can be optimized to fit the data when they are used in more complex models. Tissue–blood recycling rates (k_{ji}) and residence times can be computed from partition coefficients if estimates of uptake rates are available.

Tissue–blood partition coefficients (R_{ji}) should be determined when steady state has been achieved. Estimates based on samples obtained during the elimination phase following a single dose of the test substance may lead to underestimates of this ratio in both eliminating and noneliminating tissues unless its half-life is very long. Correction of these values for elimination has been described by several authors.

It may be important to determine the degree of plasma protein and RBC binding of the test substance; calculation of blood clearance rates using plasma or serum concentrations of the substance that have not been adjusted for the degree of binding may under- or overestimate the true rate of clearance of the test substance from the blood. This is usually done through experiments *in vitro*.

Two classical methods used in the analysis of PK data are the fitting of sums of exponential functions (two- and three-compartment mammillary models) to plasma and/or tissue data and, less frequently, the fitting of arbitrary polynomial functions to the data (noncompartmental analysis).

Noncompartmental analysis (NCA) is limited in that it is not descriptive or predictive; concentrations must be interpolated from data. The appeal of NCA is that the shape of the blood concentration-versus-time curve is not assumed to be represented by an exponential function and, therefore, estimates of metabolic and PK parameters are not biased by this assumption. In order to minimize errors in parameter estimates that are introduced by interpolation, a large number of data points that adequately define the concentration-versus-time curve are needed (Gabrielsson and Weiner, 2017).

Analysis of data using simple mammillary compartmental models allows the estimation of all of the basic parameters mentioned earlier, if data for individual tissues are analyzed with one- or two-compartment models and if combined with results from two- to three-compartment analyses of blood data. “Curve stripping” analysis can be applied to such simple models through the use of common spreadsheet programs (i.e., Lotus 1-2-3 or Excel), as long as a linear regression function is provided in the program. Optimization of the coefficients and exponents estimated may require the use of more sophisticated software: a number of scientific data analysis packages such as RS/1 and SigmaPlot have the necessary capabilities. Specialized programs such as NONLIN, CONSAM, or SIMUSOLV will be needed when more complex models must be analyzed. Coefficients and exponents from mammillary models can be used to calculate other parameters; however, they should not be taken too literally, since mammillary models assume that all inputs are to a central pool (blood), which equilibrates without limitation into other compartments. This approach does not include details such as blood flow limitations, anatomical volumes, or other physiological limits in the animal.

Physiologically based pharmacokinetic (PBPK) models were developed to overcome the limitations of simple mammalian models. Physiologically based models describe the disposition of test substances via compartmental models which incorporate anatomical, biochemical, and physiological features of specific tissues in the whole animal (Connally and Anderson, 1991; Vinegar and Jepson, 1996). The types of information added include organ-specific blood flows, volumes, growth models, and metabolism rates. Metabolic parameters often are obtained from *in vitro* studies (i.e., enzyme reaction rates in cultured hepatocytes, plasma protein binding, etc.), while other parameters are becoming available as standard parameters in the literature. Parameters from mammillary models can be used to compute the value of parameters used in PBPK models, using tissue-specific blood flows, anatomical volumes, and other information (literature

values). Estimation of parameters for a simple mammillary model is often the first data reduction step in creating a physiological model.

Because PBPK models are based on physiological and anatomical measurements and all mammals are inherently similar, they provide a rational basis for relating data obtained from animals to humans. Estimates of predicted disposition patterns for test substances in humans may be obtained by adjusting biochemical parameters in models validated for animals; adjustments are based on experimental results of animal and human *in vitro* tests and substitution of appropriate human tissue sizes and blood flows. Development of these models requires special software capable of simultaneously solving multiple (often very complex) differential equations, some of which were mentioned earlier. Several detailed descriptions of data analysis have been reported.

19.8.1 Use of Data from Metabolism and Pharmacokinetic Studies

Information from metabolism and PK studies can be used in the design and analysis of data from other toxicity studies. Some examples are described in the succeeding text.

19.8.1.1 Design of Toxicity Studies The concentration versus-time curve and peak and steady-state concentrations of the test substance in blood or plasma provide information on the distribution and persistence of the substance in the animal which may suggest essential elements in the design of the toxicity studies. For example, when metabolic and PK studies indicate that the test compound accumulates in the bone marrow, long-term toxicity tests should include evaluation of the test compound's effect on hematopoietic function and morphology. If a test compound is found to accumulate in milk, an investigator may need to plan to perform reproductive toxicity studies with *in utero* exposure and a nursing phase (cross-fostering study). In addition, information from metabolic and PK studies can be used to predict the amount of test compound that enters biological compartments (tissues, organs, etc.) that may not suffer a toxic insult but may serve as depots for indirect or secondary exposure.

19.9 NONCOMPARTMENTAL ANALYSIS

Noncompartmental analysis (NCA) is appealing for the evaluation of nonclinical TK and PK studies as it does not rely on assumptions about body compartments. In addition, NCA tends to be faster and more cost-effective when compared to compartmental analysis. NCA relies on the collection of a large number of data points over time. These data points are usually collected as blood or plasma samples and are used to adequately define the concentration-versus-time curve (Gabrielsson and Weiner, 2017).

Although the NCA approach has limitations and does not provide the level of detail seen with compartmental approaches, it does provide essential information and is commonly used in pharmaceutical research. The typical parameters (as defined in Table 19.1) that are calculated using NCA include but are not limited to AUC, V_d , Cl, $T_{1/2}$, T_{max} , and C_{max} .

19.10 PHYSIOLOGICALLY BASED PHARMACOKINETIC (PBPK) MODELING

Pharmacokinetic parameters are descriptive in nature. They quantitatively describe the manner in which a test material is absorbed and excreted, such that a specific blood or tissue level is achieved or maintained. In the past, experiments had to be done by every route of administration to gather the data appropriate for describing the PK behavior of a chemical administered by different routes. The development of more sophisticated and readily accessible computers has led to the development of a different approach, that of PK modeling. In this computerized model, different compartments are represented as shown in boxes and the movement of the material in and out of the compartments is defined by the rate constants. These can be determined either *in vivo* or *in vitro*. Other physiological parameters are brought into play as well, such as octanol/water partition coefficient, blood flow through an organ, respiration rate (for the inhalation route of exposure), rate of microsomal metabolism, and so on.

Pharmacokinetic modeling is the process of developing mathematical explanations of absorption, distribution, metabolism, and excretion of chemicals in organisms. Two commonly used types of compartmental PK models are (i) data based and (ii) physiologically based. The data-based PK models correspond to mathematical descriptions of the temporal change in the blood/tissue level of a xenobiotic in the animal species of interest. This procedure considers the organism as a single homogeneous compartment or as a multicompartmental system with elimination occurring in specific compartments of the model. The number, behavior, and volume of these hypothetical compartments are estimated by the type of equation chosen to describe the data, and not necessarily by the physiological characteristics of the model species in which the blood/tissue concentration data were acquired. It can provide a powerful tool for both the discovery of new drugs and the optimization of their development (Lavé et al., 2007).

Although these data-based PK models can be used for interpolation, they should not be used for extrapolation outside the range of doses, dose routes, and species used in the study on which they were based. In order to use the data-based models to describe the PK behavior of a chemical administered at various doses by different routes, extensive animal experimentation would be required to generate similar blood time course data under respective conditions. Even within the

same species of animal, the time-dependent nature of critical biological determinants of the disposition (e.g., tissue glutathione depletion and resynthesis) cannot easily be included or evaluated with the data-based PK modeling approach. Further, due to the lack of actual anatomical, physiological, and biochemical realism, these data-based compartmental models cannot easily be used in interspecies extrapolation, particularly to predict PK behavior of chemicals in humans. These various extrapolations, which are essential for the conduct of dose–response assessment of chemicals, can be performed more confidently with a PBPK modeling approach. This chapter presents the principles and methods of PBPK modeling as applied to the study of toxicologically important chemicals.

PBPK modeling is the development of mathematical descriptions of the uptake and disposition of chemicals based on quantitative interrelationships among the critical biological determinants of these processes. These determinants include partition coefficients, rates of biochemical reactions, and physiological characteristics of the animal species. The biological and mechanistic basis of the PBPK models enables them to be used, with limited animal experimentation, for extrapolation of the kinetic behavior of chemicals from high dose to low dose, from one exposure route to another, and from test animal species to people.

The development of PBPK models is performed in four interconnected steps: model representation, model parameterization, model stimulation, and model validation. Model representation involves the development of conceptual, functional, and computational descriptions of the relevant compartments of the animal as well as the exposure and metabolic pathways of the chemical. Model parameterization involves obtaining independent measures of the mechanistic determinants, such as physiological, physicochemical, and biochemical parameters, which are included in one or more of the PBPK model equations. Model simulation involves the prediction of the uptake and disposition of a chemical for defined exposure scenarios using a numerical integration algorithm, simulation software, and computer. Finally, the model validation step involves the comparison of the *a priori* predictions of the PBPK model with experimental data to refute, validate, or refine the model description and the characterization of the sensitivity of tissue dose to changes in model parameter values. PBPK models after appropriate testing and validation can be used to conduct extrapolations of the PK behavior of chemicals from one exposure route/scenario to another, from high dose to low dose, and from one species to another.

The PBPK model development for a chemical is preceded by the definition of the problem, which in toxicology may often be related to the apparent complex nature of toxicity. Examples of such apparent complex toxic responses include nonlinearity in dose–response, sex/species differences in tissue response, differential response of tissues to chemical exposure, qualitatively, and/or quantitatively different responses for the

same cumulative dose administered by different routes/scenarios, and so on. In these instances, PBPK modeling studies can be utilized to evaluate the PK basis of the apparent complex nature of toxicity induced by the chemical. One of the values of PBPK modeling, in fact, is that accurate description of target tissue dose often resolves behavior that appears complex at the administered dose level.

The principal application of PBPK models is in the prediction of the target tissue dose of the toxic parent chemical or its reactive metabolite. Use of the target tissue dose of the toxic moiety of a chemical in risk assessment calculations provides a better basis of relating to the observed toxic effects than the external or exposure concentration of the parent chemical. Because PBPK models facilitate the prediction of target tissue dose for various exposure scenarios, routes, doses, and species, they can help reduce the uncertainty associated with the conventional extrapolation approaches.

Direct application of modeling includes the following:

- High-dose–low-dose extrapolation
- Route–route extrapolation
- Exposure scenario extrapolation
- Interspecies extrapolation

19.11 BIOLOGICALLY DERIVED MATERIALS

The progress and products of biotechnology have brought some new challenges to the assessment of PKs and TKs. While the reasons for why this data is needed (demonstrating exposure, displaying dose dependency, correlating any findings of toxicity to exposure, and determining steady state for systemic agent levels) are certainly as compelling as with traditional drugs, there are a whole set of special problems involved (Dennis et al., 2002; Baumann, 2006).

These special concerns for biologically derived products are the following:

Assay Sensitivity/Specificity

- Needs to be at 1 ng mL⁻¹ or lower.
- Cross-reactivity to native protein may confound results.
- If test article is the same as native protein, how do you tell the difference?
- Western blot can be used to demonstrate specificity.
- Antibody interference may occur with assay.

Low Systemic Levels

- Rapid metabolism: Metabolites may be endogenous proteins or amino acids.
- Extensive metabolism: Metabolites may be incorporated into cell structures rapidly.
- Rapid distribution.

- Rapid hepatic clearance.
- Route of administration may bypass first-pass metabolism:
 - SC
 - ICV, IT
 - Buccal

Endogenous Protein

- May cross-react and lead to false-positive blood levels
- Can radiolabel to tell the difference between administered molecule and endogenous molecule:
 - However, the label may lead to different distribution
 - What is the specific activity if diluted with unlabeled endogenous material?

Sample Volume

- May need to be large to increase sensitivity
- May need to be small because of competing assays:
 - Immune factors (antibodies, globulins)
 - Hormones
 - Disease state modifiers
 - In humans, concomitant medications

Distribution

- Rapidly cleared from blood.
- Frequently distributed mid-lymphatics.
- Target and off-target receptor binding found in a portion of drug molecule population in the body rapidly predominate.
- Pharmacodynamics very different from PKs.
- Delivery rarely by oral route.
- Available test material supply will be very limited in early development.

The upshot of these points is that it may not be practical to follow established guidelines for ADME evaluation. Binding proteins, immunoreactive metabolites, and antibodies could interfere with the immunoassays used to measure the activity of biotechnologically derived pharmaceuticals. The link between immunoreactivity and pharmacological activity may be difficult to establish, making the data difficult to interpret. In radiolabeled distribution studies, if the label alters the physicochemical and biological properties of the test material, its PK behavior may change. These analytical difficulties make accurate characterization of the distribution, metabolism, and excretion of a protein more difficult. However, as immunoassay-based methods of measuring levels of large molecules have improved, this situation has improved, and as more information on species-specific PKs of large molecules (such as monoclonal antibodies (mAb)) has become available, cross-species scaling of the PKs of such molecules has also become possible (Zhao et al., 2015).

AUC and C_{\max} are commonly measured to identify safety ratios for new chemical entities. Since the analytical methods used for biotechnologically derived pharmaceuticals may lack specificity, a clinical marker of biological activity or efficacy may sometimes be more appropriate than exposure data.

It is therefore essential that before pivotal (repeat dose) pre-clinical studies are initiated, bioanalytical assay development must be completed. This has to cover potential test species and normal (and diseased humans). The assays must be validated in the sampling matrix of the toxicity test species, and one should also develop suitable assays for antibodies to the test article.

19.11.1 Immunoassay Methods

Competitive inhibition of radiolabeled hormone antibody binding by unlabeled hormone (either as a standard or an unknown mixture) is the principle of most RIAs. A standard curve for measuring antigen (hormone) binding to antibody is constructed by placing known amounts of radiolabeled antigen and the antibody into a set of test tubes. Varying amounts of unlabeled antigen are added to the test tubes. Antigen–antibody complexes are separated from the antigen and the amount of radioactivity from each sample is measured to detect how much unlabeled antigen is bound to the antibody. Smaller amounts of radiolabeled antigen–antibody complexes are present in the fractions containing higher amounts of unlabeled antigen. A standard curve must be constructed to correlate the percentage of radiolabeled antigen bound with the concentration of unlabeled antigen present.

Two methods are commonly employed in RIAs to separate antigen–antibody complexes. The first, the double-antibody technique, precipitates antigen–antibody complexes out of solution by utilizing a second antibody, which binds to the first antibody. The second most commonly used method is the dextran-coated activated charcoal technique. Addition of dextran-coated activated charcoal to the sample followed immediately by centrifugation absorbs free antigen and leaves antigen–antibody complexes in the supernatant fraction. This technique works best when the molecular weight of the antigen is 30 kDa or less. Also, sufficient carrier protein must be present to prevent adsorption of unbound antibody.

Once a standard curve has been constructed, the RIA can determine the concentration of hormone in a sample (usually plasma or urine). The values of hormone levels are usually accurate using the RIA, but certain factors (e.g., pH or ionic strength) can affect antigen binding to the antibody. Thus, similar conditions must be used for the standard and the sample.

Problems of RIAs include lack of specificity. This problem is usually due to nonspecific cross-reactivity of the antibody.

RIA represents an analytical approach of great sensitivity. Unlike assays that often require large amounts of tissue (or blood), the greater sensitivity of the RIAs or mAb techniques can be achieved using small samples of biological fluids. Some of these RIA methodologies are more useful than others and to some extent depend on the degree of hormonal cross-reactions or, in the case of mAb methods, their degree of sensitivity.

Enzyme-linked immunosorbent assay (ELISA) is comparable to the immunoradiometric assay (IRMA) except that an enzyme tag is attached to the antibody instead of a radioactive label. ELISAs have the advantage of no radioactive materials and produce an end product that can be assessed with a spectrophotometer. The molecule of interest is bound to the enzyme-labeled antibody, and the excess antibody is removed for IRMAs. After excess antibody has been removed or the second antibody containing the enzyme has been added (two-site assay), the substrate and cofactors necessary are added in order to visualize and record enzyme activity. The level of molecule of interest present is directly related to the level of enzymatic activity. The sensitivity of the ELISAs can be enhanced by increasing the incubation time for producing substrate.

IRMAs are like RIAs in that a radiolabeled substance is used in an antigen–antibody reaction, except that the radioactive label is attached to the antibody instead of the hormone. Furthermore, excess of antibody, rather than limited quantity, is present in the assay. All the unknown antigen becomes bound in an IRMA rather than just a portion, as in a RIA; IRMAs are more sensitive. In the one-site assay, the excess antibody that is not bound to the sample is removed by addition of a precipitating binder. In a two-site assay, a molecule with at least two antibody-binding sites is adsorbed onto a solid phase, to which one of the antibodies is attached. After binding to this antibody is completed, a second antibody labeled with ¹²⁵I is added to the assay. This antibody reacts with the second antibody-binding site to form a “sandwich,” composed of antibody–hormone-labeled antibody. The amount of hormone present is proportional to the amount of radioactivity measured in the assay.

With enzyme-multiplied immunoassay technique (EMIT) assays, enzyme tags are used instead of radiolabels. The antibody binding alters the enzyme characteristics, allowing for measurement of target molecules without separating the bound and free components (i.e., homogeneous assay). The enzyme is attached to the molecule being tested. This enzyme-labeled antigen is incubated with the sample and with antibody to the molecule. Binding of the antibody to the enzyme-linked molecule either physically blocks the active site of the enzyme or changes the protein conformation so that the enzyme is no longer active. After antibody binding occurs, the enzyme substrate and cofactor are added, and enzyme activity is measured. If the sample contains subject molecules, it will compete with enzyme-linked molecules for antibody

binding, enzyme will not be blocked by antibody, and more enzyme activity will be measurable.

Most protein drug entities can now be assessed using mAb techniques. It is possible to produce antisera containing a variety of polyclonal antibodies that recognize and bind many parts of the molecule. Polyclonal antisera can create some nonspecificity problems such as cross-reactivity and variation in binding affinity. Therefore, it is oftentimes desirable to produce a group of antibodies that selectively bind to a specific region of the molecule (i.e., antigenic determinant). In the past, investigators produced antisera to antigenic determinants of the molecule by cleaving the molecule and immunizing an animal with the fragment of the hormone containing the antigenic determinant of interest. This approach solved some problems with cross-reactivity of antisera with other similar antigenic determinants, but problems were still associated with the heterogeneous collection of antibodies found in polyclonal antisera.

The production of mAbs offers investigators a homogeneous collection of antibodies that could bind selectively to a specific antigenic determinant with the same affinity. In addition to protein isolation and diagnostic techniques, mAbs have contributed greatly to RIAs.

While mAbs offer a highly sensitive, specific method for detecting antigen, sometimes increasing mAb specificity compromises affinity of the antibody for the antigen. In addition, there is usually decreased complement fixation, and costs are usually high for preparing and maintaining hybridomas that produce mAbs (Table 19.16).

The mAb techniques provide a means of producing a specific antibody for binding antigen. This technique is useful for studying protein structure relations (or alterations) and has been used for devising specific RIAs.

19.11.1.1 Metabolism and Elimination Biologics are usually not excreted unchanged in urine. They are degraded to small peptides and individual amino acids with pathways equally and generally understood for endogenous compounds. Their metabolites (amino acids) are reutilized in the endogenous amino acid pool for the *de novo* biosynthesis of structural or functional body proteins.

TABLE 19.16 Advantages and Disadvantages of Monoclonal Antibodies Compared with Polyclonal Antisera

Advantages	Disadvantages
Sensitivity	Overly specific
Quantities available	Decreased affinity
Immunologically defined	Diminished complement fixation
Detection of neoantigens on cell membrane	Labor intensive; high cost

The metabolism of biologics is highly dependent on structure (including sugars), charge (density and distribution), size, and hydrophilicity/lipophilicity. Sites of metabolism of biologics are the liver, the kidneys, and the blood and the extravascular sites of administration. In the liver, hepatocytes are mainly responsible for the catabolism of biologics using carrier-mediated membrane transport as well as endocytosis/pinocytosis for transport process. The kidneys play a major role in the catabolism of many small polypeptides. After being filtered by the glomeruli, some proteins are reabsorbed by the proximal tubule by endocytosis, while small amino acid chains are hydrolyzed at the brush border. Controversy exists surrounding glomerular filtration selectivity regarding size, molecular conformation, and charge of the protein (Tang et al., 2004). The often observed incomplete bioavailability of biologics after extravascular injection can be attributed to local metabolism. Catabolism at extravascular sites has been observed for, for example, insulin, calcitonin, and interferon- β (for review, see Mohler et al., 1992).

Several biologics, especially antibodies, show high inter-individual variation of PK parameters, which is mainly clearance driven. It is now clear that mAbs which target cellular antigens have far more complex, nonlinear PKs such that the half-life of these drugs can be both dose and time dependent (Lobo et al., 2004). When antigen concentration is high, half-life is short because the mAb is rapidly cleared from the blood through antigen–mAb interaction. As the antigen is depleted, clearance decreases and half-life is consequently prolonged. As the mAb accumulates, a new steady state is reached. Eventually, the target is totally depleted, at which time the clearance of mAb will be at its slowest. At this point, half-life will be at its longest, approaching the half-life of endogenous IgG (~21 days). More probable than total target depletion is saturation of the target–mAb binding with similar consequences.

Due to catabolism of proteins to (mostly) endogenous amino acids, classical biotransformation studies are performed for small molecules and are not needed. Additionally, limitations of current analytical methods to detect and distinguish metabolites, and the putative lack of pharmacological or toxicological activity of the metabolites, remain as obstacles. Similarly, mass balance studies usually used to determine the excretion pathways of small molecules (and their metabolites) are not used for biologics.

The majority of therapeutic biologics, especially after chronic administration, elicit an immune response in test animal species and often also in humans. This is an inherent property when administering nonhuman sequence proteins of sufficient size. Initial success in reducing immunogenicity has been achieved by replacing biologics obtained from non-human sources with human sequences. Antibody formation can also occur in immunocompetent recipients after treatment with products derived from human sera and tissues and also with recombinant human proteins that are identical or nearly

identical in sequence to native human proteins. The mechanism for generation of antibodies of recombinant human proteins is not well understood. In most cases, the underlying mechanism is the breaking of immune tolerance that typically exists to self-antigens (Baumann, 2006). Other reasons for immunogenicity relate to manufacturing, formulation, and storage (e.g., aggregates). These are especially addressed when modifications of these processes are performed which might influence the physicochemical properties of the product. An immune response to a product does not mean it cannot be developed. However, the development and use of a product may be complicated and, in rare cases, impossible. In certain cases, some patients develop antibodies which neutralize the biological activity of the therapeutic product and become unresponsive to treatment. Alterations in the PK profile due to immunomediated clearance mechanisms may affect the PK profiles and the interpretation of the preclinical toxicity data. Last but not least, safety issues like immunomediated toxicity may be raised. Detection and characterization of the immune response in patients are expected by the authorities (USFDA, 2002).

The development and usefulness of appropriate animal models for testing immunogenicity are still unclear. Conventional animal models have poorly predicted immunogenicity problems in humans. One limitation of traditional animal models is that tolerance, a key aspect of the immune response, is highly species-specific. However, characterization of the immune response in research and preclinical development is necessary to get a valid interpretation of the preclinical efficacy and safety data.

Not only the compound structure itself but also the administration route may affect immunogenicity. Extravascular injection is known to stimulate antibody formation more than IV application. This is most likely due to increased immunogenicity of protein aggregates and precipitates formed at the injection site.

To lower the systemic clearance and increase elimination half-lives, several strategies have been developed including polyethylene glycol (PEG) attachment (PEGylation), glycosylation, or fusion to proteins with decreasing clearance and prolonged serum half-lives. PEGylation improves the PK behaviors by increasing the effective size of the protein, with most significant effects for proteins smaller than 70 kDa. However, conjugation of the protein may also alter receptor affinity and biodistribution, changing the concentration–response profile for the protein independent of effects on PKs. PEGylation can also reduce immunogenicity and aggregation.

19.12 POINTS TO CONSIDER

Probably the most important thing to remember is that what we historically (and currently) measure and model in PKs (levels of free molecules in plasma) are a more readily available

TABLE 19.17 Examples of Stereoselective Differences in Metabolism (R) versus (S) Ifosfamide

Parameter	Phenobarbital	R	S	R/S
Term half-life (min)	–	34.3	41.8	0.820
	+	19.8	19.41	1.02
AUC (µM min)	–	4853	6259	0.820
	+	1479	1356	1.03
2-Dechloro metabolite AUC	–	799	2794	0.287
	+	229	1205	0.186
3-Dechloro metabolite AUC	–	1380	996	1.41
	+	192	1175	0.159

surrogate for what we are really interested in—levels of drug molecules at the sites of action. These are almost always within cells—and intracellular concentrations are much more difficult to measure (Dollery, 2013).

Stereoisomerism will influence metabolism and toxicity. For example, Lu et al. (1998) reported a comparison between (*S*)-(-)-ifosfamide and (*R*)-(+)-ifosfamide. They demonstrated that there were significant differences between the two stereoisomers with regard to PK behavior and major metabolite formation, as shown in Table 19.17.

When considering safe and efficacious use of drugs in children (pediatrics), it is important to realize that neonates and juveniles are not just scaled-down versions of adults—both their physiologies and their metabolisms/PKs are frequently different. Subsequently the PKs, pharmacodynamics, and toxicodynamics for neonates and juveniles require their own evaluations (Kearns, 2015).

In addition, treatment of animals with phenobarbital not only increased overall rates of metabolism and clearance but also shifted the metabolite patterns. One of the more common methods used for determining an exposure to (or the amount of) a metabolite produced is to determine an AUC for the metabolite. Further, one of the more common methods for representing a racemically preferred metabolite is to calculate the ratio of the *R* to the *S*. For example, the 3-dechloro metabolite of ifosfamide was produced in higher amounts from the *R* enantiomer, while the 2-dechloro metabolite was the major metabolite produced from the *S* enantiomer in naive animals. Treatment with phenobarbital shifted the metabolism so that the 3-dechloro metabolite was no longer the major metabolite for the *S* enantiomer.

In the last decade, our understanding of the function and significance of transporters in both systemic and organ-specific absorption of drug molecules (and their retention in potential therapeutic or toxicologically significant organs) has become clear. Table 19.18 presents a summary comparison of these functions in humans and the three major nonrodent species (monkey, pig, and dog).

Given that transporters can impact a drug's disposition and pharmacological activity and that drugs can also alter transporter expression or activity (by being a transporter substrate or inhibitor), the evaluation of transporter-mediated drug interactions has become a consideration during drug development. Recently, the USFDA (2020) released a guidance document aimed at evaluating the transporter- (and cytochrome P450 enzyme-) mediated drug interaction potential of an investigational drug product.

SAFETY PHARMACOLOGY

Safety pharmacology is the evaluation and study of the potentially life-threatening pharmacologic effects of a potential drug which is unrelated to the desired therapeutic effect, and therefore may present a hazard—particularly in individuals who already have one or more compromised or limited organ system functions. Unlike other nonclinical evaluations of the safety of a drug, these evaluations are usually conducted at doses not significantly excess of the intended clinical dose, rather, safety pharmacology looks at alterations in normal physiologic function at systemic levels of a therapeutically relevant level. This topic has, in the range of clinical exposure, undergone significant change since the last edition because of a variety of changed regulatory conditions.

General/safety pharmacology was an emerging discipline within the pharmaceutical industry prior to 2002 (Hite, 1997), when ICH guidance was promulgated, and it became a major area of both concern and activity. It seeks to identify unanticipated effects of new drug candidates on major organ function (i.e., secondary pharmacological effects) and ensures that they are critically assessed in a variety of animal models. A survey was conducted to obtain customer input on the role and strategies of this emerging discipline. Overlooked in importance by all but a few (Zbinden, 1966, 1984) for many years, the Japanese clearly became the leaders in developing and requiring such information, while the United States was in a position behind Japan and the EU in both having formal requirements and implementing industrial programs (Aghajafari et al., 2002; Committee for Proprietary Medicinal Products (CPMP), 1997; Committee for Proprietary Medicinal Products (CPMP), 2000). While major companies were aware and largely addressing the need by the mid-1990s (Kinter

et al., 1994; Murphy et al., 1995; Sullivan and Kinter, 1995), and EMA promulgated guidelines in 2000, it was only with the ICH S7 guidance (ICH, 2005) that United States and global regulatory interest came to play.

Although historically, companies have conducted evaluations of cardiovascular and central nervous system (CNS) functions, few routinely evaluated respiratory, gastrointestinal (GI), and renal functions, only a few conducted a ligand-binding/activity panel as part of their pharmacological profiling. Since 2001, studies to evaluate the cardiovascular, respiratory, pulmonary, and CNS safety pharmacology aspects of all but a few new drugs have been required (these exceptions will be discussed shortly) before they are evaluated clinically (i.e., have human exposure).

It is recognized that it is important that the tests employed detect bidirectional drug effects and that the tests performed be validated in both directions with appropriate reference (control) substances and be sensitive in the acute therapeutic range (Folke, 2000; Redfern et al., 2002). This requirement is less appropriate for multiparameter procedures. Blind testing could be an advantage. Ethical considerations are important, but the ultimate ethical criterion is the assessment of risk for humans. Safety pharmacology studies should not be overinclusive, but should be performed to the most exacting standards, including Good Laboratory Practice (GLP) compliance and results now must be reported with an accompanying SEND data set. Safety pharmacology data are acknowledged to be important to be available during the planning stage for phase I studies, but such is still less often the case than not. Partly, this arises from the viewpoint that human tolerance (particularly in a well-designed and executed phase I study in normal volunteers) is, in itself, an adequate assessment of safety pharmacology.

This is, of course, backward—such human tolerance is rather, properly, an extension (and expression) of the non-clinical safety pharmacology.

The other point of view in the past has been that properly executed repeated-dose preclinical safety studies meeting the current design will (or could) fill these needs. Recognizing that undesired pharmacological activities of novel drugs or biologics may limit development of a therapeutic agent prior to the characterization of any toxicological effects in rodent species, general pharmacology assays have traditionally been used to screen new agents for pharmacological effects on the central and peripheral nervous systems, the autonomic nervous system and smooth muscles, the respiratory and cardiovascular systems, the digestive system, and the physiological mechanisms of water and electrolyte balance (Cavero, 2009). In large animal species, such as dogs and nonhuman primates, a smaller number of animals per study limit their use for screening assays, but these species may play an important role in more detailed mechanistic studies. For drugs and biologics that must be tested in nonhuman primates because of species-specific action of the test agent, functional pharmacology data are often collected during acute or subacute toxicity studies. This requires careful experimental design to minimize any impact that pharmacological effects or instrumentation may have on the assessment of toxicity. In addition, with many new therapies targeted at immunological diseases, the pharmacological effect of therapeutics on the immune system presents new challenges for pharmacology profiling. The applications of pharmacology assays by organ system in both rodent and large animal species are discussed, as well as practical issues in assessing pharmacological end points in the context of toxicity studies (Martin et al., 1997; Matsuzawa et al., 1997; Pugsley et al., 2008; Dorato et al., 2015; Pugsley and Curtis, 2015).

Pharmacoepidemiology studies in Europe and the United States show that adverse drug reactions (ADRs) now may account for up to 10% of the admissions of patients to hospitals at a cost of hundreds of millions of US dollars annually (Sjoquist, 2000). This represents a considerable increase compared to 20 years ago. A partial explanation is the many shortcomings of clinical trials and their relevance for healthcare. ADRs are often poorly studied and documented in these studies and very seldom included in health economic analyses of the value of new drugs. Pharmacovigilance is product—rather than utilization—oriented and quite invisible in clinical medicine. This is regrettable, since up to 50% of ADRs are dose-dependent and thus preventable. Hopefully, the rapid progress in molecular and clinical pharmacogenetics will provide new tools for clinicians to choose and dose drugs according to the individual needs of patients. A good starting point for those not well versed in pharmacology and the range of potential mechanisms of action and of interaction can be found in Goodman and Gilman (Brunton et al., 2011).

20.1 REGULATORY REQUIREMENTS

While the ICH guidelines promulgated in November 2000 (implemented in Europe in the three regions in June 2001) are the announced international standards for regulation, the actual situation in different countries took more than a decade to truly “harmonize.”

In the EU, the CPMP issued a draft “Note for Guidance on Safety Pharmacology Studies in Medicinal Product Development” in 1998.

The actual requirements of the initial November 8, 2000 (finalized July 2001), ICH (S7A) guidelines provided only broad outlines of requirements. They called for the conduct of studies in a core battery to assess effects on the cardiovascular (Table 20.1), respiratory (Table 20.2), central nervous (Table 20.3), and secondary organ systems (Table 20.4). Follow-up studies for the care battery are also required on a case-by-case basis for the three main organ systems:

- *CNS*: Behavioral pharmacology, learning and memory, specific ligand binding, neurochemistry, visual, auditory and/or electrophysiology examinations, and so on
- *Cardiovascular system*: Behavioral pharmacology, learning and memory, specific ligand binding, neurochemistry, visual, auditory, and/or electrophysiology examinations, and so on

TABLE 20.1 Cardiovascular System Safety Pharmacology Evaluations

Core

- Hemodynamics (blood pressure, heart rate)
- Autonomic function (cardiovascular challenge)
- Electrophysiology (ECG in dog)

QT prolongation (noncore)

- An additional guideline, ICH S7B, is in preparation which will address the assessment of potential for QT prolongation. In the meantime, CPMP 986/96 indicates the following preclinical studies should be conducted prior to first administration to man:
 - Cardiac action potential *in vitro*
 - ECG (QT measurements) in a cardiovascular study which would be covered in the core battery
 - hERG channel interactions (hERG expressed in HEK293 cells)

TABLE 20.2 Respiratory System Safety Pharmacology Evaluation

Respiratory functions

- Measurement of rate and relative tidal volume in conscious animals

Pulmonary function

- Measurement of rate, tidal volume, and lung resistance and compliance in anesthetized animals

TABLE 20.3 Central Nervous System (CNS) Safety Pharmacology Evaluation

Irwin test or functional observation battery
General assessment of effects on gross behavior and physiological state^a

Locomotor activity
Specific test for sedative, excitatory effects of compounds

Neuromuscular function
Assessment of grip strength

Rotarod
Test of motor coordination

Anesthetic interactions
Test for central interaction with barbiturates

Anti-/proconvulsant activity
Potentiation or inhibition of effects of pentylenetetrazole

Tail flick
Tests for modulation of nociception (also hot plate, Randall–Selitto, tail pinch)

Body temperature
Measurement of effects on thermoregulation

Autonomic function
Interaction with autonomic neurotransmitters *in vitro* or *in vivo*

Drug dependency
Test for physical dependence, tolerance, and substitution potential

Learning and memory
Measurement of learning ability and cognitive function in rats

^aUsually a functional observational battery (FOB) is integrated into rodent (rat dose range finding or) repeat-dose toxicity studies to meet this requirement.

- *Respiratory system*: Tidal volume, bronchial resistance, compliance, pulmonary arterial pressure, blood gases

Conditions are also defined under which studies are not necessary:

- Locally applied agents (e.g., dermal or ocular) where systemic exposure or distribution to the vital organs is low.
- Cytotoxic agents for treatment of end-stage cancer patients.
- Biotechnology-derived products that achieve highly specific receptor targeting. Recent regulatory opinions and actions by the FDA have called this exclusion into question, leading recommendations for specific cardiovascular testing strategies for biologics (Vargas et al., 2008). Likewise, specific recommendations for oligonucleotides (which are small molecules) are supported (Berman et al., 2014).
- New salts having similar pharmacokinetics and pharmacodynamics to already well-characterized drugs.

TABLE 20.4 Secondary Organ System Safety Pharmacology Evaluation

Renal system
Renal function: measurement of effects on urine excretion in saline-loaded rats
Renal dynamics: measurement of renal blood flow, GFR, and clearance

GI system
GI function: measurement of gastric emptying and intestinal transit
Acid secretion: measurement of gastric acid secretion (Shay rat)
GI irritation: assessment of potential irritancy to the gastric mucosa
Emesis: nausea, vomiting

Immune system
Passive cutaneous anaphylaxis (PCA): test for potential antigenicity of compounds

Other
Blood coagulation
in vitro platelet aggregation
in vitro hemolysis

In recent years, there has been increasing support to perform as many safety pharmacology assessments not as separate freestanding studies, but rather more toward incorporating as many of these assessments as possible into existing general toxicology studies, especially while recently available technology makes this more feasible (Redfern et al., 2013).

20.2 STUDY DESIGNS AND PRINCIPLES

As a starting place, unlike older pharmacology studies, safety pharmacology studies are conducted as GLP studies unless being performed as screens. At the same time, unlike other safety assessment studies, these do not need to vastly exceed intended therapeutic doses so as to identify signs of toxicity. In this sense, they are closer to hazard tests.

General guidance for dose (or concentration) section for such studies is as follows (ICH, 2000, 2011; Gad, 2012):

- *In vivo* studies
 - Designed to define the dose–response curve of the adverse effects
 - Doses should include and exceed primary pharmacodynamic or therapeutic range
 - In the absence of safety pharmacology parameters, the highest doses equal or exceed some adverse effects (toxic range)
- *In vitro* studies
 - Generally designed to establish an effect–concentration relationship (range of concentrations)

Consideration in the selection and design of specific studies is straightforward.

- The following factors should be considered (selection):
 - Effects related to the therapeutic class
 - Adverse effects associated with members of the chemical/therapeutic class
 - Ligand binding or enzyme data suggesting a potential for adverse effects
 - Data from investigations that warrant further investigation
- A hierarchy of organ systems can be developed:
 - Importance with respect to life-supporting functions:
 - Cardiovascular
 - Respiratory
 - CNS
 - Functions which can be transiently disrupted without causing irreversible harm

The absence of observed activity may represent either a true- or false-negative effect. If an assay is valid for the particular test article and fails to indicate activity, it is an appropriate indicator of future events (Green, 1997). However, if the assay is insensitive or incapable of response, the test represents a form of bias, albeit unconscious. Many biological products demonstrate a specificity of response that limits the utility of commonly employed safety studies. Specificity for many biologics arises from both their physicochemical properties and their similarity to endogenous substances which are regulated in a carefully controlled manner. To overcome the issue of a lack of predictive value, various approaches may be used. For example, a multiple testing strategy of mutually reinforcing studies may be employed, or safety studies may be adaptively fit to the biological circumstance.

A separate issue is how and when to consider isomers, metabolites, and the actual finished product:

- Generally, the parent compound and its major metabolite(s) that achieve systemic exposure should be evaluated.
- It may be important to test active metabolites from humans.
- Testing of individual isomers should also be considered.
- Studies with the finished product are only necessary if kinetics/dynamics are substantially altered in comparison to the active substance previously tested.

There are also special considerations as to how to statistically evaluate specific aspects of these studies. Specifically, analysis of time to event becomes very important (Anderson et al., 2000).

20.3 ORGAN SYSTEM-SPECIFIC TESTS

20.3.1 General Considerations in Selection and Design of Safety Pharmacology Studies

The following factors should be considered (selection):

- Effects related to the therapeutic class (e.g., proarrhythmia is a common feature of antiarrhythmic drugs)
- Adverse effects associated with members of the chemical/therapeutic class (e.g., antipsychotics and QT prolongation)
- Receptor/enzyme/ion channel binding data suggesting a potential for adverse effects
- Any data from previous studies that warrant further investigation

A hierarchy of organ systems is considered:

- Importance with respect to life-supporting functions:
 - Cardiovascular
 - Respiratory
 - Central nervous
 - Functions which can be transiently disrupted without causing irreversible harm (e.g., urinary system, GI tract)

20.3.2 Studies on Metabolites, Isomers, and Finished Products

Generally, the parent compound and its major metabolite(s) that achieve systemic exposure need to be evaluated. This means that either the test species must be metabolically comparable to humans or human metabolites must also be evaluated. The testing of individual isomers also needs to be considered.

20.4 CARDIOVASCULAR

While the initial greatest concern for cardiovascular risks was associated with QT prolongation (first raised by the CAST study in 1989), it has become clear since that there are a range of potentially life-threatening cardiovascular pharmacologic drug effects which must be evaluated (see Braunwald, 2008; Gad, 2008) by drugs not intended to have cardiac effects (see Table 20.5). The cardiovascular system is one of the primary vital functions which must be examined during safety pharmacology studies. Cardiovascular system functioning is maintained by cardiac electrical activity and by pump muscle function, which contribute to hemodynamic efficacy, and is both complex and the subject of a range of organ-specific toxicities (Gad, 2015a).

TABLE 20.5 Noncardiac Drugs Known to Induce or Worsen Heart Failure According to the Suggested Mechanism(s) Implicated

Drug Class	Drug
Cardiomyopathy	
Cytotoxic drugs	Doxorubicin, epirubicin, and other anthracyclines; mitoxantrone, cyclophosphamide, 5-fluorouracil, capecitabine
Immunomodulating drugs/antibodies	Trastuzumab, interferon- α 2, interleukin-2, infliximab, etanercept
Antifungal drugs	Itraconazole, amphotericin B
Antipsychotic drugs	Clozapine
Pulmonary hypertension	
Antimigraine drugs	Methysergide, ergotamine
Appetite suppressants	Fenfluramine, fluramine, phentermine
Heart valve abnormalities	
Antimigraine drugs	Methysergide, ergotamine
Appetite suppressants	Fenfluramine, fluramine, phentermine
Antiparkinsonian drugs	Pergolide
Fluid overload	
NSAIDs, including cyclooxygenase-2 inhibitors	All
Antidiabetic drugs	Rosiglitazone, pioglitazone, troglitazone
Glucocorticoids	All
Herbal drugs	Herbal drugs containing licorice or adulterated with NSAIDs

The aim of cardiovascular safety pharmacology is to evaluate the effects of test substances on the most pertinent components of this system, in order to detect potentially undesirable effects before engaging in clinical trials (Lacroix and Provost, 2000). In the basic program, a detailed hemodynamic evaluation is carried out in the anesthetized dog. It is completed by cardiac and/or cellular electrophysiology investigations in order to assess the arrhythmogenic risk. The basic program can be preceded by rapid and simple testing procedures, during the early drug discovery stage. It should be completed, if necessary, by specific supplementary studies, depending on the data obtained during the early clinical trials. The current gold standard study is performed using unrestrained radiotelemetrized dogs (Gauvin et al., 2006) and can measure multiple end points continuously.

20.4.1 Hemodynamics, ECG, and Respiration in Anesthetized Dogs or Primates

Anesthetized studies use modular instruments data capture systems to record six-lead ECG (I, II, III, aV_r, aV_p, and aV_f)

(Hamlin, 2008), left ventricular pressure variables, arterial blood pressure and respiratory measurement of arterial blood flow in selected vascular beds, cardiac output, and arterial blood gas measurement; ECG intervals are measured from the lead II. ECG and QT interval can be corrected for heart rate using Bazett's, Fridericia's, or Van de Water's formulas. Different formulas are appropriate for different species (Solovien et al., 2006).

20.4.2 Cardiac Conduction Studies

In addition to the earlier hemodynamic measurements, intra-ventricular, intra-arterial, and atrioventricular conduction times and velocities can be measured using epicardial electrodes in the anesthetized and thoracotomized dog.

20.4.3 Conscious Dog, Primate, or Minipig Telemetry Studies

Effects on blood pressure, heart rate, lead II ECG, core body temperature, and locomotor activity can be explored using Data Sciences International (DSI) telemetry (or similar) implanted devices in guinea pigs, dogs, pigs, and primates. Effects on behavior can be captured on video using CCTV for dog and primate studies. Repeated administration and interaction studies may also be performed. This approach has the advantages of avoiding the effects of both anesthesia and restraint of the animal. Myocardial contractibility has also been suggested for inclusion in these studies, and telemetry methods are now available for this (Markert et al., 2007). It is occasionally not feasible to conduct initial studies on dogs as they are prone to emetic responses, forcing conduction of such studies to pigs. However, the animal size (depth of tissues around implanted sensors) makes enhanced levels of sensor-transmitted power critical.

20.4.4 Six-Lead ECG Measurement in the Conscious Dog and Minipig

Conscious studies use Integrated Telemetry System devices for measurement of blood pressure and six chest lead ECG measurements (V2, V4, V6, V10, rV2, and rV4). ECG interval analysis is performed on the V2 lead (RR, PR, QT, QTc intervals, QRS duration). QT dispersion can also be measured in either of these species (Milano, 2012). Locomotor activity can be monitored and behavior captured on video using CCTV:

- In addition to validated systems for automatic measurement of ECG parameters, ECGs can be reviewed by our veterinary cardiology services to detect any transparent abnormalities.
- Colonies of telemetered animals can be set up and maintained for repeat use.

- Respiration rate measurements can be taken from dogs in slings using a pneumograph system.
- An animal-specific correction of QT interval can also be derived for each dog/primate based on individual variability of QT interval with rate using the Framingham equation.

Concerns over the arrhythmogenic effects of several marketed compounds resulted in the issue of the “pointsto-consider” document, CPMP 986/96, by the EMA (<http://www.fda.gov/ohrms/dockets/ac/03/briefing/pubs/cpmp.pdf>).

Studies to assess the effects of compound and any known metabolites on ECG and cardiac action potentials are recommended. Changes in action potential duration and other parameters measured are a functional consequence of effects on the ion channels which contribute to the action potential. This *in vitro* test is considered to provide a reliable risk assessment of the potential for a compound to prolong QT interval in man. The guinea pig had also been recommended for such testing (Lacroix, 2002) based on prior use history, but few GLP labs have supported or offer such use.

20.4.5 Systems for Recording Cardiac Action Potentials

These include a range of currently available methodologies, some of which can be incorporated into existing study designs:

- Isolated ventricular Purkinje fibers from dog or sheep
- Isolated right ventricular papillary muscle from guinea pig
- Continuous intracellular recording of action potentials and online analysis of resting membrane potential, maximum rate of depolarization, upstroke amplitude, and action potential duration using NOTOCORD-hem data acquisition system
- Assessment of use-dependent and inverse use-dependent actions by stimulation at normal, bradycardic, and tachycardic frequencies (e.g., see in the succeeding text inverse use-dependent properties of sotalol in dog Purkinje fibers)

20.4.6 Special Case (and Concern): QT Prolongation

Drugs that alter ventricular repolarization (generally recognized as drugs that prolong the QT interval) have been associated with malignant ventricular arrhythmias (especially the distinctive polymorphic ventricular tachycardia called Torsades de pointes) and death. Many of the drugs now known to alter ventricular repolarization were developed as antiarrhythmics (e.g., dofetilide, sotalol), but others (e.g., cisapride, terfenadine) were developed without the expectation of any effect upon electrically excitable mem-

branes (Fenichel and Koerner, 1999). This has led to ICH promulgating ICH S7B (ICH, 2002) with specific guidance for evaluation.

The QT interval of the ECG is reflected in three main ways: First, electrophysiologically, it reflects the depolarization and repolarization phase of ventricular myocytes. Second, mechanically, it represents the time of contraction of the ventricles. Lastly, physiologically, its duration is a function of numerous variables (heart rate, diseases, nutrition, diurnal cycle, etc.). Diagnostically, a prolongation of its duration indicates an enhanced risk for ventricular arrhythmias (Torsades de pointes) and sudden cardiac death.

The association between abnormalities of repolarization and life-threatening arrhythmias is stronger than some other associations between laboratory abnormalities and clinical events. For example, there are drugs (tacrine) and inborn errors of metabolism (Gilbert's syndrome) that cause wild excursions in liver function tests, but with no adverse consequences. In contrast, although the severity or proarrhythmia at a given QT duration varies from drug to drug and from patient to patient, no drug is known to alter ventricular repolarization without inducing arrhythmias,¹ and each of the several congenital long QT syndromes is associated with an elevated incidence of malignant arrhythmias.

With any given repolarization-altering drug, the risk of malignant arrhythmia seems to increase with increasing QT interval, but there is no well-established threshold duration below which a prolonged QT interval is known to be harmless. The extent of QT prolongation seen with a given drug and patient may be nonlinearly related to patient factors (sex, electrolyte levels, etc.) and to serum levels of the drug and/or its metabolites. The actual incidence of malignant arrhythmias, even in association with the drugs most known to induce them, is relatively low, so failure to observe malignant arrhythmias during clinical trials of ordinary size and duration does not provide substantial reassurance.

Abnormal repolarization and the associated arrhythmias are the end results of a causative chain that starts with alternations in the channels of ionic flux through cell membranes. Some cells (e.g., those of the Purkinje system or mid-myocardium) seem especially susceptible to these changes. At a substrate level, the links on the chain are alterations in the time course of the action potential, alterations in the propagation of action potentials within a given cell, and alterations in the propagation of action potentials from cell to cell within

¹Some QT-prolonging drugs (e.g., amiodarone; see Hohnloser et al. (1994)) are not reported to have caused many arrhythmic deaths, but this observation must be interpreted carefully. In a population with a high incidence of life-threatening arrhythmias, a drug with both proarrhythmic and antiarrhythmic effects might cause a net reduction in arrhythmias, and the arrhythmias that it had induced might not be attributed to it. In a population whose native arrhythmias were not life-threatening, the same drug might result in a net decrease in mortality.

syncytia and from tissue to tissue within the heart. At a higher level of aggregation, one sees “afterdepolarizations” in the terminal portion of the action potential, spontaneous beats triggered by afterdepolarizations, propagation of these beats to other cells, and reentrant excitation.

With these considerations in mind, the problem of altered repolarization should be integrated into drug development by (Malik and Camm, 2001):

- *In vitro* screening of the drug and its metabolites for effects on ion channels (especially I_{Kr})
- *In vitro* screening of the drug and its metabolites for effects on action potential duration
- Screening of the drug and its metabolites for altered repolarization in animal models
- Focused preclinical studies for proarrhythmia if altered repolarization is seen in preclinical screening or in patients

20.4.7 Some Specific Techniques Which Can Be Employed

20.4.7.1 Cloned Human Potassium Channels

- Assessment of effects on cloned human ether-à-go-go-related gene (hERG) K^+ channels stably expressed in a cell line by measurement of whole-cell K current (I_{Kr}) using voltage clamp.
- Other cloned human ion channels (e.g., KvLQT1/minK-IKs currents) are also possible.

20.4.7.2 Cardiac Action Potential In Vitro: Purkinje Fibers

- Intracellular recording of action potentials from cardiac Purkinje fibers isolated from dog or sheep ventricle
- Measurement of maximum rate of depolarization and action potential duration to detect sodium and potassium channel interactions, respectively, according to recommendations in the EMA “points-to-consider” document—CPMP 986/96 (2000)

20.4.7.3 Monophasic Action Potential in Anesthetized Guinea Pigs

- Epicardial monophasic action potential recording using suction/contact pressure electrodes according to Carlsson et al. (1997)
- Simultaneous measurement of ECG

20.4.7.4 ECG by Telemetry in Conscious Guinea Pigs Lead II ECG recording using DSI telemetry device. Repeated administration and interaction studies can be performed.

20.4.7.5 Hemodynamics and ECG in Anesthetized or Conscious Dogs or Primates

- Conscious studies using DSI telemetry for blood pressure and lead II ECG or the ITS system for blood pressure and six chest lead ECG measurements (including QT dispersion)
- Anesthetized studies using MI² data capture system with additional measurement of blood flow in selected vascular beds, cardiac output, and respiratory and left ventricular function

20.4.8 Relevance of hERG to QT Prolongation

Compounds which are associated with ADRs of QT prolongation, arrhythmias such as Torsades de pointes, and sudden death predominantly have a secondary pharmacological interaction with the rapidly activating delayed rectifier potassium channel I_{Kr} . The gene encoding this channel has been identified as hERG. Testing of compounds for interactions with the hERG channel allows the identification of potential risk of QT prolongation in humans and can be used as a screen in development candidate selection.

20.4.8.1 Expression and Recording Systems HEK293 cells have been transfected with cDNA for hERG1 to produce a stable expression system. The cell line has been obtained under license for the laboratory of Craig January at the University of Wisconsin (Mohammad et al., 1997).

20.5 CENTRAL NERVOUS SYSTEM

The primary screening tool for CNS safety pharmacology evaluation is the functional observational screen, which seeks to use objective but noninvasive methods for evaluating the pharmacologic effects of a drug on peripheral and nervous system effects.

Initially, the starting basis for such screens was the Irwin screen (Irwin, 1968), which is used to screen for effects in mice and still one of the ICH S7-designated primary screens for fulfilling the regulatory requirements for S7 evaluation of new drugs.

More commonly used is the rat functional observational battery (FOB), initially developed by Gad (1982) and subsequently further modified (Mattsson et al., 1996). Haggerty (1991) and Moscardo et al. (2007) present an excellent description of the rodent FOB as currently performed in the pharmaceutical industry. Other modifications/versions which are included under the ICH screening guidelines cover the use of the dog. Gad has developed, validated, and published FOB designs for dogs (Gad and Gad, 2003) primates, and most recently minipigs. In recent years, it has become common to incorporate a modified FOB into early

dose–response skin studies in rodents rather than have an independent study.

The neurobehavioral screens which serve to meet the primary regulatory requirement for CNS safety pharmacology evaluation all, of necessity, actually evaluate both central and peripheral nervous system functions. Such evaluations used, to the maximum extent possible, semiquantitative evaluations of a wide range of end points which serve to determine if there are effects on the primary functional domains of the CNS. The methods are noninvasive and use basic instruments to get quantitative data where possible—an electronic thermometer (to measure rectal/core body temperature), a strain gauge with T-bar animal grip (to measure forelimb grip strength), a sand table (to measure hind limb splay), an activity stage (to measure locomotor activity), and rotarod (to evaluate motor coordination).

Other required equipment usually includes a ditcher (for auditory startle), a penlight (for pupil response), and a blunt probe (for various touch-based reflexes). The complete screen should be performed in at least two (and preferably three) time intervals after a single dose of the drug.

There are four broad classes of approaches to any subsequent and more detailed assessment of nervous system effects of drugs in animals.

20.5.1 Isolated Tissue Assays

The classic approach to screening for nervous system effect is a series of isolated tissue preparation bioassays, conducted with appropriate standards, to determine if the material acts pharmacologically directly on neural receptor sites or trans-

mission properties. Though these bioassays are normally performed by a classical pharmacologist, a good technician can be trained to conduct them. The required equipment consists of a Magnus (or similar style) tissue bath (Nodine and Sigler, 1964; Turner, 1965; Offermeier and Ariens, 1966), physiograph or kymograph, force transducer, glassware, stimulator, and bench spectrophotometer. The assays utilized in the screening battery are listed in Table 20.6, along with the original reference describing each preparation and assay. The assays are performed as per the original author's descriptions with only minor modifications, except that control standards (as listed in Table 20.6) are always used. Only those assays that are appropriate for the neurological/muscular alterations observed in the screen are utilized. Note that all these are intact organ preparations, not minced tissue preparations as others (Bondy, 1979) have recommended for biochemical assays.

The first modification in each assay is that, where available, both positive and negative standard controls (pharmacological agonists and antagonists, respectively) are employed. Before the preparation is utilized to assay the test material, the tissue preparation is exposed to the agonist to ensure that the preparation is functional and to provide a baseline dose–response curve against which the activity of the test material can be quantitatively compared. After the test material has been assayed (if a dose–response curve has been generated), one can determine whether the antagonist will selectively block the activity of the test material. If so, specific activity at that receptor can be considered as established. In this assay sequence, it must be kept in mind that a test material may act to either stimulate or depress

TABLE 20.6 Isolated Tissue Pharmacologic Assays

Assay System	End Point	Standards (Agonist/Antagonist)	References
Rat ileum	General activity	None (side-spectrum assay for intrinsic activity)	Domer (1971)
Guinea pig vas deferens	Muscarinic Nicotinic Muscarinic	Methacholine/atropine Methacholine/hexamethonium Methacholine/atropine	Leach (1956)
Rat serosal strip	Nicotinic	Methacholine/hexamethonium	Khayyal et al. (1974)
Rat vas deferens	Alpha-adrenergic	Norepinephrine/phenoxybenzamine	Rossum (1965)
Rat uterus	Beta-adrenergic	Epinephrine/propranolol	Levy and Tozzi (1963)
Rat uterus	Kinin receptors	Bradykinin/none	Gecse et al. (1976)
Guinea pig tracheal chain	Dopaminergic	Dopamine/none	Domer (1971)
Rat serosal strips	Tryptaminergic	5-Hydroxytryptamine (serotonin)/dibenzylamine or lysergic acid dibromide	Lin and Yeoh (1965)
Guinea pig tracheal chain	Histaminergic	Histamine/benadryl	Castillo and De Beer (1947a, b) Cox et al. (1975)
Guinea pig ileum (electrically stimulated)	Endorphin receptors	Methenkephalin/none	
Red blood cell hemolysis	Membrane stabilization	Chlorpromazine (not a receptor-mediated activity)	Seeman and Weinstein (1966)
Frog rectus abdominis	Membrane depolarization	Decamethonium iodide (not a receptor-mediated activity)	Burns and Paton (1951)

activity, and therefore the roles of the standard agonists and antagonists may be reversed.

Commonly overlooked when performing these assays is the possibility of metabolism to be in an active form that can be assessed in this *in vitro* model. The test material should be tested in both original and “metabolized” forms. The metabolized form is prepared by incubating a 5% solution (in aerated Tyrode’s solution) or other appropriate physiological salt solution with strips of suitably prepared test species liver for 30 minutes. A filtered supernatant is then collected from this incubation and tested for activity. Suitable metabolic blanks should also be tested.

20.5.2 Electrophysiology Methods

There are a number of electrophysiological techniques available which can be used to detect and/or assess neurotoxicity. These techniques can be divided into two broad general categories: those focused on CNS function and those focused on peripheral nervous system function (Seppalainen, 1975).

First, however is the function of the individual components of the nervous system, how they are connected together, and how they operate as a complete system should be very briefly overviewed.

Data collection and communication in the nervous system occur by means of graded potentials, action potentials, and synaptic coupling of neurons. These electrical potentials may be recorded and analyzed at two different levels depending on the electrical coupling arrangements: individual cells (i.e., intracellular and extracellular) or multiple cells (e.g., electroencephalogram (EEG), evoked potentials (EPs), and slow potentials). These potentials may be recorded in specific central or peripheral nervous system areas (e.g., visual cortex, hippocampus, sensory and motor nerves, and muscle spindles) during various behavioral states or in *in vitro* preparations (e.g., nerve–muscle, retinal photoreceptor, and brain slice).

20.5.3 CNS Function: Electroencephalography

The EEG is a dynamic measure reflecting the instantaneous integrated synaptic activity of the CNS, which most probably represents, in coded form, all ongoing processes under higher nervous control. Changes in frequency, amplitude, variability, and pattern of the EEG are thought to be directly related to underlying biochemical changes, which are believed to be directly related to defined aspects of behavior. Therefore, changes in the EEG should be reflected by alterations in behavior and vice versa.

The human EEG is easily recorded and readily quantified, is obtained noninvasively (scalp recording), samples several regions of the brain simultaneously, requires minimal cooperation from the subject, and is minimally influenced by prior testing. Therefore, it is a very useful and recommended

clinical test in cases in which exposure to drugs produces symptoms of CNS involvement and in which long-term exposures to high concentrations are suspected of causing CNS damage.

Since the EEG recorded using scalp electrodes is an average of the multiple activity of many small areas of cortical surface beneath the electrodes, it is possible that in situations involving noncortical lesions, the EEG may not accurately reflect the organic brain damage present. Noncortical lesions following acute or long-term low-level exposures to toxicants are well documented in neurotoxicology (Norton, 1980). The drawback mentioned earlier can be partially overcome by utilizing activation or evocative techniques, such as hyperventilation, photic stimulation, or sleep, which can increase the amount of information gleaned from a standard EEG.

As a research tool, the utility of the EEG lies in the fact that it reflects instantaneous changes in the state of the CNS. The pattern can thus be used to monitor the sleep–wakefulness cycle activation or deactivation of the brain stem and the state of anesthesia during an acute electrophysiological procedure. Another advantage of the EEG, which is shared by all CNS electrophysiological techniques, is that it can assess the differential effects of toxicants (or drugs) on various brain areas or structures. Finally, specific CNS regions (e.g., the hippocampus) have particular patterns of after discharge following chemical or electrical stimulation which can be quantitatively examined and utilized as a tool in neurotoxicology.

The EEG does have some disadvantages, or, more correctly, some limitations. It cannot provide information about the effects of toxicants on the integrity of sensory receptors or of sensory or motor pathways. As a corollary, it cannot provide an assessment of the effects of toxicants on sensory system capacities. Finally, the EEG does not provide specific information at the cellular level and therefore lacks the rigor to provide detailed mechanisms of action.

Rats represent an excellent model for this as they are cheap, resist infection during chronic electrode and cannula implantation, and are relatively easy to train so that behavioral assessments can be made concurrently.

Depending on the time of drug exposure, the type of scientific information desired, and the necessity of behavioral correlations, a researcher can perform acute and/or chronic EEG experiments. Limitations of the former are that most drugs that produce general anesthesia modify the pattern of EEG activity and thus can complicate subtle effects of toxicants. However, this limitation can be partially avoided if the effect is robust enough. For sleep–wakefulness studies, it is also essential to monitor and record the electromyogram (EMG). Similarly, specific methods exist for assessing pain (Mogil, 2013).

Excellent reviews of these electrophysiology approaches can be found in Fox et al. (1982) and Takeuchi and Koike (1985).

20.5.4 Neurochemical and Biochemical Assays

Though some very elegant methods are now available to study the biochemistry of the brains and nervous system, none has yet discovered any generalized marker chemicals which will serve as reliable indicators or early warnings of neurotoxic actions or potential actions. There are, however, some useful methods. Before looking at these, however, one should understand the basic problems involved.

Normal biochemical events surrounding the maintenance and functions of the nervous system center around energy metabolism, biosynthesis of macromolecules, and neurotransmitter synthesis, storage, release, uptake, and degradation. Measurement of these events is complicated by the sequenced nature of the components of the nervous system and the transient and labile nature of the moieties involved. Use of measurements of alternations in these functions as indicators of neurotoxicity is further complicated by our lack of a complete understanding of the normal operation of these systems and by the multitude of day-to-day occurrences (such as diurnal cycle, diet, temperature, age, sex, and endocrine status) which are constantly modulating the baseline system. For detailed discussions of these difficulties, the reader is advised to see Johnson (1975) and Damstra and Bondy (1980, 1982).

Added to the spectrum of pharmacologic evaluation of CNS-active drugs for safety reasons has been a requirement to assess the addictive (abuse) potential of new drugs (FDA, 2010); starting with a determination that the drug is CNS active (either due to the target therapeutic activity or determination that there is receptor finding in the CNS), GLP studies are required to determine if there is an addictive/abuse potential in the therapeutic range of doses. These study types are (Kallman, 2015) a dependence/withdrawal study, a drug discrimination study, and a self-administration study. These studies are generally required prior to filing of an NDA.

20.6 RESPIRATORY/PULMONARY SYSTEM

The known effects of drugs from a variety of pharmacologic/therapeutic classes on the respiratory system and worldwide regulatory requirements support the need for conducting respiratory evaluations in safety pharmacology. Pharmaceuticals differ from industrial and environmental chemicals in that the scope of concern for their adverse safety effects on the respiratory system extends both to reversible functional degradations and to effects on the respiratory system's functionality due to systemically distributed agents administered by routes other than direct respiration. This is the realm of the relatively new field of safety pharmacology.

As early as 1964, it became apparent that β -adrenergic blocking agents could lead to bronchoconstriction (and possible death) in asthmatics (McNeill, 1964). Since then, many

similar adverse effects have been identified. These known effects of drugs from a variety of pharmacologic/therapeutic classes on the respiratory system are summarized in Tables 20.7–20.9. Resulting worldwide regulatory requirements (Tables 20.10 and 20.11) require the conduct of pre-

TABLE 20.7 Drugs Known to Cause Pulmonary Disease

<i>Chemotherapeutic</i>	<i>Analgesics</i>
Cytotoxic	Heroin ^a
Azathioprine	Methadone ^a
Bleomycin ^a	Naloxone ^a
Busulfan	Ethchlorvynol ^a
Chlorambucil	Propoxyphene ^a
Cyclophosphamide	Salicylates ^a
Etoposide	
Melphalan	<i>Cardiovascular</i>
Mitomycin ^a	Amiodarone ^a
Nitrosoureas	Angiotensin-converting enzyme inhibitors
Procarbazine	Anticoagulants
Vinblastine	Betablockers ^a
Ifosfamide	Dipyridamole
Noncytotoxic	Fibrinolytic agents ^a
Methotrexate ^a	Protamine ^a
Cytosine arabinoside ^a	Tocainide
Bleomycin ^a	
Procarbazine ^a	<i>Inhalants</i>
	Aspirated oil
<i>Antibiotic</i>	Oxygen ^a
Amphotericin B ^a	
Nitrofurantoin	<i>Intravenous</i>
Acute ^a	Blood ^a
Chronic	Ethanolamine oleate (sodium morrhuate) ^a
Sulfasalazine	Ethiodized oil (lymphangiogram)
Sulfonamides	Talc
Pentamidine	Fat emulsion
<i>Anti-inflammatory</i>	
Acetylsalicylic acid ^a	<i>Miscellaneous</i>
Gold	Bromocriptine
Methotrexate	Dantrolene
Nonsteroidal anti-inflammatory agents	Hydrochlorothiazide ^a
Penicillamine ^a	Methysergide
	Oral contraceptives
<i>Immunosuppressive</i>	Tocolytic agents ^a
Cyclosporin	Tricyclics ^a
Interleukin-2 ^a	L-Tryptophan
	Radiation
	Systemic lupus erythematosus (drug induced) ^a
	Complement-mediated leukostasis ^a

Under ICH (S7A) and FDA guidelines, all new drugs (with limited exception—see Chapter 22) must be evaluated for pharmacologic safety in three core organ systems (the central nervous system, cardiovascular system, and respiratory system). Table 20.10 presents the required determinations under these regulations for mandated respiratory system evaluations.

TABLE 20.10 Required Respiratory System Safety Pharmacology Evaluation

Respiratory functions

Measurement of rate, tidal volume, and lung resistance and compliance in anesthetized animals

scribed respiratory evaluations prior to drug in humans. The objective of such studies is to evaluate the potential for drugs to cause nonintended pharmacologic or toxicologic effects that influence respiratory function. Changes in respiratory function can result either from alterations in the pumping apparatus that controls the pattern of pulmonary ventilation or

from changes in the mechanical properties of the lung that determine the transpulmonary pressure (work) required for lung inflation and deflation.

The respiratory system is responsible for generating and regulating the transpulmonary pressures needed to inflate and deflate the lung. Normal gas exchange between the lung and blood requires breathing patterns that ensure appropriate alveolar ventilation. Ventilatory disorders that alter alveolar ventilation are defined as hypoventilation or hyperventilation syndromes. Hyperventilation results in an increase in the partial pressure of arterial CO₂ above normal limits and can lead to acidosis, pulmonary hypertension, congestive heart failure, headache, and disturbed sleep. Hypoventilation results in a decrease in the partial pressure of arterial CO₂ below normal limits and can lead to alkalosis, syncope, epileptic attacks, reduced cardiac output, and muscle weakness.

Normal ventilation requires that the pumping apparatus provide both adequate total pulmonary ventilation (minute volume) and the appropriate depth (tidal volume) and frequency of breathing. The depth and frequency of breathing required for alveolar ventilation are determined primarily by an anatomic dead space of the lung. In general, a rapid shallow breathing pattern (tachypnea) is less efficient than a slower deeper breathing pattern that achieves the same minute volume. Thus, any change in minute volume, tidal volume, or the rate of breathing can influence the efficiency of ventilation (Milic-Emili, 1982). The inspiratory and expiratory phases of individual breathing have rates of airflow and durations that are distinct and independently controlled (Boggs, 1992). Thus, by characterizing changes in the airflow rate and duration of each of these phases, mechanisms responsible for changes in tidal volume or respiratory rate can be identified (Milic-Emili, 1982; Indans, 2002). For example, a decrease in

airflow during inspiration (the active phase) is generally indicative of a decrease in respiratory drive, while a decrease in airflow during expiration (the passive phase) is generally indicative of an obstructive disorder.

Mechanisms of ventilatory disorders can also be characterized as either central or peripheral. Central mechanisms involve the neurologic components of the pumping apparatus that are located in the CNS and include the medullary central pattern generator (CPG) as well as integration centers located in the medulla, pons, hypothalamus, and cortex of the brain that regulate the output of the CPG (Boggs, 1992). The major neurologic inputs from the peripheral nervous system that influence the CPG are the arterial chemoreceptors (Boggs, 1992). Many drugs stimulate or depress ventilation by selective interaction with the CNS (Eldridge and Millhorn, 1981; Mueller, 1982; Keats, 1985) or arterial chemoreceptors (Heymans, 1955; Heymans and Neil, 1958).

Defects in the pumping apparatus are classified as hypo- or hyperventilation syndromes and are best evaluated by examining ventilatory parameters in a conscious animal model. The ventilatory parameters include respiratory rate, tidal volume, minute volume, peak (or mean) inspiratory flow, peak (or mean) expiratory flow, and fractional inspiratory time. Defects in mechanical properties of the lung are classified as obstructive or restrictive disorders and can be evaluated in animal models by performing flow-volume and pressure-volume maneuvers, respectively. The parameters used to detect airway obstruction include peak expiratory flow, forced expiratory flow at 25 and 75% of forced vital capacity, and a timed forced expiratory volume, while the parameters used to detect lung restriction include total lung capacity, inspiratory capacity, functional residual capacity, and compliance. Measurement of dynamic lung resistance and compliance, obtained continuously during tidal breathing, is an alternative method for evaluating obstructive and restrictive disorders, respectively, and is used when the response to drug treatment is expected to be immediate (within minutes postdose). The species used in the safety pharmacology studies are the same as those generally used in the toxicology studies (rats and dogs) since pharmacokinetic and toxicologic/pathologic data are available in these species. These data can be used to help select test measurement intervals and doses and to aid in the interpretation of functional change. The techniques and procedures for measuring respiratory function parameters are well established in guinea pigs, rats, and dogs (Amdur and Mead, 1958; King, 1966; Mauderly, 1974; Diamond and O'Donnell, 1977; Murphy, 1994).

The key questions in safety pharmacology of the respiratory system are as follows:

- Does the substance effect of the mechanisms of respiratory control (central or peripheral) leading to hypoventilation (respiratory depression) or hyperventilation (respiratory stimulation)?

- Does the substance act on a component of the respiratory system to induce, for example, bronchospasm, obstruction, and fibrosis?
- Does the substance induce acute effects, or can we expect chronic effects?
- Are the effects observed dose-dependent or independent?

The classic approach to measuring respiratory function in laboratory animals is plethysmography. It has two basic governing principles (Palecek, 1969; O'Neil and Raub, 1984; Brown and Miller, 1987; Boggs, 1992):

1. The animal (mice, rat, or dog), anesthetized or not, restrained or not, is placed in a chamber (single or double) with pneumotachographs.
2. The variations of pressure in chamber(s) at the time of the inspiration and the expiration make it possible to obtain the respiratory flow of the animal.

There are three main types of body plethysmographs: constant volume, constant pressure, and pressure volume. The constant-volume body plethysmograph is a sealed box that detects volume change by the measurement of pressure changes inside the box. While inside the plethysmograph, inhalation of room air (from outside the plethysmograph) by the test animal induces an increase in lung volume (chest expansion) and thus an increase in plethysmograph pressure. On the other hand, exhalation to the atmosphere (outside the plethysmograph) induces a decrease in the plethysmograph pressure. The magnitude of lung volume change can be obtained via measurement of the change in plethysmographic pressure and the appropriate calibration factor. The plethysmograph is calibrated by injecting or withdrawing a predetermined change in box pressure. To avoid an adiabatic artifact, the rate of air injection or withdrawal is kept the same as that of chest expansion, indicated by the same dP/dt (change in pressure over time).

The constant-pressure body plethysmograph is a box with a pneumotachograph port built into its wall. This plethysmograph detects volume changes via integration of the flow rate, $\int \Delta \text{Flow}$, which is monitored by the pneumotachograph port. There is an outward flow (air moving from the plethysmograph to the atmosphere) during inspiration and inward flow during expiration. Alternatively, in place of a pneumotachograph, a spirometer can be attached to the constant-pressure plethysmograph to detect volume changes. For the detection of plethysmograph pressure and flow rate, sensitive pressure transducers are usually employed. It is important that the transducer be capable of responding to volume changes in a linear fashion within the volume range studied. The plethysmograph should have negligible leaks, and temperature should not change during all respiratory maneuvers. The plethysmo-

graph should also have linear characteristics with no hysteresis. Dynamic accuracy requires an adequate frequency response. A fast integrated flow of plethysmograph, with a flat amplitude response for sinusoidal inputs up to 240 Hz, has been developed for rats, mice, and guinea pigs (Sinnott, 1981). Similar plethysmographs can also be provided for use with large animals.

A third type of pressure-volume plethysmograph has the mixed characteristics of the two types of body box mentioned earlier. For a constant-pressure plethysmograph, the change in volume at first is associated with gas compression or expansion. This fraction of the volume change can be corrected by electronically adding the plethysmographic pressure change to the volume signal. Therefore, the combined pressure-volume plethysmograph has excellent frequency-response characteristics and a wide range of sensitivities (Leigh and Mead, 1974).

If volume, flow rate, and pressure changes are detected at the same time, several respiratory variables can be derived simultaneously from the raw signals. The whole-body plethysmograph method can then be used to measure most respiratory variables, such as tidal volume and breathing frequency, and minute variables, such as tidal volume, breathing frequency, minute ventilation, compliance, pulmonary resistance, functional residual capacity, pressure-volume characteristics, and maximal expiratory flow-volume curves. Table 20.12 defines the parameters that are typically determined by these methods.

Selection of the proper reference values for the interpretation of findings is essential (Drazen, 1984; American Thoracic Society, 1991).

20.6.1 Design of Respiratory Function Safety Studies

The objective of a safety pharmacology evaluation of the respiratory system is to determine whether the drug has the potential to produce a change in respiratory function. Since a complete evaluation of respiratory function must include both the pumping apparatus and the lung, respiratory function safety studies are best designed to evaluate both of these functional components. The total respiratory system is evaluated first by testing for drug-induced changes in ventilatory patterns of intact conscious animals. This is followed by an evaluation of drug-induced effects on the mechanical properties of the lung in anesthetized/paralyzed animals. Together, these evaluations are used to determine (McNeill, 1964) whether drug-induced changes in the total respiratory system have occurred and (Touway and Le Mosquet, 2000) whether these changes are related to pulmonary or extrapulmonary factors.

The time intervals selected for measuring ventilatory patterns following oral administration of a drug should be based on pharmacokinetic data. The times selected generally include the time to reach peak plasma concentration of the drug (T_{\max}),

TABLE 20.12 Functional Respiratory Responses to Standard Pharmacologic Agents

	Theophylline	Pentobarbital	Diazepam	Codeine
Parameters	10 mg kg ⁻¹ PO	35 mg kg ⁻¹ IP	35 mg kg ⁻¹ IP	100 mg kg ⁻¹ IP

+ is an increase and - a decrease; F, respiratory rate; PEF, the pulmonary exhalation rate; PIF, the pulmonary inhalation rate; s, seconds; Tc, exhalation time; Ti, inhalation time or duration; TV, tidal volume.

at least one time before and one after T_{max} , and one time that is approximately 24 h after dosing to evaluate possible delayed effects. If the drug is given as a bolus intravenous (IV) injection, ventilatory parameters are monitored for approximately 5 min predose and continuously for 20–30 min postdose; 1, 2, 4, and 24 h time intervals are also monitored to evaluate possible delayed effects. If administered by inhalation or IV infusion, ventilatory parameters would generally be monitored continuously during the exposure period and at 1, 2, 3, and 24 h time intervals after dosing.

The time interval showing the greatest ventilatory change is selected for evaluating lung mechanics. However, if no ventilatory change occurred, the T_{max} would be used. If the mechanical properties of the lung need to be evaluated within 30 min after dosing, then dynamic measurements of compliance and resistance are performed. Measurements include a predose baseline and continuous measurements for up to approximately 1 h postdose. If the mechanical properties of the lung need to be measured at 30 min or longer after dosing, then a single time point is selected, and the pressure-volume and flow-volume maneuvers are performed.

Supplemental studies including blood gas analysis, end-tidal CO₂ measurements, or responses to CO₂ gas and NaCN can be conducted to gain after the ventilatory and lung mechanical findings have been evaluated. In general, these would be conducted as separate studies.

20.6.2 Capnography

The measurements of rates, volumes, and capacities provided by plethysmograph measurements have a limited ability to detect and evaluate some ventilatory disorders (Murphy, 1994) that markedly affect blood gases.

Detection of hypo- or hyperventilation syndromes requires measurement of the partial pressure of arterial CO₂ (PaCO₂). In humans and large animal models, this can be accomplished

by collecting arterial blood with a catheter or needle and analyzing for PaCO₂ using a blood gas analyzer. In conscious rodents, however, obtaining arterial blood samples by needle puncture or catheterization during ventilatory measurements is generally not practical. An alternative and noninvasive method for monitoring PaCO₂ is the measurement of peak expired (end-tidal) CO₂ concentrations. This technique has been successfully used in humans (Nuzzo and Anton, 1986) and recently has been adapted for use in conscious rats (Murphy, 1994). Measuring end-tidal CO₂ in rats requires the use of a nasal mask and a microcapnometer (Columbus Instruments, Columbus, OH) for sampling air from the mask and calculating end-tidal CO₂ concentrations. End-tidal CO₂ values in rats are responsive to ventilatory changes and accurately reflect changes in PaCO₂ (Murphy, 1994).

A noninvasive procedure in conscious rats has been developed for use in helping to distinguish between the central and peripheral nervous system effects of drugs on ventilation. Exposure to CO₂ gas stimulates ventilation primarily through a central mechanism (Borison, 1977). In contrast, a bolus injection of NaCN produces a transient stimulation of ventilation through a mechanism that involves selective stimulation of peripheral chemoreceptors (Heymans and Neil, 1958). Thus, to distinguish central from peripheral nervous system effects, our procedure measures the change in ventilatory response (pretreatment vs. posttreatment) to both a 5 min exposure to 8% CO₂ gas and a bolus IV injection of 300 μg kg⁻¹ of NaCN. In this paradigm, a central depressant (e.g., morphine sulfate) inhibits the CO₂ response and has little effect on the NaCN response.

The species selected for use in safety pharmacology studies should be the same as those used in toxicology studies. The advantages of using these species (rat, dog, or monkey) are that (McNeill, 1964) the pharmacokinetic data generated in these species can be used to define the test measurement intervals and (Touvay and Le Mosquet, 2000) acute toxicity data

can be used to select the appropriate high dose. Further, the toxicologic/pathologic findings in these species can be used to help define the mechanism of functional change. The rat is the primary choice since rats are readily available, and techniques for measuring pulmonary function are well established in this species.

20.7 SECONDARY ORGAN SYSTEM

The kidneys are an important target for toxic effects of drug candidates. It is mandatory to select accurate, clinically relevant parameters in order to be in a position to detect putative nephrotoxic effects during the safety pharmacology program. The glomerular filtration rate appears to be of major interest since it is associated with the definition of acute renal failure. Measurement of the renal blood flow, proteinuria, enzymuria, fractional excretion of sodium, etc., is also highly useful to detect any possible renal impact of a new compound. Although the rat is, by far, the most widely used animal species, there are no specific (clinically relevant) reasons to choose it. Various parameters may vary according to the species, sex, strain, age, and so on. Since in most cases acute renal failure occurs following administration of drugs in patients with preexisting risk factors, it is suggested that sensitized animal models be validated and used (salt depletion, dehydration, coadministration of pharmacologic agents, etc.).

The potential effects of new drugs on the digestive system can be examined in a number of model systems of which intestinal motility in the mouse and gastric emptying in the rat are examples recommended for safety pharmacology evaluation (Gad, 2015b). Intestinal motility, assessed by the transit of carmine dye in the mouse, and gastric motility, assessed by stomach weight in the rat, were examined using a range of clinical drugs or potent pharmacological agents known to affect GI function. Assessment of both models in the guinea pig was also evaluated. Activity was demonstrated with codeine, diazepam, atropine, and CCK-8 (all of which inhibited gastric function). However, neither model gave consistent and reliable results with the remaining reference compounds, namely, metoclopramide, bethanechol, cisapride, deoxycholate, carbachol, and domperidone. In conclusion, this investigation questions the usefulness of simple models of GI transport in the rodent as a means of detecting potential effects of a new drug on the digestive system. This finding should be of concern to the pharmaceutical industry as these simple models are routinely used as part of a regulatory safety pharmacology “package” of studies.

Several classic assays have been designed to examine the effects of a test article on GI function. GI transit rate is most often measured with a test employing a forced meal of an aqueous suspension of activated charcoal (Janssen and Jageneau, 1957). The test article is given via the appropriate

route at a preset time prior to the charcoal meal. For example, a compound intended for use via IV injection would be injected intravenously in mice 30 min prior to delivering a charcoal meal by gavage. The distance traveled from the stomach by the black-colored charcoal meal to a specific anatomic location within the intestine is measured at a fixed time after this meal, usually 20 or 30 min later. In validating this procedure at the Mason laboratories, we tested the ability of a parasympatholytic agent, IV atropine sulfate, to inhibit GI transit. In a dose-dependent fashion, 30 and 50 mg kg⁻¹ atropine sulfate significantly decreased the distance traveled by the charcoal meal.

Another important safety assay of the GI system is the influence of test article on the formation of ulcers (Shay et al., 1945). After overnight fasting, young rats are given the test article and euthanized 4 or 6 h later. The mucosal surface of the stomach and duodenum is scored for the presence of hyperemia, hemorrhage, and ulcers. The dose-dependent ulcerative properties of NSAIDs are clearly demonstrated in this assay, making it important in the development of other NSAIDs that are not as caustic to the GI mucosa (Cashin et al., 1977; Bramm et al., 1981; Darias et al., 1994; Diadone et al., 1994).

Additional digestive system safety pharmacology tests include effects of test articles on gastric emptying rate and gastric secretion. Gastric emptying rate is measured in rats using a solution of phenol red (or Evans blue) delivered via oral gavage a preset time after administration of the test article (Megens et al., 1991). The dilution of phenol red after 30 min in the rat's stomach is determined colorimetrically at 558 nm in a spectrophotometer. This is compared to a group of control rats that are euthanized immediately after phenol red administration. The influence of test articles on gastric juice secretion is accomplished by ligating the pyloric sphincter under anesthesia in rats following a fasting period (Shay et al., 1945; Graf et al., 1982; Takasuna et al., 1992). Immediately after recovery from anesthesia, each rat is given a preset dose of the test article. The fluid content of the rat's stomach is recovered after a set period of time, usually 4 h. The volume and contents of the stomach are measured to determine the effect of the test article on gastric secretions. Electrolyte concentrations, pH, and protein content of gastric secretions can be measured in this assay (Takasuna et al., 1992).

20.7.1 Gastric Emptying Rate and Gastric pH Changes: A New Model

Sometimes new technologies for safety pharmacology can come from clinical settings. The Heidelberg pH capsule (HC) was developed over 30 years ago at Heidelberg University in West Germany. H.G. Noller invented and first tested this device on over 10 000 adult patients over a 3-year

period. The HC is a pill-sized device containing an anti-mony–silver chloride electrode for measuring pH and a high-frequency transmitter operating at an average frequency of 1.9 MHz. The transmitter in the HC is activated by immersion in physiologic saline by a permeable membrane enclosing the battery compartment. Thus, when a patient swallows the HC, the fluid contents of the stomach activate the transmitter. Transmitted signals are picked up via a belt receiver and can be displayed and recorded. The profile of changes in pH over time correlates with the movement of the HC through the different regions of the GI tract (Mojaverian et al., 1989). The pH of the fasted human stomach is very acidic, on average of about 1 pH. When the HC moves through the pyloric sphincter and into the duodenum, there is a rapid increase in pH of over 4 pH units. Thus, one can get a fairly precise measure of gastric emptying rate in humans with this noninvasive technique. Additional pH changes have been correlated with transition of the HC through the duodenum, jejunum, and colon.

Mojaverian et al. have used the HC extensively to examine the influence of gender, posture, age, and content and frequency of food ingestion on the gastric emptying rate (or gastric residence time) in healthy volunteers (Mojaverian et al., 1989, 1991). While developed for clinical use in people, the HC may be a useful tool for measuring important digestive system parameters in laboratory animals. The size of the HC, approximately the size of a No. 1 gelatin capsule (7 mm diameter, 20 mm long), prohibits its use in small animals (Mojaverian et al., 1989). It may be useful in studies with dogs and possibly in nonhuman primates. In particular, the HC could be used to measure gastric emptying rate in a totally noninvasive manner in dogs (Itoh et al., 1986). Dogs are readily trainable to accept pills and to wear a receiver belt and could be tested after administration of a test compound (Lui et al., 1986; Vashi and Meyer, 1988). This technique for measuring gastric emptying rate in dogs is also advantageous in that it is not a terminal procedure. The influence of test articles on the pH within different portions of the GI system could also be measured with the HC (Youngberg et al., 1985). The major drawback for using the HC for safety pharmacology screening is the price of the capsules and the receiver system.

20.8 RENAL FUNCTION TESTS

There are three major sets of evaluations of the potential adverse effect of a drug on renal function. These are tests to determine glomerular function, tubular function, and hemodynamic function (Pugsley and Curtis, 2015).

“Strong signals” of a potential problem will generally be detected in clinical chemistry/urinalysis data collected as part of the repeat-dose general toxicology studies conducted prior to IND.

It should be noted that while assessment of renal function is generally a secondary safety pharmacology evaluation to be addressed before filing for an NDA or perhaps initiation of phase III trials, in the case where the intended patient population already has impaired renal function, this evaluation should be considered a primary evaluation to be performed before undertaking initial chemical trials in patients.

20.9 SUMMARY

The initiative to all mandated safety pharmacology studies to the drug development process is overdue in arriving. However, its actual implementation and the use of the resulting data in risk/benefit decision will take some time to be worked out.

21

SPECIAL CONCERNS FOR THE PRECLINICAL EVALUATION OF BIOTECHNOLOGY PRODUCTS

Although many assume that biotechnology is a recent concept, the application of this science has been understood for many years utilized in its simplest form in the fermentation of beer, wine, and bread by microbial agents. Modern biotechnology can be divided into five research and development areas: recombinant DNA (rDNA) technology, monoclonal antibody (mAb) technology, vaccinology, cell and tissue therapy, and bioprocess technology (Mackett, 1993; Malinowski, 1999). The commercialization of these processes is based on the premise that biotechnology can cost-effectively produce large quantities of a highly purified product.

Biotechnology as a continuous source of new and more efficient targeted therapeutics has been with us since the mid-1980s (Maulik and Patel, 1997). While (as one should expect) some of the early promises of efficacy and safety have not quite been met, biotechnology has turned out to be a valuable source of new and valuable therapeutics and currently accounts for one-third of all new therapeutics entering the marketplace. Table 21.1 lists the proteins approved in 2019 and 2020 that have more than a billion dollars a year in global sales. While a consistently increasing pattern of new therapeutics being biotech products has seemingly stabilized, the future of these is still unclear.

Protein and other biotechnology-derived therapeutics have some fundamental differences from traditional small (synthetic organic) molecules and so require modified or different approaches to characterize their toxicity, evaluate their safety, and optimize their therapeutic use. Table 21.2 presents a comparative summary of these differences as now practiced.

What has become clear in recent years, however, is that while almost all safety concerns for biologic therapeutics are over- or undesired expressions of their intended pharmacol-

ogy (“on-target hits” as opposed to off-receptor target hits), such effects can be both distal to the intended therapeutic target tissue and may have significant “lag” periods (perhaps even years) before they are seen in patients (Giezen et al., 2008). A prime example would be progressive multifocal leukoencephalopathy (PML), a brain infection primarily related to immunosuppressive drugs for MS. Herein lies a challenge for nonclinical safety assessment that has not yet been addressed.

The decades of ongoing profits (past the time of patent expiry) have set these molecules apart from their small-molecule cousins, but the reality of “biosimilar” competition seems to finally be arriving (though as of mid-2021, 31 such have actually been approved). Mid-2021 brings the news that eight out of ten biotechnology drugs fail to show efficacy in clinical trials (Weisman, 2016)—though this is not significantly worse than for new small molecules.

However, potential risks to patients may require modification of traditional nonclinical studies to adequately detect/predict risks to patients. The use of imaging technology (such as MRIs) in primates to detect effects, such as swelling and bleeding in the brain, and the more complex and slow developing and prolonged diseases, such as Alzheimer’s, may require additional studies.

Among all the other aspects of increasing understanding of what is involved in the evaluation and development of biologically derived therapeutics has been a continuing evolution of what is needed to evaluate the safety of these products. In the beginning, there was a stark duality of expectations. On the one side, early advocates of biotechnology held that there were unlikely to be any safety concerns other than those due to hyper-pharmacology over-activity at the target receptors (Vallbracht et al., 1982; Weissinger, 1989; Thomas and Myers, 1998) and contamination (such as

TABLE 21.1 Blockbuster Biotech Approvals (2019 and 2020)

Company	Product	Reference Product	Indication	Time from BLA Acceptance to Approval	Approval Date
Samsung Bioepis/Merck	Ontruzant (trastuzumab-dttb)	Herceptin (Roche/Genentech)	Early-stage (adjuvant) breast cancer	15 months	January 18, 2019
Pfizer	Trazimera (trastuzumab-qyyp)	Herceptin (Roche/Genentech)	Early-stage (adjuvant) breast cancer	20.5 months	March 11, 2019
Samsung Bioepis	Eticovo (etanercept-ykro)	Enebrel (Amgen)	TNF inhibitor for RA and associated autoimmune diseases	23 months	April 25, 2019
Pfizer	Zirabev (bevacizumab-bvzr)	Avastin (Roche)	Non-squamous nonsmall cell lung cancer	12 months	June 27, 2019
Amgen/Allergan	Kanjinti (trastuzumab-anns)	Herceptin (Roche/Genentech)	Early-stage (adjuvant) breast cancer	22.5 months	June 13, 2019
Pfizer	Ruxience (rituximab-pvvr)	Rituxan (Roche/Genentech)	Non-Hodgkin's lymphoma	12 months	July 23, 2019
Samsung Bioepis	Hadlima (adalimumab-bwwd)	Humira (AbbVie)	Plaque psoriasis	12 months	July 23, 2019
Sandoz	Ziextenzo (pegfilgrastim-bmez)	Neulasta (Amgen)	To decrease the incidence of infection manifested by febril neutropenia	50 months	November 4, 2019
Pfizer	Abrilada (adalimumab-afzb)	Humira (AbbVie)	Plaque psoriasis	12 months	November 15, 2019
Amgen	Avsola (infliximab-axxq)	Remicade (Johnson & Johnson)	Reducing signs and symptoms in adults with active ankylosing spondylitis	12 months	December 6, 2019
Pfizer	Nyvepria (pegfilgrastim-apgf)	Neulasta (Amgen)	To decrease the incidence of infection manifested by febril neutropenia	12 months	June 10, 2020
Mylan	Hulio (adalimumab-fkjp)	Humira (AbbVie)	Plaque psoriasis	12 months	July 6, 2020
Amgen	Riabni (rituximab-arrx)	Rituxan (Roche/Genentech)	Non-Hodgkin's lymphoma	12 months	December 17, 2020

TABLE 21.2 Comparison of Protein Therapeutic Agents with Small-Molecule Drugs

Parameter	Proteins	Small Molecules
Drug substance	Heterogeneous mixture Broad specifications during development Specifications may change during development	Single entity; high chemical purity Exception: racemic mixtures Specifications well defined early in development
Drug product	Usually intravenously or subcutaneously	Generally oral; few formulations during development
Impurities	Difficult to standardize	Purity standards well established
Bridging requirements	Significant for drug substance	Bioequivalence procedures
Biological activity	May mimic naturally occurring molecules Primary mechanism of toxicity Predictive based on mechanism	Less predictive
Nonspecificity	Variable significance	Usually significant Drug–drug interactions
Chronic toxicity	Lack of models because of species-determined biological specificity and antigenicity	Models sometimes relevant
Impurities	Toxicity not a major issue May impact immunogenicity	May be significant Purity standards well established

occurred with the Cutter product early on in the early history of the polio vaccine; Offit, 2005). On the other hand, there were those that cautioned against the possibility of extreme and unforeseeable toxicities (such as occurred with TGN-412). The truth, as is usually the case, has turned out to be in between. We have come to understand that the toxicity of protein moieties primarily arises from either overexpression of their desired therapeutic effects (i.e., largely disordering of the immune system) such as seen with interferons (IFNs) and interleukins (Fent and Zbinden, 1997) or due to “off-target effects” that is at tissues other than the intended target(s) (Cavagnaro, 2008). Additionally, there are cases of immune responses to therapeutic and of antibody neutralization products (Vallbracht et al., 1982; Weissinger, 1989).

Additionally, as “biosimilar” products enter the marketplace (still a slow process in the United States with only one approval as of late 2015, but undoubtedly an increasing occurrence due to cost considerations), there are new concerns raised by doctors and patients (Alkon, 2015).

The principal purposes of preclinical safety evaluation in this context remain:

- a. To detect harmful (toxic) effects
- b. To exclude other potentially harmful effects
- c. To determine their relationship to dose and duration of treatment
- d. If possible to discover their mechanism or at least pathogenesis

The information from (a) to (d) should be used to predict possible adverse actions in the target species, in order to

- Warn clinicians about unacceptable risks
- Warn clinicians about risks that should be monitored
- Remind themselves and others of the possibility of toxic effects not detected because they could not be displayed by the test systems used (e.g., headache in a nonhuman species or carcinogenicity in a 1-month experiment) or were not sought

In addition, the toxicologist, as a general biological scientist, should always be alert to physiological and pharmacological effects manifested in her or his experiments, because they may illuminate mechanisms of health and disease both of academic and practical importance (Folb, 2006; Cavagnaro, 2008; Ellis et al., 2013). Table 21.3 points out the common differences between current small- and large-molecule safety assessment program.

The objectives of the preclinical safety studies on biologically derived therapeutics are to identify the pharmacodynamic (PD) and toxicodynamic actions (and comparative response curves) that are likely to be encountered throughout the course of clinical development and use. The selection

TABLE 21.3 Differences between Chronic Use Nonclinical Safety Assessment Plans for Large and Small Molecules

Biopharmaceuticals	Small-Molecule Pharmaceuticals
“Case-by-case” approach to nonclinical safety evaluation	Similar nonclinical safety studies for most products
Pharmacology used to select species	Metabolism used to select species
Single species common for repeat-dose studies beyond 28 days	Rodent and nonrodent typical
Dosing sequences may not be donate	Dosing daily unless justified
Immunogenicity important	Generally not immunogenic
Genetic toxicology not required	Genetic toxicology required
Metabolism studies not appropriate	Metabolism studies requires
Longest repeat dose typically 6 months nonrodent	Nonrodent may be up to 12 months
Two-year carcinogenicity rare	Two-year carcinogenicity required
Developmental toxically in relevant species may be required	Developmental toxically in two species required

and design of such studies should first consider what may be known about other products which are structurally and/or pharmacologically similar. The nonclinical program and study designs should then proceed to consider:

1. Intended manner of use, including dose, route of administration, and particulars of dosing regimen
2. Age and physiologic condition of intended patient population
3. Selection of relevant model species
4. Stability of the formulated drug substance under the conditions of use
5. Physiologic (disease) state of intended patients

In the area of bioengineered products, many of which are complex proteins of potent but sparsely studied activities in living systems, the investigative responsibilities of the toxicologist are likely to be very important, because the toxicologist may be the first observer able to study the effects of repeated administration of a range of doses on a living system (Griffiths and Lumley, 1998). It is now possible to frame a classification of the types of biologically derived therapeutic products (Table 21.4).

Each type of product has some specific considerations. The range of materials is enormous. The deciding factors for the toxicologist should be the precision with which the material can be characterized by physicochemical or other means, as that should be inversely related to the burden of repeated biological testing necessary to assure safety, and

TABLE 21.4 Classification of Bioengineered Products on Practical Grounds

Type	Bioengineering Involvement	Pharmacological Properties	Physicochemical Characterization	Example
1. Low molecular weight substance	New production route	Well known	Rigorous	Amino acid 6-APA
2. High molecular weight substance	New production route	Fairly well known	Extensive	Human hormones, for example, hGH, hPTH
3a. Endogenous high molecular weight substance	First ever production	Some knowledge	Moderate	IFN
3b. Endogenous high molecular weight substance	First ever production perhaps gene splicing to make hybrid molecule	Scanty to limited knowledge	Moderate	Other lymphokines, tumor necrosis factor, etc.
4. Engineered antigen	Partly or totally synthetic ag + rDNA production	Probably predictable	Rigorous	Synthetic vaccine for poliomyelitis or hepatitis B
5. Monoclonal antibody (or component)	Hybridoma human cell line	Probably predictable antigenicity	Moderate	Antitumor antibody for imaging anti-idiotypic antibody as vaccine
6. Living organism	Removal of pathogenicity by genetic manipulation	Uncertain	Limited	As vaccine immunogen, for example, <i>Salmonella typhimurium</i> TY21a, modified herpes or to carry antigen, for example, vaccinia

the extent of prior knowledge of its biological properties and what tissues they are expressed in. The greater our ignorance of the latter, the more far-reaching should be the toxicologist's studies in order to discern the biological (PD) properties of the substance. Exposure of the individual must also be considered, as different criteria may apply to deliberate administration of a living organism, which could spread in the community. Another challenge is to understand and then interpret the specific risk–benefit considerations.

As in any safety evaluation, the planned work should be related to the intended use and treatment of the target species (almost always humans), for example, one dose in a few gravely ill patients or multiple doses of the entire healthy community as prophylaxis against a trivial condition. Contrast, say, what might be appropriate for tumor necrosis factor, as in an experimental trial in a few sufferers from late-stage cancer, with the requirements for a candidate vaccine against dental caries to be widely administered to healthy children.

Because of the rapid development of new biotechnology products, toxicology and safety assessment departments at pharmaceutical companies are presently or soon will be confronted with the development of testing protocols for the assessment of safety evaluation for long-term clinical use of rDNA products. Routine toxicology assessment as performed in the past using standard protocols may not apply and may in fact represent unnecessary or inappropriate studies. Because of the relatively nontoxic nature and species specificity of many of the new biotechnology products, less evaluation in rodent species may be required than for some of the chemicals of the past. What is needed in dealing with the products of these new technologies is the rethinking of traditional toxicology testing approaches.

21.1 REGULATION

The regulation of biologically derived therapeutics actually has a long history and also continues to evolve (see Table 21.5). This history led to the PHS Act providing a somewhat mixed description of the products under its authority, which in turn serves to define biologics for CBER: “[A biologic is] any virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product, or arsphenamine or its

TABLE 21.5 Historical Perspectives of Biologic Therapeutics

1902	Federal Virus, Serum and Toxin Act/PHS (after tetanus contaminated diphtheria antitoxin led to deaths of 10 children). Intent was to ensure safety, purity, and potency.
1906	Pure Food and Drug Act (Upton Sinclair's <i>The Jungle</i>)
1937	Division of Biologics Control/NIH
1938	FD&C Act (sulfanilamide elixir), biologics exempt!
1955	Division of Biological Standards Established (poliovirus)
1962	FD&C Amendments (thalidomide)
1972	Bureau of Biologics/FDA
1978	Good Manufacturing Practices Regulations
1979	Good Laboratory Practices Regulations
1982	Bureau of Biologics merged with Bureau of Drugs ⇒ National Center for Drugs and Biologics
1983	Orphan Drug Act
1984	Drug Price Competition and Patent Term Restoration Act
1992	User fees
1997	ICH harmonized guidelines
2002	Responsibility for regulation of biological substances divided between CDER and Center for Biologics

derivative (or any other trivalent organic arsenic compound), applicable to the prevention, treatment, or cure of disease, or injuries in man.” 21 CFR 600.3 states that “(h) Biological product means any virus, therapeutic serum, toxin, antitoxin, or analogous product applicable to the prevention, treatment or cure of diseases or injuries in man.” Confusion of authority and responsibility between the three human health product centers of the Food and Drug Administration (FDA) (CDER, CBER, and CDRH) led in 1992 to the promulgation of three intercenter agreements. The agreement between CDER and CBER states that the following biological products require licensure and come under CBER’s authority (Mathieu, 1997; CBER, 2006; Chen et al. 2021):

- Vaccines, regardless of the method of manufacture (vaccines were defined as agents administered for the purpose of eliciting an antigen-specific cellular or humoral response) (CBER, 1997)
- *In vivo* diagnostic allergenic products and allergens intended for use as “hyposensitization agents”
- Human blood or human blood-derived products, including placental blood-derived products, animal-derived procoagulant products and animal- or cell culture-derived hemoglobin-based products intended to act as red blood cell substitutes
- Immunoglobulin products
- Products composed of, or intended to contain, intact cells or intact microorganisms
- Proteins, peptides, or carbohydrate products produced by cell culture, excluding antibiotics, hormones, and products previously derived from human or animal
- Tissue regulated as drugs
- Protein products made in animal body fluid by genetic alteration of transgenic animals, animal venoms, or constituents of venoms

Other classes of products identified as CBER-regulated products include the following:

- Synthetically produced allergenic products intended to specifically alter the immune response to a specific antigen or allergen.
- Certain drugs used in conjunction with blood banking or transfusion As will be seen at the end of this chapter in Section 21.7 (where the National Institutes of Health (NIH) also has some regulatory role), there is still some ambiguity of authority in areas where technology has outrun regulatory foresight.

Within the United States, the regulation of therapeutics is split on relatively arbitrary grounds. This is presented in Table 2.5. This chapter reflects both current FDA practices

and the ICH guidelines. EMA guidances started with that of CPMP (1989) but subsequently have come from EMEA (now EMA). Most recently, subsequent to the TGN1412 near disaster, EMA has issued new guidances meant to issue a more conservative approach to clinical trials (EMA, 2017, 2021). With harmonization has come regulatory guidance from ICH (such as ICH S6(R1), 2014).

21.2 PRECLINICAL SAFETY ASSESSMENT

Because of the complexity and wide diversity of biologic products, their safety is evaluated on a case-by-case basis (in accordance with CBER’s promulgated points to consider as summarized in Table 21.6) until such time as enough data on either specific products or a class of products are available.

Generally, *in vivo* nonclinical studies should be designed to include a sufficient number of animals per group to permit a valid estimation of a drug’s toxicologic, pharmacologic, and immunogenetic effects in terms of incidence, severity, and the dose–response relationships involved. The latter point requires, as pointed out throughout this text, thoughtful selection of doses (and, for biologics, regimens of treatment). Comparable formulation, routes, and regimens of administration duration of exposure and suitable time to allow expression of expected response are also important proper design features. Tables 21.6–21.9 summarize the basic testing requirements for each of three subsets of biologically derived drugs.

The number of species necessary in preclinical testing programs varies. However, there is no specific requirement for the routine use of two species (e.g., one rodent and one nonrodent) in toxicology studies of biological products. Proper species selection for use in these trials is essential. Table 21.10 summarizes the key considerations for species selection.

In each stage of product development, it is important to determine exposure by measuring pharmacokinetic (PK) (including ADME) or PD end points. This includes the following: (i) measurements of the biologic in plasma or target organs, (ii) the distribution and persistence of cells for cellular therapies, (iii) measurements of viral shedding and recovery of certain values, (iv) localization of targeted novel delivery systems, and (v) tissue tropism, including germline tissue, of vectors used in gene therapies.

Such studies provide important information for a better interpretation of the toxicity observed in animals and aid in the selection of not only the proposed initial human dose but of the dose-escalation scheme and the frequency of dosing in the clinical trial(s). Further, once such exposure data are available in humans, the data can be used to better correlate the human and animal findings. Toxicity studies should be performed in the same species used to assess efficacy (pharmacodynamics). Often times, exposure, toxicity, and immunogenicity are measured in the same study, particularly when nonrodents are used.

TABLE 21.6 Points to Consider in the Preclinical Safety Assessment of Biologics

Rationale
<i>In vitro</i> or <i>in vivo</i> studies
Potency assays
Receptor characteristics (across species)
Physiological modeling
Scientific literature
Scientific speculation
Indication
Replacement therapy (long term)
Nonpharmacodynamic treatment (prophylactic or diagnostic)
Pharmacodynamic treatment (short term or long term)
Pharmacological activity (pharmacodynamics)
Primary end points
Secondary end points
<i>In vivo</i> model selection
Species-specific effects
Effects independent of species
Animal model of disease
Pharmacokinetics and ADME: correlation with
Pharmacodynamics
Low dose
High dose
General toxicity
Single dose (acute)
Repeated dose (subacute or subchronic)
Specific toxicity (may include one or more of the following studies)
Local irritation (local reactogenicity)
Antigenicity
Chronic toxicity
Reproduction toxicity, including teratogenic potential
Mutagenicity
Tumorigenicity
Carcinogenicity
Other toxicity concerns (e.g., neurotoxicity, immunotoxicity)

Toxicity studies should be designed not only to identify a safe dose but also a toxic dose threshold (and the spectrum of toxicodynamics) to anticipate the product's safety and to better define the therapeutic index in humans. Specific product considerations that may complicate the process of defining a toxic dose may include limits based on formulation, lack of significant systemic absorption, or the amount of the product available. The lack of significant toxicity in animals does not necessarily mean that the product is safe. The margin of safety for the initial starting dose, however, will likely be adequate.

Acute studies should be irrelevant for biologics, except when acting as “canaries in the coal mine” for drugs such as TGN-412.

Studies are often 1–2 weeks in duration and routinely include body weight determinations, clinical observations, and gross necropsy findings. Additional antemortem studies may be performed as appropriate, especially in large animals

TABLE 21.7 Biotechnology-Derived Drug Test Matrix

Test Requirement	Species
Develop bioanalytical for three species (man/rodent/nonrodent)	NA
<i>Initial clinical trial/IND requirement</i>	
Pilot single-dose toxicity in rodents (IV ^a)	R
Pilot single-dose toxicity in nonrodents (IV)	D
Genotoxicity only if appropriate (species cases)—check guidance for SRNA drug	
Safety pharmacology: CV <i>in vivo</i> (IV)	
Safety pharmacology: respiratory—rodent (IV)	R
Pivotal/repeat dose in rodents (match clinical plan ^b)	R/M
Pivotal/repeat dose in nonrodents (14–28 days) (match clinical plan ^b)	
Develop bioanalytical for three species (man/rodent/nonrodent)	N/A
Allergenicity (rodent)	
<i>To support continued clinical development</i>	
Pivotal/repeat dose in appropriate species to support marketing approval

^aRecommended.

^bMay be required.

(e.g., observation of local reactogenicity, PK evaluations, hematological, and/or clinical biochemistry measurements). Histological evaluations may also be performed.

The duration of repeat-dose studies should be at least as long as the proposed dosing exposure in clinical study. These studies are designed to establish a dose–response relationship, define target organ(s) of toxicity, and determine whether observed toxicities are reversible. Evaluation parameters should include not only those routinely performed in the acute

TABLE 21.9 Biologics Test Matrix

Test Requirement	Species
Initial clinical trial/IND requirement	
1. Acute toxicity in rodents (oral and IV ^a)	R/M
2. Acute toxicity in nonrodents (oral)	D/S/P
3. Seven-day DRF toxicity in rodents (oral)	R/M
4. Seven-day DRF toxicity in nonrodents (oral)	D/S/P
5. Genotoxicity: bacterial mutagenicity (Ames) ^b	<i>In vitro</i>
6. Pivotal/repeat dose in rodents (28-day oral)	R/M

^aRecommended.
^bMay be required.

studies but those performed in the additional studies as well. Special tests such as ophthalmoscopic, electrocardiograph, allergenicity, body temperature, and blood pressure monitoring are often included. Depending on the study duration, PK sampling at multiple time points may be necessary to better characterize the kinetics of response. As mentioned, a group of animals will be examined at term, and some may be

reserved for at treatment-free or recovery period to evaluate the reversibility of any findings.

Specific (local tissue tolerance) toxicity studies may be necessary due to special characteristics of the product or the clinical indication. Adjuvanted vaccines are routinely evaluated for local (injection site) reactions, and cellular therapies are routinely screened for tumorigenic potential. Research is also needed to better predict the sensitizing potential of biological products and to determine the relevance of serum antibody levels following repeat dosing in animals and humans.

While carcinogenicity studies have not been performed routinely for biological products, they may be appropriate for products proposed for chronic use. Reproductive toxicology studies will probably become more common, especially as more women of childbearing potential participate in early clinical trials. In the past, such studies have not been conducted for biologics. Reproductive toxicology studies have been performed with many of the recently approved therapeutics (e.g., IFNs, interleukins, cytokines, growth factors). Such studies also have been conducted in the development of AIDS vaccines intended for use in pregnant women. The standard protocol designs were modified to address specific vaccine-related concerns, including dosing in relationship to immunologic effects.

The development of biologics to treat various nervous system diseases (immunologically based and otherwise) has involved additional, specific neurotoxicological studies on these products. However, despite the fact that most products regulated as biologics have an immune component or impact directly or indirectly on the immune system, standardized

TABLE 21.10 Factors to Consider in Species Selection for Protein Therapeutic Development

Cross-Reactivity	Immunogenicity
Cross-reactivity alone is not sufficient to identify a relevant species. Suitable affinity and potency to give valid results are also necessary. How close does the level of potency have to be to the situation in humans to be meaningful?	An emerging issue as more mAbs are developed for chronic use is the impact of neutralizing antibodies on repeat-dose studies. This is a significant scientific problem that might be partially overcome by the use of the surrogate antibodies. What is the potential for the regulatory acceptability of surrogate antibodies for immunogenicity reasons?
How can alternative approaches be “front-loaded” into the development pathway without leading to a standard two-species approach?	To what extent is immunogenicity considered in species selection for safety and toxicology studies? Should this be given more priority in the selection of relevant species for long-term toxicity studies for mAbs that are intended for chronic indications?
What is the possibility of assigning greater value to nonconventional preclinical studies, such as genetically altered rodents and surrogate antibodies that are scientifically relevant?	
If, after a variety of cross-reactivity testing that includes binding studies, functional activity in cell-based systems, sequence homology, and tissue cross-reactivity studies, the only relevant species is chimpanzees, is it justified, scientifically and ethically, to use the chimpanzees to study the effects of the monoclonal antibody (mAb)?	

immunotoxicity tests that are potentially useful in screening large numbers of chemicals for their ability to adversely affect the immune system have not proven essential in assessing the safety of biological products.

Throughout the various phases of product development, additional preclinical safety studies may be necessary due to unexpected toxicity, significant changes in the manufacturing process or the final formulation, or changes in the clinical indications. In some cases, the ideal assessment of the safety of novel biological therapies may require alternative approaches, such as *in vitro* or *in vivo* organogenesis model systems, animal models of tolerance, animal models of disease, or transgenic animal models.

21.3 RECOMBINANT DNA TECHNOLOGY

The concept of rDNA technology is based on the premise that a gene sentence may be taken from an animal or human gene responsible for the production of a particular protein and inserted into the DNA of *Escherichia coli*, a single-cell bacterium. The bacterial cells then divide very rapidly, making billions of copies of themselves, including a replica of the gene that has been inserted.

There are unique ways to insert human genes into bacteria. In addition to chromosomal DNA, bacteria have numerous copies of extrachromosomal circular DNA called plasmids, which are not attached to the bacterial chromosome. These plasmids can be transferred from one bacterium to another by conjugation (e.g., mating) and can be isolated from bacteria and easily purified. Through the use of restriction enzymes (i.e., a family of enzymes that can cut DNA at specific base sequences), the gene sentence to be inserted can be isolated, and the plasmid DNA can be opened. While in the open state, the desired piece of animal or human DNA can be inserted. Through the use of ligase enzymes, complementary ends of the plasmid can be connected, thereby producing a recombinant plasmid recombined by joining two heterologous pieces of DNA. This recombinant plasmid can then be put back into the bacteria, and the bacteria will express the new gene function that has been inserted.

A unique characteristic of plasmids is that thousands are produced within each bacterium to the point that up to 40% of the total DNA of the bacterium may in fact be plasmid DNA. Hence, a single piece of human DNA that heretofore could only be obtained in low concentrations can be recombined with a plasmid, and the DNA sequence multiplied by a million- or a billion-fold (i.e., cloned). Use of cloning techniques may produce many grams of a particular human protein, instead of the few molecules that are produced in normal cells.

Examples of the early application of rDNA technology in medicine are the development of recombinant human growth hormone (HGH); human insulin; human IFNs, thought to have anticancer activity in addition to antiviral activity; interleukins (regulatory proteins from lymphocytes that are

believed to be important in the treatment of immunodeficiency diseases and cancer); tumor necrosis factor; epidermal and bone marrow progenitor cell growth factors; and the production of vaccines (Table 21.1).

HGH and insulin produced by rDNA technology are already registered with the US FDA for therapeutic use. The applications of rDNA technology agriculture should improve the quality of domesticated animals through the production of new and improved vaccines, growth-promoting hormones, and less-expensive food additives. Seed crops will be produced that offer improved yields and better resistance to environmental conditions. Further applications may include the insertion of genes into plants or bacteria for production of toxins that can act as biochemical pesticides or allelopathic agents (chemicals that act as natural herbicides to prevent the growth of other plant species in the same geographical area).

21.3.1 General Safety Issues

rDNA technology represents one of the most innovative achievements in biology in the last century. Although the new technology has generated much enthusiasm for its potential applications, it has also raised concerns among both scientists and the public in general. Many of the early fears of the inadvertent development of an “Andromeda strain” during the genetic engineering of a specific microbe have long since vanished. However, other concerns remain. Can a gene cloned for toxic production from an rDNA microbe be transferred into normal bacterial flora? Could antibiotic-resistant genes be cloned and inadvertently inserted into clinically relevant pathogens not presently antibiotic resistant? To reduce these possibilities, the NIH has only certified nonconjugative plasmids (e.g., nomating) for use in rDNA microbes.

Studies by Levine et al. (1983) have addressed the issue of plasmid mobilizations, the movement of plasmids between different host cells. Human volunteers fed tetracycline along with *E. coli* HS-4 (typical of the normal intestinal flora of humans) bearing highly mobilized plasmids (e.g., pJBK5) that carried resistance to chloramphenicol, and tetracycline became cocolonized with *E. coli* HS-4 bearing the antibiotic-resistant

TABLE 21.11 Consequences of Immunogenicity

Loss of Efficacy	Enhancement of Efficacy

HCG	Anaphylaxis
GM-CSF/IL3	Serum sickness

Note: Immunogenicity in humans may be a major safety concern.

plasmid. However, the use of a poorly mobilizable plasmid (pBR325) did not result in plasmid transfer.

Taken as a whole, these studies establish the safety of rDNA research when poorly mobilizable cloning vectors are used while supporting the rationale for biologic containment of highly mobilizable plasmids. They also point out the need to protect laboratory workers on antibiotic therapy from potential exposure to rDNA organisms carrying any sort of antibiotic-resistant genes. A reassuring point is the relatively poor survival of rDNA strains of *E. coli* in the intestinal environment. For example, in most successful studies, 50 billion *E. coli* HS-4 organisms were required to ensure survival within the harsh environment of a human's stomach.

21.3.2 Specific Toxicological Concerns

While rDNA techniques offer exciting possibilities, there are many unanswered questions about the potential toxicity that each new product represents. For example, acute clinical toxicities of IFNs include flu-like syndrome, fever, chills, malaise, anorexia, fatigue, and headache. Chronic dose-limiting toxicities include neutropenia, thrombocytopenia, impairment of myeloid maturation, reversible dose-related hepatotoxicity, some neurological toxicity (stupor, psychosis, peripheral neuropathy), and gastrointestinal toxicity. Some of these toxicities would be difficult to ascertain in rodents and, in fact, may be species-specific.

A particular toxicity associated with the administration of IFN to human and experimental animals has been depression of the cytochrome P450 monooxygenase (MFO)-metabolizing enzymes. As a consequence of MFO inhibition following treatment with IFN, the sleep time of mice treated with hexobarbital is increased, as is the toxicity of acetaminophen (Stebbing and Weck, 1984). Possible effects on the metabolism of chemotherapeutic agents or other drugs processed by the P450 MFOs should be anticipated.

The *in vivo* antitumor effects of IFNs are believed to be related to both augmentation of natural killer cell activity and antiproliferative effects. Antiproliferative activity probably also accounts for the bone marrow suppression observed in some individuals given IFN and could potentially produce effects in a routine preclinical reproduction or teratology evaluation. Dosing studies performed in newborn mice with homologous IFN have resulted in death at high doses and a marked wasting syndrome when given over an extended period (Gresser and Bourali, 1970). Both effects were attributed to the antiproliferative activity of IFNs. Inhibition of proliferation and metabolism represent potential dose-limiting toxicities of this family of rDNA molecules.

21.4 IMMUNOGENICITY/ALLERGENICITY

Human biopharmaceuticals are commonly immunogenic (elicit and antibody response) in nonhuman species.

Immunogenicity should be evaluated in repeat-dose nonclinical safety studies to help determine whether antibody may have influenced pharmacology, toxicity, or exposure. If immunogenicity decreases exposure or neutralizes the activity of the biopharmaceutical, it may not be appropriate to continue the study or conduct studies of longer duration in that species. It is important to confirm biological activity of administered biological in "no-effect" studies where the top dose is the NOEL. The immunogenicity of a biopharmaceutical in nonclinical species is not necessarily predictive of a potential for antibody formation in humans, but the potential consequences (summarized in Table 21.11) must be considered. Table 21.12 summarizes the strategies to conduct a bioanalytical evaluation of immunogenicity responses.

21.5 MONOCLONAL ANTIBODY TECHNOLOGY

Offering an impressive potential for human therapy, mAbs have become the first commercialized products of the new biotechnology. They have become widely used in diagnostic medicine and are very successful as therapeutic agents in cancer (Oldham, 1983). In clinical diagnostic medicine, they have provided us with the sensitivity not heretofore available for specific and rapid diagnosis of a particular drug level or infectious disease process.

Antibodies are important in the body as defense against infectious agents. They are extremely specific proteins that are produced in response to a foreign material, or antigen, by lymphoid cells of the immune system and share the property of being able to bind specifically to the inducing antigenic epitope (a single antigenic determinant; that portion of the antigen which combines with the antibody paratope). Unfortunately, under most conditions of antigenic stimulation, a family of antibodies is produced, each with a slightly different antigenic specificity.

In 1975, Kohler and Milstein observed that if an antibody-producing cell was fused with a myeloma tumor cell; a rapidly dividing hybrid was produced that synthesized a monospecific antibody. Each hybridoma formed then became a "factory," producing antibodies monospecific to a particular sensitizing antigenic epitope. Cell cloning allows selection of hybrids producing antibody with the desired characteristics.

mAbs are thought to represent a major advance in cancer therapy because they have a very high therapeutic-to-toxic index when compared with anticancer drugs or radiation therapy and should provide a greater degree of specificity for the tumor cell than other forms of therapy. The conjugation of toxins with mAbs is theoretically very exciting because a high-specific toxin activity could be achieved at the tumor target cell.

Clinically, mAbs are also proposed as drug delivery vehicles in certain tumors where specific tumor-associated antigens are expressed. In this context, investigators have found that by conjugating toxins such as the A chain polypeptide of the plant protein ricin or the bacterial toxin from *Corynebacterium*

ADAs, antidrug antibodies.

diphtheriae to mAbs specific for certain tumor type, as few as one or two molecules of antibody–toxin conjugate can destroy a tumor cell *in vitro*. Some success has also been obtained in clinical trials with mAb–toxin conjugates.

mAbs have also been proposed for detoxification of individuals suffering from drug overdose or chemical intoxication, as well as for radioimaging of tumor burden or metastatic foci. In veterinary medicine, mAbs are already being used to develop new rapid methods for diagnosis of infections in poultry, cattle, and other animals.

21.5.1 Toxicological Concerns with Monoclonal Antibodies

It has been clear for a while that there are certain problems implicit in the use of mAbs in therapeutic uses. Hansel et al. (2010) overviewed the scope of the recognized issues, and the issues (and incidences of problems) have only expanded with ever-broadening uses of products (see Table 21.13). For example, there may be modulation of the antigenic determinant on the target cell, so that the mAb cannot recognize its appropriate antigenic epitope. Second, the tumor cell may release free antigens so that the mAb is effectively neutralized before it can reach the target cell. Third, antibodies to mouse epitopes on the mAb could be induced (this may be overcome in the future by the use of human–human hybrids or the use of immunosuppressive agents to prevent the development of antibodies). Fourth, mAbs have an extremely short half-life in systemic circulation, which would require that they be intermittently infused to provide the beneficial effect. Lastly, there may be an unwanted release of the toxin from its conjugate; or specificity problems may develop, whereby the antibody–toxin conjugates end up in an inappropriate organ.

The clinical toxicology findings associated with the use of mAbs in therapeutic trials have included fever, chills, flushing, dyspnea, hypotension and tachycardia, anaphylactic and anaphylactoid reactions, urticaria, rash, nausea, elevated creatinine levels, headache, bronchospasm, and serum sickness (Oldham, 1983). Few of these reactions can potentially be predicted from safety evaluation in rodents. A major problem with using the intact ricin or diphtheria toxin molecule, containing both the A and B polypeptide chains, has been the dissociation of the parent molecule from the mAb, leading to toxicity of the reticuloendothelial system. A promising solution to this problem comes from separating the A chain (toxic moiety) from the B chain (cell association moiety) and preparing only A chain conjugates. This results in much lower toxicity if the A chain should become dissociated from the antibody conjugate because cellular association does not occur.

The FDA website provides a list of mAbs that have been reviewed and were found to have evidence of fetal risk.

Since an mAb is a fusion product of a malignant mouse cell and an antibody-producing cell, there is some concern about the safety of the production process itself (Petricciani, 1983). Methods for the production of mAbs raise two general safety issues: (i) the theoretical risk of transferring in the product factors associated with malignancy (e.g., oncogene factors) and (ii) the use of animals for antibody production that are known to harbor a number of microbial agents, some of which can produce diseases in humans.

Preclinical studies should address the potential toxicity due to inappropriate release of the conjugated toxin. Preclinical toxicology of mAbs may not require extensive animal studies but should examine for cross-reactivity with antigenic epitopes present on normal cells *in vitro* and for the presence of human or rodent viruses. Early clinical trial should involve biodistribution studies with radiolabeled material.

TABLE 21.13 Side Effects of Licensed Monoclonal Antibodies

Target	mAb	Type	FDA Approval	Indications ^a	Selected Side Effects
Platelet glycoprotein IIb/IIIa	Abciximab (ReoPro; Centocor Ortho Biotech, Eli Lilly)	Chimeric antibody fragment: c7E3 Fab	1994	Prevention of ischemic cardiac complications of percutaneous coronary interventions and unstable angina	Hypersensitivity and immunogenicity Increased risk of bleeding Thrombocytopenia
Tumor necrosis factor- α	Adalimumab (Humira; Abbott)	Fully human	2002	Rheumatoid arthritis Ankylosing spondylitis	Infusion reactions and immunogenicity Hypersensitivity reactions

CRS, cytokine release syndrome; EGFR, epidermal growth factor receptor; ERBB2, also known as HER2/neu; FDA, Food and Drug Administration; GI, gastrointestinal; HAMA, human antimouse antibodies; *KRAS*, v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog; PML, progressive multifocal leukoencephalopathy; RSV, respiratory syncytial virus; URTI, upper respiratory tract infection.

*Some of these indications are not currently licensed.

The level of regulatory concern with the safety of the products of biotechnology underwent a sea change in early 2006 with the near catastrophe with TGN1412, a superagonist anti-CD28 mAb that induces the production of anti-inflammatory cytokines by directly stimulating T cells.

A German company, TeGenero, had first-in-man clinical trial of the product initiated by a clinical research organization (CRO) at a clinic within a hospital in London. Eight healthy young males were enrolled, and six received a dose of the drug, while two received placebo. Within 90 min after receiving a single intravenous (IV) dose of the drug, all six volunteers had a systemic inflammatory response characterized by a rapid induction of proinflammatory cytokines and accompanied by headache, myalgias, nausea, diarrhea, erythema, vasodilation, and hypotension. Within 12–16 h after infusion, they became critically ill, with pulmonary infiltrates and lung injury, renal failure, and disseminated intravascular coagulation. Severe and unexpected depletion of lymphocytes and monocytes occurred within 24 h after infusion. All six patients were transferred to the care of the authors at an intensive care unit at a public hospital, where they received intensive cardiopulmonary support (including dialysis), high-dose methylprednisolone, and an anti-inter-leukin-2 (IL-2) receptor antagonist antibody. Prolonged cardiovascular shock and acute respiratory distress syndrome developed in two patients, who required intensive organ support for 8–16 days. Despite evidence of multiple cytokine release syndrome (CRS), all six patients survived (Goodyear, 2006; Suntharalingam et al., 2006). This response has been characterized as a “cytokine storm,” similar to that seen earlier with OKT3.

The preclinical evaluation which occurred before the trial was conducted was a set piece approach to the then-guideline requirements. Studies were conducted in rats, mice, and primates, with the repeat-dose studies in the rats and mice being once a week for 4 weeks at doses up to 50 mg kg⁻¹, with these doses being characterized as well tolerated with transient increases in CD4 and CD8 (which were expected) and of IL-2, IL-5, and IL-6, but with no signs of first-dose CRS. There was cross-reactivity in stained lymphoid tissue and astrocytes in both human and primate tissues, but no histopathology signs of CNS toxicity were seen in safety studies. The NOAEL was set at 50 mg kg⁻¹ in the primate (cynomolgus monkey), and with FDA human equivalent dose (HED)-style allometric scaling and safety factor of 10, then additional safety factor applied proposed 0.1 mg kg⁻¹ for first-in-man clinical trials, which was the dose used in the trial.

What was not done for this highly humanized mAb was to use the appropriate model (either a knockout mouse responsive to the humanized molecule or evaluation of a suitable homolog molecule).

The EMEA response has been to put in place the minimum active biological effective level (MABEL) approach to setting first doses in clinical trials (EMA, 2017). In the case of

TGN1412, based on biologic activity in the rat, a safe dose would have been set at 0.005 mg kg⁻¹.

21.6 BIOPROCESS TECHNOLOGY

In the chemical and pharmaceutical industry, rDNA technology will allow the synthesis of chemical that can only be practically achieved through a bioprocess. For example, methylation of a particular carbon in a chemical structure might be done quite easily with a recombinant-engineered bacteria. This technology will allow the synthesis of a family of isomers and the development of a synthetic process that cannot be achieved by strict physical chemical processes.

This area of rDNA technology also has application in the degradation of solid waste materials: in wastewater recovery, in leaching minerals from ore-containing rock, in improved oil recovery, and in the decontamination of chemical waste dumps through the engineering of microorganisms that can destroy specific toxic contaminants.

21.7 GENE THERAPY PRODUCTS

Gene therapy products, while holding tremendous promise, have so far delivered but limited (two cases as of this writing) positive outcomes. The concept involved—inserting functioning genes in place (or places) where nonfunctional or malfunctioning genes have produced a disease state—is stunning. But the public outcry over the death of Jesse Gelsinger, an 18-year-old in a clinical trial at the University of Pennsylvania's Institute of Human Gene Therapy in 2000, has led to a significant slowdown in the rate of evaluation. This tragic event, probably due to an innate immune response to a protein in the vector's protein coat (Stephenson, 2001), has led to increased restrictions.

Five aspects specific to gene therapy need to be evaluated to assess the safety of a therapy:

1. DNA/RNA biodistribution
 2. Gene transfer and biological activity
 3. Risk of vertical transmission of the gene
 4. The safety of the vector (the means of delivering the gene to the intended site)
 5. The safety of the product protein
1. Evaluate DNA/RNA biodistribution
 - Radiolabeling
 - Southern blot
 - PCR
 - Real-time PCR
 - *In situ* PCR

2. Evaluate gene transfer and biological activity
 - Immunohistochemistry
 - Western blot
 - Enzyme-linked immunosorbent assay (ELISA)
 - Flow cytometry
3. Evaluate the risk of vertical transmission
 - To gonads
 - If yes, then look at semen/germ cells (probably required anyway)
 - To circulating blood
 - If so, how long (persistence)?
4. Assess the safety of the vector.
 - Identify a suitable model species.
 - Assess the acute toxicity of the vector particle (in rabbits):
 - At high dose, potential for an anaphylactic response (not seen in mice)
 - Also look for neutrophil proliferation
5. Assess the safety of the product protein
 - Using data from preclinical pharmacology toxicology (“safety”) studies to support the safety of clinical trials
 - Ones not appropriate for generator (instead, assess integration/insertion frequency in a mammalian cell)
 - Standard rodent carcinogenicity *probably* not appropriate

Regulatory authority for gene therapy products is unique in that overlapping responsibilities extend to both CBER and NIH.

CBER	Division of Cell and Gene Therapies Manufacturing Division of Clinical Trial Design and Analysis Preclinical pharmacology and toxicology Clinical trial design, safety, and efficacy 20% of CBER clinical protocols are now for gene therapy
NIH	Recombinant DNA Advisory Committee (RAC) No authority for approval for clinical trials, but all adverse events must be reported

This duplicating authority has led to both misunderstanding and problems in trials, as investigators must report adverse responses to both. But each has a different definition of what constitutes a reportable adverse response.

Currently, gene therapy is restricted to life-threatening and severely disabling diseases, but when a larger safety database has been accumulated, there should be expanded opportunities for therapy. It is not possible or desirable to identify a uniform “recipe” for the safety studies that should be conducted with gene therapy products, to support either the first dose in humans or extended clinical evaluation. Each product should be treated on a case-by-case basis, taking into consideration a number of important factors, such as the clinical indication, the duration

of expression of the gene, and whether DNA transfer will be *in vivo* or *ex vivo*. For example, elimination of a tumor may require short-term treatment such as the transient expression of a suicidal gene. On the other hand, treatment may be long term, such as the replacement of a missing enzyme in the liver, where the goal may be lifetime expression. Gene therapy is currently an area of limited but rapidly advancing knowledge, and study design should be based on previous experience, together with ongoing feedback from the clinic throughout development. Considerable early thought should also be given to appropriate assays and their sensitivities. The choice of assay will need to be justified and the basic “toolkit” of assays properly considered and evaluated in advance.

21.7.1 Vectors

In gene therapy, genes typically are delivered using a vector which may be nonviral or viral. The complete construct should be tested; separate safety evaluation studies of vectors *per se* are not generally recommended except to explore mechanisms of action if potentially harmful effects have been demonstrated in a previous investigation, for example, red cell agglutination on IV administration. If a novel non-viral vector is to be used, evidence of its lack of toxicity and information on its basic pharmacokinetics will be an essential component of the preclinical package. The interaction between the vector and the gene is quite important, perhaps more so with the nonviral gene therapeutics, where the physicochemical properties of the particles themselves very much determine which tissues take up the gene. For viral vectors, it is important to have sufficient knowledge of how they replicate, how to render the viruses replication incompetent, any inherent pathogenicity and immunogenicity, and any risk of recombination with wild-type virus.

Conventional pharmaceutical quality assurance procedures should be applied to gene therapy products as well as appropriate infectivity tests for self-replicating/living vectors.

21.7.2 Studies to Support the First Dose in Man

The most scientific approach is to replicate, in an appropriate animal, the type of dosing that would be expected to be used in humans, employing the “dose for dose/animal to human” principle. A single, suitable animal species should suffice. If viral vectors are used, the animal species should be sensitive to infection by the wild-type virus. Studies should not automatically be done in primates, but, initially, the commonly used laboratory species should be utilized. Only if those are demonstrated to be unsuitable should the next step be to consider the use of a primate.

Based on these general principles, the first dose in humans should be supported by a single-dose study in an appropriate animal species by the intended clinical route. Several dose levels should be explored, as some gene therapy expression products have a narrow therapeutic index.

There are many circumstances when a single-dose IV study can provide useful information; for example, if the intended treatment route is intraperitoneal (IP), or if the product will be administered to an open wound or injected into a muscle or a tumor, it might accidentally enter a blood vessel, and the knowledge gained from an IV study would be of value as well as one by the clinical route. Hence, if the intended clinical route is not IV, the absence of an additional study with IV dosing would require specific justification.

The physiological consequences of the gene product should be explored in these studies, particularly with totally novel gene products. In addition, all the standard toxicological evaluations should be carried out, including examination of functional end points *in vivo* including cardiovascular and respiratory effects.

21.7.3 Distribution of the Gene and Gene Product

The distribution of the gene must be evaluated carefully in time-point assays. The choice of assay used, with regard to their specificity and sensitivity, must be justified. The objectives are to identify the tissues in which the gene is present, to demonstrate whether or not the gene product is expressed in particular tissues, and to demonstrate the time course of gene expression, that is, how long it persists.

Some regulatory authorities, including the United Kingdom, are particularly concerned that the possibility of alteration to germline cells should be excluded. Both male and female gonads should therefore be examined. If the gene is found there, then it is necessary to examine the gonads at a more detailed level to ascertain whether the gene is present in the actual germ cells. Where gene persistence is short as, for example, in nonintegrating nonreplicating vectors, assay of the gonads at an appropriate time point will minimize false-positive findings.

21.7.4 Studies to Support Multiple Doses in Humans

The animal studies should parallel the intended treatment regime in humans. At their present stage of development, a single dose of a gene therapeutic may not be totally curative, so multiple cycles of treatment may be used clinically rather than a single period of administration. It is appropriate to explore this in animal safety work, that is, the cycle regimen should be paralleled in the animal, up to a maximum of three cycles. The duration of follow-up in the test animals after completion of the last test cycle should be based on the duration of gene expression, up to a maximum of 6 months. There may be situations, particularly if long-term gene expression is the goal, when there could be an argument for a longer follow-up but that should be considered on a case-by-case basis.

There should not be blind adoption of a checklist of assays and observations, but appropriate investigations should be selected, based on earlier findings in the single-dose studies. Increasing the number of doses raises more concern about the

immune response. There may be indications of this, such as lymphocyte infiltration at the site of administration, and there are many markers from single-dose studies that would indicate when it might be appropriate to examine the immune response to the gene product and selection markers, for example, immunity to adenoviral vectors, or to expressed proteins, resulting in accelerated loss of the transgene.

21.7.5 Unnecessary Studies

Genotoxicity and carcinogenicity studies are not generally recommended or required. Eliminating the possibility of the gene being inserted in the germline ensures that some elements of concern about reproduction toxicology have already been addressed; hence, classical reproduction and developmental toxicity studies are not generally recommended. They should be considered on a case-by-case basis; for example, if the treatment were to be intended to manage a long-term metabolic disease, the patients would then survive to reach reproductive competence.

Drug interaction studies are not generally appropriate, with the exception of gene-directed enzyme prodrug therapy (involving a gene expressing an enzyme that activates a prodrug given subsequently). In the latter case, it is necessary to demonstrate the presence of the prodrug as well as the gene in the animal and to consider the potential toxicity of the active metabolite(s) both locally (which is the desired pharmacological effect) and systemically (the undesirable effects).

21.7.6 Ex Vivo Procedures

Ex Vivo procedures involve removing cells and transfecting or transducing them. The cells should be checked to confirm that they are all healthy and that they are still expressing their normal surface markers; observations of normal growth characteristics can also be reassuring. Animal studies are of limited value to test the safety of transfected or transduced human cells.

21.7.7 Change of Gene or Vector

Currently, only a limited number of vectors are available, although there is a large array of inserted genes. If the therapy involves developing a construct of a new gene in a well-characterized vector, it is important to use existing information on the vector. Rather than regenerating data on the vector itself, bridging studies of the construct should be carried out, that is, additional studies involving a limited toxicology evaluation to specifically characterize the nature of the new gene. Since the safety of the vector is already known, this should drive more exploration of the effects of the gene and the gene product rather than the vector itself.

If the vector is changed, a full safety evaluation may be required. However, if the changes are minor compared to the

structure of a fully evaluated vector, it is appropriate for safety to be addressed by bridging studies. For example, if there is only a minor change on one of the condensation peptides of a nonviral, self-assembling vector, then some simple bridging work, rather than a full evaluation, may be appropriate.

The possibility of abbreviated testing is referred to in FDA (2012b), a guidance document on somatic cell and gene therapy published by the US FDA. According to that guideline, if changes are made to the vector backbone which do not alter the safety properties of the vector and the same route of administration and a similar dosing regimen is used to that employed previously, then truncated testing may be appropriate, depending upon the gene being expressed. When a promoter sequence or a targeting sequence in a viral or nonviral vector is changed, or the expression of viral gene products is considerably altered, the vector should be considered as a new vector, even though it may have the same gene as the previous version of that vector.

21.7.8 Change of Route

It is quite possible that a treatment may be initiated using, for example, intratumoral injections to deliver a gene, which may subsequently be administered systemically. As a considerable amount of relevant information will have already been generated to support the intratumoral route, this would be another case for doing bridging studies. Comparative distribution studies will help to identify how much more safety evaluation may be required.

21.7.9 Insertional Mutagenesis

The long-term management of genetic disorders will require integration of the therapeutic DNA into the host genome, or the maintenance of a stable episomal gene. The target of homologous recombination is still not achievable, and until that time, the problem of insertional mutagenesis—that is, inappropriate insertion of DNA into the host genome—must be addressed. How can the risk be quantified? Characterization of gene expression over time is more important than the copy number of the gene. An increased copy number can equate to an increased risk of insertional mutagenesis, but on the other hand it also equates to an increase in the desired product. Insertional mutagenesis is a safety problem, and it is important to advise and warn patients who receive genes which will become integrated into the genome of this potential risk associated with their treatment.

21.8 VACCINES

Vaccination against viral and bacterial diseases has been one of the success stories of human and veterinary medicine. Probably the most outstanding example of the effectiveness

of vaccination is the eradication of smallpox. In 1967 between 10 and 15 million cases of smallpox occurred annually in some 33 countries. By 1977, the last naturally occurring case was reported in Somalia. Polio too has been controlled in developed countries, for example, the number of cases in the United States was reduced from over 40 000 per year in the early 1950s, before a vaccine was available, to only a handful of cases in the 1980s. Diphtheria is now almost unheard of yet over 45 000 cases in 1940 led to 2480 deaths from diphtheria in the United Kingdom (similar numbers to those who died from AIDS in the United Kingdom in the entire 1980s). This has been reduced in the United Kingdom to only 13 cases and no deaths from the bacterium between 1986 and 1991. The scale of the problem is enormous—over 10 million deaths worldwide per year are due to infectious disease. The WHO figures suggest that cancers, circulatory problems, and injuries cause fewer deaths in developing countries than infectious diseases (Tinoco and Crowe, 2018; Plotkin et al., 2018), and yet, with Covid-19, a significant portion in the population of the United States (66 million individuals as of late October of 2020) were resistant to being vaccinated despite more than 600 000 having died of the disease to date (Thorpe, 2013). FDA provided a new guidance for developing vaccines and biologics for treating COVID-19 (FDA, 2021). Covid vaccines have thus far (as of late 2021) spanned such a time and extent of the population that the range of adverse effects has been made different in both understanding causality and extent of severity.

The process of developing vaccines is becoming increasingly complex due to the nature of the infections being protected against, the nature of the cultures in which the effected individuals live, and societal concerns as to vaccine safety (Plotkin et al., 2018). Kaufmann (1996), Kaufmann et al. (2014) provided an excellent addressal of this process and the inherent problems.

21.8.1 Approaches to Vaccination

There are three significant strategies for vaccination. One involves vaccination with either killed pathogenic organisms or subunits of the pathogenic organism. The second utilizes live attenuated viruses or bacteria that do not cause disease but have been derived from the pathogenic parent organism. Most recently, mRNA vaccines use messenger RNA fragments to “inform” cells about a protein or a piece of a protein that then triggers an immune response in the body. The infectious virus itself is not involved in the process.

Inactivated vaccines are made from virulent pathogens by destroying their infectivity usually with β -propiolactone or formalin to ensure the retention of full immunogenicity. Vaccines prepared in this way are relatively safe and stimulate circulating antibody against the pathogens surface proteins, thereby conferring resistance to disease. Two or three vaccinations are usually required to give strong protection, and

booster doses are often required a number of years later to top up flagging immunity.

Subunit vaccines can be seen as a subcategory of inactivated vaccines because similar considerations apply to subunits and whole organisms. Doses, routes, duration of immunity, and efficacy of these vaccines are all very comparable. In this case, a part of the pathogen, such as a surface protein, is used to elicit antibodies that will neutralize the infectivity of the pathogenic agent. The widespread use of hepatitis B virus (HBV) surface antigen purified from the blood of carriers (or more recently from recombinant yeast) shows that this can be a very effective way to immunize. HBV surface antigen, the product of a single gene, assembles into a highly antigenic 22 nm particle which if used in three 40 µg doses at 0, 1, and 6 months gives virtually complete protection against infection with HBV.

Another example that can be included in the subunit vaccine class is the use of bacterial toxoids. Many bacteria produce toxins which play an important role in the development of the disease caused by a particular organism. Thus, vaccines against some agents, for example, tetanus and diphtheria, consist of the toxin inactivated with formaldehyde conjugated to an adjuvant. Immunization protects from disease by stimulating antitoxin antibody which neutralizes the effects of the toxin.

A further type of vaccine included in the subunit category is the capsular polysaccharide vaccines, for example, those against *Haemophilus influenzae* and meningococcal meningitis. In this case, an extract of the polysaccharide outer capsule of the bacterium is used as a vaccine and is sometimes

conjugated to protein to improve immunogenicity. Antibody persists for several years and is able to protect against the bacterium.

About half of all vaccines have traditionally been from live attenuated mutants of parent pathogenic organisms (Walker and Gingold, 1993). In effect, live vaccines mimic natural infection yet produce subclinical symptoms and elicit long-lasting immunity often giving rise to resistance at the portal of entry. Most of today's attenuated vaccine strains have been derived by a tortuous often empirical route involving passage in culture until the pathogen is found to lose its virulence. This loss of virulence is tested in animal model systems before being tested in human volunteers. For example, the vaccine used to immunize against tuberculosis was derived after 13 years' passage in bile-containing medium by Calmette and Guérin (hence, the name BCG—bacillus Calmette–Guérin).

There has been much debate over the past 40 years as to the relative merits of live and killed vaccines often generating more heat than light. The evidence is that both routes will give adequate vaccines that can be used to protect against disease under the appropriate conditions. Table 21.14 summarizes the major points of debate. Many factors including cost, safety, number of immunizations, ease of access to vaccines, politics, and social acceptance will determine whether there is a high uptake of a particular vaccine and whether it is ultimately successful in eradicating the target disease. Even if a perfectly viable, relatively safe vaccine is available, uptake may be limited. For example, it has been estimated that vaccination against measles within the WHO EPI has prevented over 60 million cases and 1.37 million deaths. Despite these efforts,

TABLE 21.14 Relative Merits of Live versus Killed Vaccines

		Live	Killed/Subunit	mRNA
Production	Purification ^a	Relatively simple	More complex	Relatively simple
	Cost	Low ^b	Higher	low
	Route	Natural or injection	Injection	Injection
	Dose	Low, often single	High, multiple	High, multiple
Administration	Adjuvant	None	Required ^c	None
	Heat lability	Yes	No	Yes
	Need for refrigeration ^d	Yes	Yes	Yes
	Antibody response	IgG; IgA	IgG	IgG
Efficacy	Duration of immunity	Many years	Often less	
	Cell-mediated response	Good	Poor	Good
	Interference	Occasional OPV only ^e	No	No
Safety	Reversion to virulence	Rarely ^f		never
	Side effects	Low level ^g	No	low

^aIncreasing safety standards mean that for new vaccines, some of the older methodologies would not be acceptable.

^bThe price for new vaccines will approach that of killed subunit vaccines as safety standards are increased.

^cVery few adjuvants for human use are acceptable.

^dThe need for refrigeration increases the costs significantly.

^eEspecially in the Third World.

^fAt very low levels (<1 case per 10⁶ vaccinations).

^gThis varies from occasional mild symptoms with rubella and measles vaccines to possible brain damage with pertussis vaccine.

there are still some 70 million cases of measles annually, resulting in nearly 1.5 million deaths; consequently, a recent WHO congress adopted the following goals:

1. Increasing immunization coverage
2. Improving surveillance
3. Developing laboratory services and improving vaccine quality
4. Training
5. Promoting social mobilization
6. Developing rehabilitation services
7. Research and development

This again also serves to illustrate the importance of factors other than the efficacy of the vaccine itself in disease prevention.

The single most important issue in developed countries is the safety of a vaccine; a single death in a million vaccinations for a new vaccine would be unacceptable (except possibly if it were an effective AIDS vaccine). While this is obviously important in a third-world country, other issues such as cost and how to deliver the vaccine are of paramount importance.

21.8.2 Genetic Engineering and Vaccine Development

Not all protective antigens are as simple to identify, clone, and express as the surface antigen gene of hepatitis. The entire sequence of the HBV genome became available, and as it is less than 10 kb, it was relatively simple to establish which open reading frame to express. It has been known for many years that irradiated malarial sporozoites protect against malaria. As the sporozoite stage in the life cycle of the malarial parasite can only be grown in small quantities, it was left to rDNA technology to identify, clone, and express components of the sporozoite that might be of use in vaccine production. The genome of the malarial parasite is many thousands of times larger than the genome of HBV and therefore provides a different scale of problem; not only was there little sequence data available, but there was also no idea of which gene products may be protective.

The starting point of any rDNA work is to generate a library of DNA in *E. coli* which is representative of the organism under study. Once having a cDNA bank or a genomic library, there are three basic ways of identifying and isolating a gene of interest.

21.8.2.1 DNA/Oligonucleotide Hybridization If there is some preexisting knowledge of the nucleic acid sequence, or where purified mRNA is available, it is possible to detect recombinant clones by hybridization of ³²P-labeled DNA or RNA to bacterial colonies or bacteriophage plaques. Often, a protein has been purified, and some amino acid sequence is available which allows a corresponding nucleic acid

sequence to be synthesized. Due to the degeneracy of the genetic code, a complex mixture of oligonucleotides is required to ensure that all possible sequences are represented. Labeling this mixture of oligonucleotides yields a probe that can be used to screen a cDNA (or possibly genomic) library that might be expected to contain the gene of interest.

21.8.2.2 Hybrid Selection and Cell-Free Translation A second approach is to use hybrid selection of mRNA coupled with cell-free translation. DNA clones from a library, either individually or in pools of clones, can be immobilized by binding to a solid support and mRNA hybridized to them. Only the mRNA that corresponds to the clones will bind, and this can then be eluted and translated to a protein in a cell-free system. The protein can then be immunoprecipitated with antisera to the gene product of interest or assayed for activity. An example that encompasses both this approach and the sequence route is in the development of a vaccine for Epstein–Barr virus (EBV). It had been known since 1980 that antibody to the major membrane antigen of the virus (gp350/220) would neutralize the virus. Around 1983, a fragment of the virus genome was cloned and sequenced; using computer predictions, the *gp340/220* gene was identified. The experimental evidence that confirmed this prediction was published in 1985 and came from experimental work that managed to hybrid select EBV mRNA using genomic DNA clones. This was followed by cell-free translation of the eluted mRNA and immunoprecipitation of gp350/220 with a high-titer antibody. The DNA clone that hybridized with the gp340/220 mRNA was the one predicted to encode the *gp340/220* gene by computer analysis. The hybrid selection approach is rather labor-intensive and has for the most part been superseded by one of the forms of expression cloning.

21.8.2.3 Expression Cloning This approach is invaluable when the only means of identification are antisera against the protein or pathogen of interest.

Probably the most laborious form of this approach is its use in conjunction with a biological assay. cDNA libraries are cloned into a plasmid that will allow expression in eukaryotic cells, for example, SV40 or EBV vectors. Clones or pools of clones are then transferred to appropriate cell types, for example, COS cells for SV40 vectors and cell extracts or cell supernatant are assayed for biological activity. If a pool of clones gives the biological activity, then the individual clones can be reassayed and the desired cDNA clone identified. This methodology although tedious has allowed many of the interleukin genes to be cloned probably because the assays for these proteins are very sensitive.

Other gene products or vaccine antigens may require an enrichment step. For example, many genes expressed on the cell surface, that is, receptors, adhesion molecules, etc., have

been cloned by “panning” techniques, where the cells expressing the gene of interest are selected out either with antibody or by interaction with other cells. cDNA libraries are constructed in *E. coli*, and the library is transferred to eukaryotic cells. Those cells expressing the gene of interest are enriched for and the library transferred back to *E. coli*; this can be done for several rounds of expression, and eventually individual clones conferring the selected phenotype will be isolated.

The most extensively used form of expression cloning involves the use of plasmid or bacteriophage vectors in *E. coli* and identification of DNA clones using antisera to the protein of interest. Here a vector such as the bacteriophage λgt11 is set up so that when cDNA fragments are cloned into sites adjacent to the β-galactosidase, gene bacteria will express a β-galactosidase fusion protein containing epitopes present in the cDNA. Recombinant phage is detected with antisera. The cDNA insert is then sequenced, and the whole gene can then be isolated in a more traditional way. The antisera used can be mAbs, polyclonal monospecific antisera, or even polyclonal antisera with many antibody specificities present. A variation on this method allowed the initial cloning of the malarial sporozoite surface antigen. Malarial sporozoite stage cDNAs were introduced into the ampicillin resistance gene of the

plasmid pBR322. Low levels of expression of the sporozoite surface antigen were detected by solid-phase radioimmunoassay using an mAb specific for the protein. In this way, a cDNA clone coding for the antigen was isolated and subsequently sequenced. This information was then used to design peptide vaccines which have already been tested in humans.

The λgt11 system is a more sophisticated bacteriophage version of the plasmid system described earlier and has been used to isolate many different antigens from various stages in the life cycle of the human malarial parasite using human immune sera as well as antigens from pathogens.

21.8.2.4 Expression of Potential Vaccine Antigens In general, in the future eukaryotic cell culture is likely to be the method of choice for the production of subunit vaccine antigens where the organism to be vaccinated against replicates in eukaryotic cells. *E. coli* are unable to posttranslationally modify some vaccine candidates, for example, bacterial systems cannot add carbohydrate which is important in the antigenicity and structure of many protective antigens.

Since 1986, the US FDA has approved 22 vaccines (Table 21.15), half of them from a genetic engineering (and all, of course, from a biotechnology source). The cells used for

TABLE 21.15 Vaccines Approved by US FDA Since 1986

Vaccine	Indication	Date Approved	Company
Recombivax HB	Hepatitis B	June 23, 1986	Merck, Chiron
ProHIBIT	<i>Haemophilus influenzae</i> B	1988	Connaught
Pedvax	HIB	1989	Merck

^aSubsequently withdrawn.

such genetic engineering production of vaccine can be mammalian, insect, or bacterial.

The CBER has provided broad guidelines on the evaluation and production of vaccines (CBER, 2000). In general, the center's requirements have paralleled those for other biotechnology products. Beyond establishing sterility and lack of pyrogenicity and of viral contaminants, a single GLP toxicity study in an appropriate species (one that has been established, if possible, to be immune responsive to the vaccine) is required. If the vaccine is to be used in pregnant women or women of childbearing potential, a segment I style reproductive study should be performed in an appropriate animal species. A common concern that may require specific evaluation is dose-site reactions (local site responses). It must be remembered that it is not possible to evaluate the safety of a vaccine uncoupled with its intended adjuvant (Brennan and Dougan, 2005).

Regulatory guidance for the conduct of clinical trials on vaccines is specific. Traditional phase I trials in normal volunteers are not conducted. Rather, all trials assess not only safety but also efficacy (or at least immunogenicity). Trials may well be challenge trials—that is, after immunization subjects are purposely challenged with exposure to the infective agent of concern.

In any case, injection-site responses (erythema, edema, pain, and tenderness) and systemic responses are both evaluated in subjects (Mathieu, 1997).

The US FDA also has specific guidance on the tracking and reporting of adverse clinical responses to vaccines.

Any adverse events of product problems with vaccines should not be sent to MedWatch but to the Vaccine Adverse Event Reporting System (VAERS), operated jointly by the FDA and the national Centers for Disease Control and Prevention. For a copy of the VAERS form, call 1-800-822-7967, or download the form (in PDF format) from www.fda.gov/cber/vaers/vaers1.pdf on the FDA's website.

21.9 SPECIAL CHALLENGES

The problem with using a classical toxicological approach for evaluating an rDNA product or species-specific protein is that standard protocols are probably inappropriate and non-relevant in most cases. In the traditional approach to toxicology, a standard protocol or battery of tests is performed, followed by an estimation of the types of and degree of hazard or risk to humans. For example, conventional toxicity testing of a new rDNA product might lead to evaluation at excessively high doses in two rodent species. The production of antibody in the test species during preclinical toxicology testing may inactivate the test compound and thus invalidate the toxicity evaluation.

This approach appears somewhat irrational and without much scientific merit, since many of these new molecules are

minimally toxic or nontoxic by this sort of acute evaluation. As in the case of IFNs or mAbs, the toxic effects observed in humans might not be predicted from safety assessments in rodents. An appropriate test species should be selected. Is the rat or mouse the appropriate species to evaluate a species-specific rDNA protein such as HGH or IFNs, or would non-human primates be more suitable? Does the nonhuman primate really offer any advantages? There is some consensus that the nonhuman primate may be a more appropriate species for testing some rDNA human proteins.

In contrast, in the "pharmacological approach" to toxicology, the potential targets of toxicity are first identified (Zbinden, 1986). The criteria for relevant effects are established, usually based on experience with reference substances, and appropriate *in vivo* or *in vitro* experimental models are selected to assess the pertinent toxicological responses.

Doses should be selected that are reasonable multiples of the proposed therapeutic dose to be employed, especially since in many cases, the amount of material available for testing may be limited and not available in kilogram amounts. Preclinical rodent or primate studies should merely provide the flags to monitor during phase I clinical trials. Reason should prevail not only in the selection of methods and models for assessing the potential toxicity of the new agents but also in the use of these data for extrapolation to man. Whether US industry succeeds or fails in the biotechnology arena will depend on the quick resolution of issues such as selection of appropriate toxicologic tests, fermentation scale-up of the rDNA microbe, product purity, and expedition of regulatory pathways.

21.9.1 Purity and Homology

Major concerns in the production of a species-specific protein by rDNA technology are the purity of the product, the amount and type of contaminants present, and the homology of the product to the native molecule (Table 21.16). The toxicologist should be concerned about the acceptability and toxicity of intentional or inadvertent contaminants introduced during fermentation or isolation of the product (e.g., DNA, chemicals, *E. coli* proteins). Other issues concern the introduction of amino acid residues that might alter the

TABLE 21.16 Issues in the Safety Evaluation of Species-Specific rDNA Products

Purity
Homology to native molecule (amino acid sequence, extra amino acids, three-dimensional structure)
Type and amounts of contaminants (chemicals, <i>E. coli</i> proteins, fermentation products, foreign DNA)
Stability of clone
Immunogenicity
Toxicities (direct or secondary to therapeutic effect)

three-dimensional structure or antigenicity of the molecule, partial denaturation of the product during isolation and recovery, genetic stability of the rDNA clone during production (mutation could result in altered amino acid sequence), and the level of foreign DNA present. Although these are issues of analytical biochemistry, their impact on the potential toxicity and overall safety of the finished product is of some toxicological concern.

21.9.2 Immunogenicity

The problem of the immunogenic nature of many human rDNA proteins, and the potential to generate antibodies to a normal human protein, is of special interest to the immunotoxicologist. For example, 3 of 16 patients administered the rDNA-derived IFN- α (clone A) developed antibodies of the IgG class that were undetectable prior to or during therapy (Gutterman et al., 1982). These antibodies were capable of *in vitro* neutralization of IFN activity, although *in vivo* neutralization of IFN was not documented, since there are several different subtypes of IFN- α s containing epitopes not present on their own IFN subtype. Similarly, two patients treated with IFN- β for many months developed high-titered antibody, which in one case was correlated with an inability of the patient's fibroblasts to produce IFN (Vallbracht et al., 1982).

Virtually all patients treated with conventional porcine insulin develop circulating anti-insulin antibodies (Klaff et al., 1978) that are less frequent and in lower titer in individuals treated with more highly purified porcine (Falholt, 1982) or rDNA human insulin (Fineberg et al., 1983). In the study by Fineberg and associates, 44% of the patients developed antibodies to rDNA human insulin over a 12-month period compared to a 60% antibody frequency with porcine insulin. HGH (Genentech, Inc.) prepared by rDNA technology was observed to produce a frequency of immunogenicity similar to that seen with human insulin (~40% of the children developed antibody, according to the product insert). The ultimate goal is to develop rDNA products that will be less immunogenic than purified animal sources of these therapeutic agents.

The exact mechanism of the immunogenicity of species-specific rDNA proteins is unknown but is believed to be attributable to (i) the addition of extra amino acid residues during synthesis, which the host reads as foreign; (ii) denaturing of the native molecules; or (iii) contamination by *E. coli* polypeptides or lipopolysaccharides.

A second unanswered concern is whether the antibody induced by the recombinant protein has any discernible health effect. Other than some reports of neutralization of biological activity, little pathology has been attributed to the presence of antibodies in patients given recombinant protein therapy. It should also be noted that the question of antibody specificity has not been well studied so that it is entirely conceivable that autoimmune pathology or even an anaphylaxis response could be induced. Equally important is the concern that induced

antibody might neutralize the endogenous hormone or protein that it is intended to replace or supplement.

A third consideration is that certain routes of administration may favor immunogenicity of recombinant proteins. In early trials, rDNA proteins introduced by subcutaneous or intramuscular injections (procedures known to improve the immunogenicity of proteins) resulted in a higher frequency of antibody responses than in the IV route.

In summary, these are the clinically relevant questions about the immunogenicity of rDNA species-specific proteins: will antibody be induced in the recipient that will neutralize the therapeutic effect or lead to immune complex disease? What is the class (e.g., IgG or IgE) and specificity (i.e., reactivity against specific protein or contaminant) of the antibody induced? The former antibody type could potentially neutralize the product and produce immune complex disease, while the latter could result in an anaphylaxis response. It is possible that what the antibody induces is of insignificant health consequence, and its presence is known only because of improvements made in the sensitivity of detection methods with the introduction of the ELISA.

21.10 PLANNING A SAFETY EVALUATION PROGRAM

Safety evaluation of a candidate product should start with a consideration of specific nature and consequential hazards of the three Ps:

- The producing system
- The process
- The product

The need under each heading is to decide what data are required, then how to obtain them with the greatest efficiency and economy, and last, whether the toxicologist is necessarily the person with the appropriate skills and experimental techniques to do so. There will often be a trade-off between precise control by other means and possibly cheaper or more familiar, old-fashioned toxicological studies (Cavagnaro, 2008; Dorato et al., 2014). The inventor of a new product or process, too, may often have to do a great deal of work to show safety by excluding hypothetical hazards, which subsequent manufacturers can afford to ignore.

21.10.1 The Producing System

The questions of particular concern here are the nature of the system used to manufacture the desired substance and the precision with which it is controlled.

If the system consists of prokaryotic cells, then how well defined is their provenance and how is their consistency

demonstrated? If mammalian cells are employed, their lineage must be considered. In both instances, it is important to ensure that extraneous virus, infections, DNA, and less well-defined factors such as “slow viruses” are excluded by the origins and history of the producer strain, or because the physical (e.g., filtration) or chemical (pH, solvents, affinity separation) nature of the production process can be relied upon to exclude passage of an infectious agent.

If the degree of safety arising from these factors is weak, the toxicologist should consider appropriate studies *in vivo* to exclude contaminating agents, oncogenic factors, etc., but there is no point in doing short-term or prolonged animal experiments or other types of test unless the desired end point has first been clearly defined.

The aspect to which far more attention has been directed is the nature of the inserted gene(s) and promoters in rDNA products. Again, the toxicologist should ask how well the nucleotide sequence is known, whether there is only one reading frame, and how are any introns handled. Again, toxicity-type testing would appear to be an inefficient and expensive way to study molecular biology and biochemistry.

Last under this heading comes the consideration, for intact infectious organisms to be used directly in man, is assessment of potential pathogenicity to the range of individuals that make up our populations. The possibility of reversion to a wild and more dangerous strain, the hazard of an allergenic reaction to the organism (e.g., vaccinia), and the possibility of spread from subject to subject in a naive or incompletely immune population must be evaluated.

There may be some role for animal experimentation here, if there is a suitable model, because it gives the chance to study the organism under intense pressure from commensals and the rising immune response. Possible hazards in the manufacturing plant also need to be evaluated.

In general, conventional toxicity procedures seem to have little to offer here, except in specific instances of helping to exclude certain infections factors, perhaps ruling out oncogenicity, and examining the stability of engineered organisms for direct infection of man.

21.10.2 The Process

The toxicologist has the least to offer here. In fact, only the toxicologist's intellectual analysis and review of the literature should be required to assess the manufacturing process and any residues of its chemicals and so to set analytical limits on purity and residues in the final preparation.

21.10.3 The Product

There are two distinct and probably divergent forces affecting the way in which the toxicologist regards the final product. One is whether the toxicologist's opportunity is the first opportunity and therefore need to learn about its biology and

pharmacology, and the other is, what do scientific concern, clinical caution, and industrial pace define as the minimum it is reasonable to do before clinical trial or marketing?

21.10.4 Biology of Bioengineered Products

This may not be a useful concept scientifically, but it represents the practical point that the pace of development often forces the rapid sequence—interesting biological property, identification of responsible molecule in very small amounts (e.g., tumor necrosis factor or erythropoietin), cloning, etc.—resulting in large-scale production, perhaps even before the full structure is known. The clinical interest in administering the substance to man for investigative or therapeutic purposes must be balanced against the total lack of knowledge of its general effects on the body or of the consequences of prolonged high-level exposure to it of the function of interest.

As examples, there is the history of IFN, discovered through its antiviral actions, subsequently found to modulate mitosis and certain immune functions, capable of producing fever and probably ECG and EEG changes as evidence of membrane effects in excitable tissues. If an IFN were a novel discover, now just being produced for the first time, then investigation of its general biological effects on repeated administration to responsive animals would be important prior to study in man. The same arguments apply to other lymphokines, for example, α -IFN, IL-2, and so on.

The planning of this type of investigation as an empirical open study of responses must be carefully related to the nature and what is known of the product concerned:

1. It is necessary to work in a species capable of responding to the principal activity. IFNs are notorious for their species specificity, but most other lymphokines at least are more generally active. Work in a primate may be required, but it depends on the substance to be tested. There may be no point in working in using more than one species in pivotal studies.
2. Any test should be as broad and as general as possible, that is, monitor many variables clinically, in the laboratory and by pathology, until enough is known for there to be confidence in a focused approach. Relate any testing to the clinical circumstances of probable use. Thus, if a new synthetic antigen or engineered antigen is for testing, for administration only a few times to man, there would be no point in a multiple-dose experiment. It should suffice to show that it was antigenic in the intended preparation. Unless there were a prior reason to do so, a special search for, say, autoimmune reactions, seems unnecessary. Similarly, testing an mAb for activity is likely to be difficult if not impossible, because of species specificity and the antigenicity of the preparation.

- The toxicologist should be prepared to do nothing if the material is well known, its properties are understood, and there is adequate characterization of the nature of the preparation supplied; for example, human insulin or growth hormone produced by genetic engineering should not be submitted to prolonged safety tests in animals, provided that the molecular forms present are sufficiently well understood.

It may be useful, however, to consider limited animal studies to examine the pharmacokinetics and duration of action even of a well-known material made by a new route, unless physiochemical analyses show that to be pointless.

21.10.5 Animal Models

Species selection is probably one of the most important considerations when designing a preclinical safety program; for a biotechnologically derived pharmaceutical, it requires an understanding of the biology of the product. Since most of these either are human proteins or target human receptors, they tend to be species-specific. Studies in rodents and dogs, the species commonly used in traditional toxicity studies, may not provide scientifically meaningful data. However, nonhuman primates are not necessarily the most appropriate species either, despite their phylogenetic similarity to human beings.

Some approaches that offer guidance in selecting relevant species include a literature review; determining the extent of homology between the endogenous animal protein and the human recombinant protein; determining the activity of the protein in pharmacological models; and *in vivo* assays of the receptor/tissue binding.

A literature review may provide useful information about the physiological properties of the protein in animals and how they compare with those of the human protein in man. For example, prior to rDNA technology, growth factors and/or hormones were purified using biological fluids. Although the quantities obtained were limited, they were nevertheless

sufficient to allow investigation of the physiological properties of these proteins. Computer programs are now available for online searching of databases which hold information not only on the sequences of various animal and human proteins but also the extent of homology between an animal protein and its human equivalent, including common amino acid sequences. It should be remembered, however, that a protein showing a high degree of monology to the human protein may not necessarily share similar pharmacological activities. Evaluation of activity or lack of activity in pharmacological animal models, if available, certainly would aid species selection. Finally, *in vitro* assays which analyze receptor and/or tissue binding are commonly used to determine the appropriate species for preclinical safety evaluation.

Some biotechnologically derived pharmaceuticals will cross-react with species that can be evaluated toxicologically, while others cross-react only with nonhuman primates such as the chimpanzee—a protected species. In this case, a well-designed “safety” or “phase 0” study at doses higher than the proposed clinical dose may provide valuable safety information. However, a lack of cross-reactivity with any nonhuman species does not necessarily make preclinical safety evaluation impossible, nor does it limit toxicity testing to species in which the protein lacks relevant pharmacological activity. Some alternative possibilities are summarized in Table 21.17.

Toxicity studies traditionally are conducted using “normal” animals. However, studies in animal disease models may provide additional safety information regarding the possibility of disease exacerbation. For example, the administration of human recombinant erythropoietin was associated with hypertension in patients with chronic renal failure, and in uremic dogs, but not in normal dogs.

Species differences must be considered when choosing a model and, in particular, species-specific immunological differences between the human and the test animal. For example, in man, an anti-CD4 mAb will bind to CD4 expressed on monocytes, with subsequent fixing of complement and destruction of antigen-presenting cells. However, since CD4 molecules are not expressed on murine monocytes, these effects would not be evident in a murine model.

TABLE 21.17 Alternative Models for Toxicity Assessment

Model	Example	Caveat
Nontraditional animal model	Transgenic mice carrying appropriate human receptor	Antibody formation would need to be monitored, as it is probable that a large human protein would produce an immune response
Homologous proteins and/or systems	Testing purified animal protein in the same species or, for monoclonal antibodies, testing an antibody directed against the receptor in the animal	Data should be interpreted with caution as the biological properties of the animal protein may differ from those of the human protein
<i>In vitro</i> methods	Tissue binding assays	If no <i>in vivo</i> models are available, <i>in vitro</i> ; methods combined with <i>in vivo</i> testing in a pharmacologically nonreactive may suffice

For highly humanized proteins, the approach to proper safety evaluation starts with the identification of an appropriate nonclinical safety model.

First, evaluate for comparative tissue binding; then if no appropriate species is identified, then one can

- Either prepare and test a homolog
- Or test molecule itself in a humanized mouse model

A tissue cross-reactivity study is required by the FDA “points-to-consider document” for mAbs prior to the first clinical trial. Its usefulness is debated, but its purpose is to evaluate the potential for binding to nontarget tissues. Positive and negative controls are important for interpreting results. Tissues from humans and all nonclinical species used in safety studies should be evaluated. At minimum, the evaluation should include the 32 tissues recommended by the FDA “Points to Consider in the Manufacturing and Testing of Monoclonal Antibody Products for Human Use.”

When is it appropriate to use a homolog? According to ICH S6 guidance, “When no relevant species exists, the use of homologous proteins should be considered. While useful information may also be gained from the use of homologous proteins, it should be noted that the production process range of impurities/contaminants, pharmacokinetics, and exact pharmacological mechanism(s) may differ between the homologous form and the product intended for clinical use.”

Comparability of the homolog with the clinical candidate is critical:

- Characterize pharmacology
 - Literature: What’s known about the target in the test species compared to humans?
 - *In vitro* binding—similar affinity or neutralization?
 - Functional assays
 - *In vitro* cells
 - *In vivo* bioassays (if possible relevant)
 - Similar tissue distribution (tissue cross-reactivity for mAbs)
- Pharmacokinetics
- Is Fc activity important and similar?

Challenges of homologs

- They represent a second test article.
 - The decision must be made early in development. Sometimes, it is not possible to make a homolog. If possible, months to years needed to develop construct, clone, manufacture material, characterize pharmacology, and/or establish bioanalytical support

May be immunogenic, thus limiting usefulness

- How do you interpret the data?
 - No “validation” can be performed that homolog is predictive of human toxicities.

- What if findings are different from the clinical candidate in an appropriate toxicology species?
- How do we extrapolate safety margins to the clinical candidate?

Regulatory challenges of homologs

- No common criteria for what’s expected
 - How much comparison with the clinical candidates is enough?
 - Expectations for analytical characterization and does this need to be comparable?
 - Do all aspects of testing need to be GLP?
- Can studies with a homolog replace studies with the clinical candidate?
 - Development and reproductive testing
 - What if results are more severe than with the clinical candidate?
- Are negative findings meaningful?
 - It is not your clinical candidate, so does the data impact risk assessment?

Homologs have been used to support registration for infliximab (Remicade®) (anti-TNF) and efalizumab (Raptiva®) (anti-CD11a). In both cases, there was not an appropriate species for the clinical candidate. Chimpanzees were the only pharmacologically responsive species, but they are not acceptable for toxicity testing due to humane reasons:

“Humanizing” Mice

- Isolate CD34+ stem cells (hHPCs) from human cord blood
- Breed NOD. Cg-Prkdc^{scid}//2rg^{tmWjl}
- PND1 pup irradiated 1 cGy
- hHPCs (10⁵) injected in 25 μL PBS into the liver
- Assay tail blood for reconstitution of human immune cells

Humanized Mice Can be Used to

- Assess the *in vivo* influence of stressors and drugs on the development of immune cells
- Evaluate how toxicants can modify *in vivo* human immune responses
- Investigate whether hematopoietic stem cells from cord blood can be induced to develop into nonimmune cell types
- Determine the influence of mouse effects on human immune cells longevity and human immune cells on mouse longevity

21.10.6 Study Design

It is questionable whether traditional toxicological paradigms are applicable to biological or protein agents. If they

are not, then how can the clinician gain reassurance to administer the first dose to man, to move into multidose trials, and to even assess the agent in combination with other established medicines or biological agents? mAbs, soluble cytokine receptors, and growth factors all have been used in patients for nearly a decade, providing a wealth of experience in this area from which to learn. One of the most striking lessons is that PD effects may appear long after dosing of the agent has been discontinued.

As a class, biotechnologically derived pharmaceuticals share certain characteristics which have influenced their pre-clinical development. They are proteins and therefore toxicity was expected to be minimal and limited to an exaggeration of their desired pharmacological effects, a myth which was ultimately exploded. These agents are designed to perturb specific molecular or cell-to-cell interactions, sometimes with minimal effect on the pathophysiology of the target disease. Owing to the species-specific nature of these agents, preclinical toxicology is usually limited. For example, if a primatized anti-CD4 mAb cross-reacts only with chimpanzee and human CD4, the species of choice for toxicity tests is the chimpanzee, the use of which is restricted by its limited availability.

These characteristics of protein agents give rise to problems in clinical development, such that the traditional paradigm for preclinical testing may not be appropriate. The dose in animals may not be predictive of an appropriate starting dose for man. A surrogate marker, for example, CD4 cell counts in the pre-clinical chimpanzee model, may be useful in setting the initial human dose but may only serve to indicate a no-effect dose. Once in the clinic, trials conducted early in development are usually not sufficiently powered to distinguish effects due to the toxicity of the test agent, from those due to, for example, the underlying disease and concomitant or previous medications. Finally, short-term (3–6 months) preclinical studies do not necessarily predict the long-term effects of these agents.

The long-term toxicities of concern are opportunistic infections, lymphoproliferative disorders, and immunogenicity, manifesting as tachyphylaxis, and/or allergic reactions. Preclinical approaches which serve to identify these as potential hazards to man of a biologic drug moiety are thus needed.

The choice of toxicity studies, and the design of individual studies, will depend on the proposed clinical program. Important issues to consider are

- The frequency and route of administration, including the use of novel delivery systems
- The duration of dosing
- Special toxicity testing

21.10.7 Frequency and Route of Administration

Clinical trials for biotechnologically derived pharmaceuticals may be more complex than those for conventional pharmaceuticals, and so the route and frequency of test drug

administration should, if possible, mirror the proposed clinical use, even if that route employs a novel delivery system.

21.10.8 Duration

Traditionally, the duration of a toxicity study depends on the intended clinical use and disease duration. The potential immunogenicity of the human protein is a significant issue since antibody binding can partially or completely inhibit the biological activity of that protein, affect its catabolism, or alter its distribution and clearance. Any multiple-dose study therefore should include evaluation of the impact of antibody formation, including their neutralizing capacity. However, antibody formation in itself should not be a reason for termination of a toxicity study, particularly if the antibodies are not neutralizing or do not alter the pharmacodynamics of the protein.

Multiple-dose toxicity studies are usually conducted before single-dose administration to volunteers. Many of the clinical trials for biological agents target life-threatening illnesses, and it has therefore been suggested that single-dose toxicity studies are sufficient to support single-dose “proof-of-concept” clinical studies. While this approach promotes faster introduction into the clinic, it may be of limited use since, once in many, there is a tendency to overlook the preclinical data. Clinical development may not progress without interruption if relevant preclinical data are missing.

21.10.9 Special Toxicity Testing

In addition to multiple-dose studies, information on potential functional changes—as obtained from safety pharmacology studies—and the potential for genotoxicity, reproductive toxicity, and carcinogenicity may be required for registration. Once again, the species specificity of recombinant proteins may preclude the use of traditional animal species such as rodents and/or rabbits for safety pharmacology, reproductive toxicity, and carcinogenicity studies. Functional evaluations of cardiovascular and pulmonary systems could be incorporated into a nonhuman primate multiple-dose toxicity study. If appropriate, potential reproductive toxicity can be evaluated in a nonhuman primate.

There may be situations which warrant an assessment of carcinogenic potential, but immunogenicity and species specificity may preclude a 2-year rodent bioassay. It may be necessary to develop *in vitro* assays to address a particular concern. For example, growth factors which may have the potential to support or stimulate the growth of transformed cells should be assessed for their ability to promote growth of either malignant or normal cells.

High molecular weight compounds are unlikely to react with DNA or other chromosomal material, and therefore a genotoxicity evaluation may be of little value. However,

genotoxicity studies may provide useful information about the safety of products containing organic linkers.

21.10.10 Program Design Considerations

The standard toxicological data package for any new drug entity typically evaluates:

- Potential toxicity following single and multiple dosing
- Genotoxic potential
- Functional changes, that is, safety pharmacology studies

In addition, depending on the proposed clinical plan, the following may need evaluation:

- Toxicity following chronic dosing
- Carcinogenic potential
- Possible reproductive toxicity

Although biotechnologically derived pharmaceuticals often need customized preclinical development programs, certain issues are common to all. These include species specificity, potential immunogenicity and its impact on the duration of dosing, and the need for special toxicity testing.

21.11 CHALLENGES: BIOSIMILARS

For small molecules, the availability of generic versions after patent expiration has significantly contributed to keeping the

cost of many (particularly chronic use) medications down. Such generics have identical chemical structures to those of the marketed active molecules and demonstrate that structural equivalence is readily done by available analytical techniques.

For biologics, however, where the drug entity is produced by modified cellular processes and the precise complex molecular structure cannot precisely be defined and therefore an identical structure cannot be either achieved or proven. So it is not possible to produce “generic” biologic drugs, even after patent expiry. Though guidelines and laws have been enacted in the EU and the United States (the “Biologics Price Competition and Innovation Act” (BPCI) enacted in 2009) to provide a path to production (biologically sourced therapeutics that are equivalent in terms of efficacy and safety, “bio-similars”) and a specific guidance was enacted by the FDA (2012a), progress has been slow. As of the end of 2015, only one drug (Zarxio, a biosimilar for Amgen’s Neupogen which was first approved in 1991) has been so approved in the United States. The process of approval requires:

1. Analytical studies demonstrating that the biologic product is highly similar to the marketed (“reference”) product.
2. Animal studies showing equivalence of safety and therapeutic activity.
3. One or more clinical studies to demonstrate safety, purity, and potency under reference drug label conditions of use. Such studies must access and show equivalence for immunogenicity and either pharmacokinetics or pharmacodynamics.

TABLE 21.18 Nonclinical Studies with Marketed Biosimilars

Biosimilar versus Innovator Name/Identity/Action/Authorization Date/Reference ^a	Biological Activity/Pharmacology	Kinetics	Toxicology
Growth factor

^a Source: Data from European Public Assessment Report for each biosimilar (EMA, 2016).

The animal toxicity studies should be designed to provide a comparative evaluation of the reference and biosimilar product in a relevant animal species. As such, either PK or PD measures should be obtained to support a determination of equivalence (Baldrick and Donninger, 2012).

Examples of such nonclinical studies used to support marketing approval of biosimilars in Europe are presented in Table 21.18. The biosimilar approval process in the EU has moved along very quickly.

SAFETY ASSESSMENT OF INHALANT DRUGS AND DERMAL ROUTE DRUGS

While the two most common routes for administering a drug are either orally or parenterally (most commonly by the intravenous route), there are many other routes that can be used. The next two most common are inhalation (with all its variations) and dermal route, which both share with the oral route both the role of being a major entry path into the body (because they are the first line of defense against potentially hazardous external agents), specialized barrier functions, and immune capabilities. As such tissue interactions are dependent on the effects of the formulation (and means of administration) that the drug is given to humans, the relevant Food and Drug Administration (FDA) regulatory offices within Center for Drug Evaluation and Research (CDER)/Office of New Drugs both require that the good laboratory practice (GLP) systemic (general) toxicity studies be performed with the administration being as it will be to humans in terms of both route and regimen. Selection of route and regimen can be used to improve systemic absorption and selective of therapeutic target organ (Gad and Spainhour, 2018).

Each of these routes has special considerations as to the evaluation of their safety—both regulatory and technological—which this chapter will consider in turn.

22.1 INHALED THERAPEUTICS

Drugs and medicinal agents administered by the inhalation route include the gaseous and vaporous anesthetics, coronary vasodilators, the aerosols of bronchodilators, corticosteroids, mucolytics, expectorants, antibiotics, and peptides and proteins, where there is significant nasal absorption (Cox et al., 1970; Williams, 1974; Paterson et al., 1979; Hodson et al., 1981; Newman et al., 1981a, b; Lourenco and Cotromanes, 1982). Concerns with the environmental effects

of chlorofluorocarbons have also led to renewed interest in dry powder inhalers, which have additionally shown promise for better tolerance and absorption for some new drugs. Excessive inhalation of a drug into the pulmonary system during therapy or manufacturing may result in adverse local and/or systemic effects. Consequently, safety assessment of inhaled medicinal preparations with respect to pulmonary toxicity and the therapeutic-to-toxicity ratio is essential. The data generated is essential for charting the course of evaluation and development of a potential therapeutic agent. We also now know that a subset, nasal administration, achieves selectively more effective absorption to the central nervous system (CNS).

22.2 THE PULMONARY SYSTEM

An average man inhales approximately 7.5, 28.6, and 42.9L of air per minute during resting, light work, and heavy work periods, respectively, as well as the corresponding mean tidal volumes (T_v) of 750, 1673, and 2030 mL (National Academy of Sciences, 1958). Each breath is distributed between 300 and 400 million alveoli, where gas exchange takes place. The total alveoli surface area is approximately 75 m², which is penetrated by approximately 200 km of capillary blood vessels (Hatch and Gross, 1964). The high vascularity and large surface area of the lung ensure rapid gas exchange and entry of an inhaled drug into the bloodstream. A drug is then quickly carried to the heart and brain before reaching the liver, where first-pass metabolism occurs. The pulmonary system is, therefore, a very effective portal through which gases, vapors, and aerosols can enter the body to exert desirable therapeutic effects and undesirable side effects locally and/or systemically.

Anatomically, the pulmonary system is divided into extrathoracic and thoracic regions. The extrathoracic, or head, region includes the nasal and pharyngeal passages. The thoracic region is subdivided into tracheobronchial (TB) and alveolar (AL) regions. The TB region consists of the trachea, primary and secondary bronchi, and primary through-ciliated bronchioles. The AL region consists of nonciliated terminal bronchioles, AL ducts, and alveoli (Lippmann, 1970; Lippmann et al., 1980). The anatomical structure of the pulmonary system maximizes gas exchange but minimizes the penetration of extraneous particulate matter into the lungs. The formalized anatomy (Davis, 1961; Weibel, 1963; Horsfield and Cuning, 1968; Parent, 2015) of the branchings, the dimensions of the airways, the penetrability by particles of certain sizes, and the distribution of cell types in the respiratory tract and lungs are summarized in Figure 22.1.

22.3 PENETRATION AND ABSORPTION OF INHALED GASES AND VAPORS

Pulmonary dynamics, the dimension and geometry of the respiratory tract, and the structure of the lungs, together with the solubility and chemical reactivity of the inhalants, greatly influence the magnitude of penetration, retention, and

absorption of inhaled gases, vapors (Dahl, 1990), and aerosols (Raabe, 1982; Phalen, 2009). The quantity of an inhalant effectively retained in the pulmonary system constitutes the inhaled “dose” that causes pharmacotoxic responses.

Highly reactive and soluble gaseous or vaporous drugs react and dissolve readily in the mucosal membrane of the nasopharynx and the upper respiratory tract (URT), thereby exerting pharmacological effects or causing local irritation and/or adverse effects on the ciliated, goblet, brush border columnar, and squamous cells of the epithelium (Weibel, 1983). The dissolved drug is also absorbed into the bloodstream and transported to the target organ where it exerts systemic effects. Less reactive and less soluble gaseous or vaporous drugs are likely to penetrate beyond the URT and reach the bronchial and AL regions causing local and systemic effects. The unabsorbed gases or vapors are then exhaled. For example, ammonia gas generated from a 10% ammonia water may be inhaled for reflex respiratory stimulation purposes (O’Neill, 2013). Ammonia is extremely soluble in water at a concentration of 715 mL of ammonia per milliliter (mL) of water (Phalen, 2009) and is readily solubilized in the mucous lining causing URT irritation. By contrast, oxygen is only sparingly soluble in water (0.031 cm³ of oxygen per milliliter of water) and capable of penetrating deeply into the alveoli where gas exchange takes place. Oxygen that binds reversibly

Regions		Generations	Total cross section (cm ²)	Particle size penetration limits (µm)	Distribution				
					Cell types	Mucous glands	Smooth muscle	p-sym. innerv.	
Extrathoracic	Head	Nasopharynx			60				
		Intrathoracic	Tracheo bronchial	Trachea	0	2.54		Ciliated Goblet Brush Border Squamous Columnar

		21	3.22K						
		22	5.88K						
Alveoli	23	11.8K	<3	Type II					

FIGURE 22.1 The distribution of cell types in the respiratory tract and lungs.

with the hemoglobin of erythrocytes is unloaded at the target tissues, while the unbound oxygen is exhaled. Inhalation of properly humidified oxygen is life-supporting, but inhalation of nonhumidified oxygen may cause a reduction in the mucociliary clearance of secretions in the trachea of animals (Pavia, 1984) and humans (Lichtiger et al., 1975; Gamsu et al., 1976). Gases or vapors of low lipid solubility are also poorly absorbed in the lungs, with much of the inhaled vapor exhaled. Other pharmacological gases and vapors, such as the anesthetics (nitrous oxide, halothane, enflurane, isoflurane, etc.) and the coronary vasodilators (amyl nitrite), likewise affect the epithelium of the respiratory tract and the lungs. The absorbed drugs exert local effects on various types of epithelial cells of the respiratory tract and on type I and II cells and the alveolar macrophages (AMs) in the alveoli. Repeated inhalation of some halogenated hydrocarbon anesthetics will result in accumulation of the vapors and systemic toxicity (Chenoweth et al., 1972). By contrast, vapors such as the fluorocarbons (FC 11 and FC 12), which are used extensively as propellants for bronchodilator and corticosteroid aerosols, are absorbed rapidly but are not accumulated in the body even upon repeated inhalation (Aviado and Micozzi, 1991).

In general, dissolved gases or vapors at a nontoxic concentration are absorbed and metabolized locally by the lungs and systemically by the liver. The unchanged parent drug and its metabolites may be excreted to some extent via exhalation but mainly via the renal system. A dissolved gas or vapor at a toxic concentration, however, is likely to exert local effects such as altering the surface tension of the alveoli linings or disrupting the normal functions of the epithelial cells, the pneumocytes, and the AMs. The disrupted AMs in turn release their intracellular enzymes, causing destruction of the AL septa and contributing to histopathologic changes of the respiratory tract and the lungs. Again, the magnitude of the adverse effects is dependent on pulmonary dynamics and the solubilities of the inhalants in the mucous membrane of the URT and in the plasma or lipids of the erythrocytes.

22.4 DEPOSITION OF INHALED AEROSOLS

For inhaled aerosols, particle size is the major factor affecting the penetration, deposition, and hence the “dose” and site of pharmacological action (Dautrebande, 1962a, b; Agnew, 1984) of administered aerosols (liquid or solid). Particle size is expressed in terms of *aerodynamic diameter* (AD), defined as the diameter of a spherical particle of unit density (1 g cm^{-3}) that has the same terminal settling velocity as the particle in question, regardless of its shape and density (Marple and Rubow, 1980). The unit for AD is micrometers (μm). A sample of aerosol particles having ADs within a narrow size range is considered to be a monodisperse aerosol, whereas a sample of aerosols with a wide range of ADs is a heterodisperse, or polydisperse, aerosol. The

pattern of particle-size distribution is usually bell-shaped, with smaller and larger particles on both sides of the mean AD. An aerosol sample with a high proportion of particles of similar size has a narrow particle-size distribution or small geometric standard deviation (GSD). An aerosol sample with a GSD of less than 2 is considered to be a monodisperse aerosol. Thus, both the AD and GSD of 2 or less are considered to be optimal for pulmonary penetration and distribution in the respiratory tract and the lungs. For example, in nose breathing, aerosol particles with ADs $> 15 \mu\text{m}$ are likely to be trapped in the nasopharynx (extrathoracic, or head, region) by filtration and impaction. Particles deposited in the nasopharynx are considered to be “noninhalable” (Lippmann, 1977; Miller et al., 1979).

During mouth breathing in human, only 10–15% of $15 \mu\text{m}$ particles penetrate through the larynx to the intrathoracic TB region. Particles reaching the TB region are considered to be “inhalable” (Lippmann, 1977; Miller et al., 1979).

In natural nose and mouth breathing, only a negligible proportion of aerosol particles of AD $> 10 \mu\text{m}$ reach the lungs (Swift and Proctor, 1982). Aerosol particles of 3–4 μm in AD are considered to be optimal sizes for TB deposition. The mechanisms of deposition are by impaction along the trachea and at bronchial branchings where the direction of airflow changes and by gravity settlement in the fine airways in amounts proportional to the particle settling velocity and the time available for settlement (Hatch and Gross, 1964; Heyder et al., 1980). Aerosol particles of 1–2 μm in AD, however, decrease in TB deposition because the particles are too small for effective impaction and sedimentation (Lippmann, 1977; Chan and Lippmann, 1980; Stahlhofen et al., 1980). Consequently, the majority of the very fine particles are exhaled. However, the deposition of the ultrafine particles of approximately 0.5 μm in AD on the walls of the finest bronchioles and the alveoli increases again due to molecular diffusion processes. Even so, some 90% of the inhaled 0.5 μm particles will still be exhaled during quiet tidal breathing and much more under forced exhalation (Davis et al., 1972; Taulbee et al., 1978). Those fine particles reaching the finest bronchioles and alveoli are considered to be “respirable” (Lippmann, 1970).

In general, particles of AD $> 10 \mu\text{m}$ deposit mainly in the URT, whereas particles of 1–5 μm AD, with a GSD of less than 2, are likely to reach the lower respiratory tract (LRT), which includes the TB region and the alveoli, with small oropharyngeal loss. Similar proportions of penetration occur in other species but with the size of deep lung penetration particles decreasing in proportion to the size of air passage dimensions.

The proportion of an aerosol sample suitable for inhalation can also be determined on the basis of mass median aerodynamic diameter (MMAD), which is defined as the percentage (50%) by weight of an aerosol sample having ADs equal to or less than the stated median AD. For example, a sample with an

MMAD of 5 μm means that 50% by weight of that sample has ADs of 5 μm and smaller. The MMAD is, therefore, a good index for determining the proportion of an aerosol sample that is “noninhalable,” “inhalable,” or “respirable.” An aerosol sample with an MMAD of 5 μm and a GSD of less than 2 is considered to be optimal for pulmonary deposition and retention (Task Group on Lung Dynamics, 1966).

In addition to AD and GSD, the pulmonary dynamics of a subject also greatly influence the distribution of aerosol particles in various regions of the respiratory tract (Agnew, 1984). For example, the velocity of airflow in the respiratory tract significantly influences the pattern of TB deposition. An increase in airflow velocity in the airways increases the effectiveness of particle impaction at the bifurcations of the large airways (Dennis, 1961; Hatch and Gross, 1964; Parent, 2015). As a result, spots impacted with a high concentration of particles (hot spots) are frequently present at the carina and the bifurcations of the airways (Lee and Wang, 1977; Bell, 1978; Stahlhofen et al., 1981). Furthermore, the depth of each breath (tidal volume) also influences the distribution of aerosols. A small tidal volume permits greater impaction in the proximal conducting airways and less sedimentation in the distal airways.

In general, slow, deep inhalation followed by a period of breath holding increases the deposition of aerosols in the peripheral parts of the lungs, whereas rapid inhalation increases the deposition in the oropharynx and in the large central airways. Thus, the frequency of respiration (the flow velocity) and the depth of breath (tidal volume) influence the pattern of pulmonary penetration and deposition of inhaled aerosols. Therefore, an aerosol of ideal size will penetrate deeply into the respiratory tract and the lungs only when the aerosols are inhaled in the correct manner.

22.5 ABSORPTION AND CLEARANCE OF INHALED AEROSOLS

Soluble aerosols deposited on the epithelial linings of the respiratory tract are absorbed and metabolized in the same way as soluble gases and vapors.

Insoluble medicinal aerosols are few in number. Sodium cromoglycate (SCG) is probably the only insoluble powder to be administered as a prophylactic antiasthmatic (Wanner, 1979). Insoluble particles deposited on the ciliated linings of the URT are removed by a mucociliary clearance mechanism (Lauweryns and Baert, 1977). Particles deposited on a terminal airway devoid of ciliated cells may be endocytosed into the epithelial cells (Jones, 1984; Newhouse et al., 1976). At a toxic concentration, the cells die, and the debris is then phagocytosed and transported into the interstitial space for removal via the lymph or vascular drainages or reenters the ciliated zone of the airway. Particles deposited in the AL walls are phagocytosed by the AMs and transported from the low-surface tension surfactant in the AL lining to the high-surface

tension bronchial fluid of the ciliate airways for elimination by the mucociliary clearance mechanism (Lauweryns and Baert, 1977). The particle sizes optimal for phagocytosis are 2–3 μm , while particles smaller than 0.26 μm are less effective in activating the macrophages (Holma, 1967). In any case, AMs can phagocytose only a small fraction of a large number of deposited particles. The nonphagocytosed particles are translocated to the lymphatic system for elimination (Ferin, 1977).

Like the inhaled gases or vapors, soluble and insoluble aerosol particles can directly exert desirable and undesirable local effects at the site of deposition and/or systemic effects after solubilization, absorption, and metabolization (Sackner et al., 1975; Sackner, 1978).

22.6 PHARMACOKINETICS AND PHARMACODYNAMICS OF INHALED AEROSOLS

The inhalation route for administering drugs into the pulmonary system for treatment of respiratory diseases eliminates many bioavailability problems such as plasma binding and “first-pass” metabolism, which are encountered in parenteral or oral administration. Consequently, a small inhalation dose is adequate for achieving the desirable therapeutic response without inducing many undesirable side effects. Furthermore, the direct contact of the drug with the target site ensures rapid action. Nevertheless, the effects from inhaled drug aerosols also depend on the pharmacological properties of the aerosols and the location of their deposition in the respiratory system. For example, the classic experiments on bronchodilation drugs (Dautrebande, 1962a, b) showed that fine aerosol particles of isoproterenol penetrate deeply into the lower respiratory airways (LRAs). In this way, a high concentration of the drug aerosol can reach the beta-adrenergic receptors of the bronchial smooth muscles. Stimulation of the receptors causes relaxation of the smooth muscle fibers and results in bronchodilation (Weiner, 1984; McFadden, 1986). Such rapid bronchial responses can be produced in healthy and asthmatic subjects without inducing any cardiac effects. By contrast, the same dose of isoproterenol of large particle sizes deposits mainly along the URT, with a minimal amount reaching the smooth muscles of the LRA. The drug is quickly absorbed into the tracheal and bronchial veins and delivered immediately to the left ventricle of the heart. A high plasma concentration of the drug in the heart causes prominent cardiovascular effects such as tachycardia and hypertension. Other aerosols of beta-adrenergic drugs, such as epinephrine, isoprenaline, terbutaline, and salbutamol, induce bronchodilation effects in animals and humans (Pavia, 1984) via inhalation and stimulate ciliary beat frequency and mucus production at the site of deposition in the trachea (Wanner, 1981). Thus, the TB mucociliary clearance mechanism is also stimulated.

By contrast, anticholinergic bronchodilators, such as atropine and ipratropium bromide, cause mucus retention in the lungs (Pavia et al., 1983a, b). Therefore, in pharmacological or safety assessments of inhalant beta-adrenergic bronchodilation drugs, aerosols should be of small particle sizes suitable for deposition in the peripheral airways to minimize side effects. However, anticholinergic agents should be of larger particle sizes suitable for deposition in the large airways (Ingram et al., 1977; Hensley et al., 1978).

Other therapeutic aerosols, such as beclomethasone dipropionate, betamethasone valerate, and budesonide corticosteroid (Williams, 1974); the carbenicillin and gentamicin antibiotics (Hodson et al., 1981); the 2-mercaptoethane sulfonate (Pavia et al., 1983b) and *n*-acetylcysteine (Hollinger, 1985) mucolytics; and even vaccines for the prevention of influenza and tuberculosis (Lourenco and Cotromanes, 1982) are active by inhalation and/or oral administration. When these drugs are administered as aerosols, certain particle sizes may be targeted to a specific region or to multiple regions of the pulmonary system depending on the therapeutic target site(s). In any case, when aerosols are delivered as fine particles, the rate of absorption is increased because of an increase in the distribution area per unit mass of the drug. Thus, an effective aerosol dose of corticosteroid for treatment of asthma and bronchitis is merely a fraction of an oral dose (Williams, 1974). An aerosol of SCG dry powder, a prophylactic for preventing the onset of bronchoconstriction in asthmatic attacks (Cox et al., 1970), is effective mainly by local inhibition of the release of chemical mediators from mast cells in bronchial smooth muscle. Therefore, SCG particle sizes should be approximately 2 μm in AD for the most effective penetration into the bronchial regions (Godfrey et al., 1974; Curry et al., 1975). Likewise, therapeutic aerosols of local anesthetics and surfactants may require appropriate particle sizes to be targeted to a specific region of the pulmonary system.

Other than undesirable pharmacological effects, toxic concentrations of soluble or insoluble aerosol particles may lead to adverse physiological and/or histopathologic responses. For example, irritating aerosols cause dose-related reflex depression of the respiratory rate (Alarie, 1966, 1981a), while phagocytosed particles cause chemotaxis of AMs and neutrophils to the site of deposition (Brain, 1971). The maximum response usually occurs at 24 h and returns to normal in approximately 3 days postexposure (Kavet et al., 1978). Furthermore, a toxic quantity of phagocytosed particles may interact with the lysosomal membrane within a macrophage, releasing cytotoxic lysosomal enzymes, proteases, and free radicals that in turn damage the adjacent lung tissue (Hocking and Golde, 1979).

In general, a specific category of drug delivered to a specific site of the pulmonary system will exert a specific pharmacological or toxicological action locally or systemically. Therefore, in safety assessments of inhalants, a drug

should be delivered to the target sites of the pulmonary system according to the toxicological information required.

Finally, there are many drugs in the categories of amphetamines, anorectics, antihistamines, antipsychotics, tricyclic antidepressants, analgesics and narcotics, and beta-adrenergic blocking agents that are known to accumulate in the lung (Wilson, 1982; Hollinger, 1985) even though these drugs are not administered via the inhalation route. Therefore, in the safety assessments of these drugs, their pulmonary toxicity should also be evaluated.

22.7 METHODS FOR SAFETY ASSESSMENT OF INHALED THERAPEUTICS

Methods for evaluation of inhalation toxicity should be selected according to the pharmacological and/or the toxicological questions asked, and the design of experiments should specify the delivery route of a drug to the target sites in the pulmonary system (Gad, 2015; Royal Society of Chemistry, 2021). For example, if an immunologic response of the lungs to a drug is in question, then the lymphoid tissues of the lungs should be the major target of evaluation. The following are some of the physiological, biochemical, and pharmacological tests that are applicable for safety assessment of inhaled medicinal gases, vapors, or aerosols.

URT irritation can occur from inhalation of a medicinal gas, vapor, or aerosol. Because of the necessary fragility of the thin active gas exchange epithelial tissue, severe or repeated irritation can readily cause the development of nonfunctional scar tissue. For assessing the potential of an inhalant to cause URT irritation, the mouse body plethysmographic technique (Alarie, 1966, 1981a, b) has proven to be extremely useful. This technique operates on the principle that respiratory irritants stimulate the sensory nerve endings located at the surface of the respiratory tract from the nose to the AL region. The nerve endings in turn stimulate a variety of reflex responses (Alarie, 1973; Widdicombe, 1974) that result in characteristic changes in inspiratory and expiratory patterns and, most prominently, depression of respiratory rate. Both the potency of irritation and the concentration of the irritant are positively related to the magnitude of respiratory rate depression. The concentration response can be quantitatively expressed in terms of “ RD_{50} ,” defined as the concentration (in logarithmic scale) of the drug in the air that causes a 50% decrease in respiratory rate. The criteria for positive URT irritation in intact mice exposed to the drug atmosphere are depression in breathing frequency and a qualitative alteration of the expiratory patterns. Numerous experimental results have shown that the responses of mice correlated almost perfectly with those of humans (Alarie et al., 1980; Alarie and Luo, 1986). Thus, this technique is useful for predicting the irritancy of airborne medicinal compounds in humans. From the drug-formulating point of view, an inhalant drug with

URT-irritating properties indicates the need for an alternate route of administration. From the industrial hygiene point of view, the recognition of the irritant properties is very important. If a chemical gas, vapor, or aerosol irritates, it has a "warning property." With an adequate warning property, a worker will avoid inhaling damaging amounts of the airborne toxicant; without a warning property, a worker may unknowingly inhale an injurious amount of the toxicant.

Inhalation of a cardiovascular drug, such as an aerosol of propranolol (a beta-adrenergic receptor agonist), may affect the respiratory cycle of a subject. For evaluating the cardiopulmonary effects of an inhalant, the plethysmographic technique using a mouse or a guinea pig model is useful. The criteria for a positive response in intact mice or guinea pigs are changes in the duration of inspiration and expiration and the interval between breaths (Schaper et al., 1989).

Pulmonary sensitization may occur from inhalation of drug vapors such as enflurane (Schwettmann and Casterline, 1976) and antibiotics such as spiramycin (Davies and Pepys, 1975) and tetracycline (Menon and Das, 1977). To detect pulmonary sensitization from inhalation of drug and chemical aerosols, the body plethysmographic technique using a guinea pig model has been shown to be useful (Patterson and Kelly, 1974; Paterson, 1998; Karol and Thorne, 1988; Karol 1995; Karol and Thorne, 1988; Karol et al., 1989; Thorne and Karol, 1989). The criteria for positive pulmonary sensitization in intact guinea pigs are changes in breathing frequency and their extent and the time of onset of an airway constrictive response after induction and after a challenge dose of the test drug (Karol et al., 1989).

The mucociliary transport system of the airways can be impaired by respiratory irritants, local analgesics and anesthetics, and parasympathetic stimulants (Pavia, 1984). Any one of the earlier agents will retard the beating frequency of the cilia and the secretion of the serous fluid of the mucous membranes. As a result, the propulsion of the inhaled particles, bacteria, or endogenous debris toward the oral pharynx for expectoration or swallowing will be retarded. Conversely, inhalation of adrenergic agonists increases the activity of the mucociliary transport system and facilitates the elimination of noxious material from the pulmonary system. Laboratory evaluation of the adverse drug effects on mucociliary transport in animal models can be achieved by measuring the velocity off the linear flow of mucus in the trachea of surgically prepared animals (Rylander, 1966; Oyarzun and Clements, 1977, 1978). Clinically, the transportation of markers placed on the tracheal epithelium of normal human subjects can also be observed using a fiber-optic bronchoscopic technique (Pavia et al., 1980; Mussatto et al., 1988). The criteria of a positive response are changes in the transport time over a given distance of markers placed on the mucus or changes in the rate of mucus secretion (Davis et al., 1976; Johnson et al., 1983, 1987; Webber and Widdicombe, 1987). More comprehensive discussion on

mucociliary clearance can be found in several reviews (Last, 1982; Pavia, 1984).

Cytological studies on the bronchoalveolar lavage fluid (BALF) permit the evaluation of the effects of an inhaled drug on the epithelial lining of the respiratory tract. This fluid can be obtained from intact animals or from excised lungs (Henderson, 1984, 2005, 2019). Quantitative analyses of fluid constituents such as neutrophils, antibody-forming lymphocytes, and antigen-specific IgG provide information on the cellular and biochemical responses of the lungs to the inhaled agent (Henderson, 1984; Henderson et al., 1985, 1987). For example, BALF parameters were found to be unperturbed by the inhalation of halothane (Henderson and Loery, 1983). The criteria of a positive response are increases in protein content, increase in the number of neutrophils and macrophages for inflammation, increase in the number of lymphocytes and alteration of lymphocyte profiles for immune response, increase in cytoplasmic enzymes (lactate dehydrogenase) for cell lysis (Henderson, 2019), and the presence of antigen-specific antibodies for specific immune responses (Bice, 2007).

Morphological examination of the cellular structure of the pulmonary system is the foundation of most inhalation toxicity studies. Inhalation of airborne drug vapors or aerosols at harmful concentrations results mainly in local histopathologic changes in the epithelial cells of the airways, of which there are two types: nonciliated and ciliated cells. The nonciliated cells are the Clara cells, which contain secretory granules and smooth endoplasmic reticulum (SER); cells that have secretory granules but lack SER; and the brush cells, which have stubby microvilli and numerous cytoplasmic fibers on their free surfaces. If the concentration gradient of the drug in the lung is high enough to reach the alveoli, type I alveoli cells will also be affected (Evans, 1982). Drugs that affect the lungs via the bloodstream, such as bleomycin (Aso et al., 1976), cause changes to the endothelial cells of the vascular system that result in diffuse damage to the alveoli. The criteria of cellular damage are loss of cilia, swelling, and necrosis and sloughing of cell debris into the airway lumina. Tissues recovering from injuries are characterized by increases in the number of dividing progenitor cells followed by increases in intermediate cells that eventually differentiate into normal surface epithelium.

Pulmonary drug disposition studies are essential in research and development of new inhalant drugs. Inhaled drugs are usually absorbed and metabolized to some extent in the lungs because the lungs, like the liver, contain active enzyme systems. A drug may be metabolized to an inactive compound for excretion or to a highly reactive toxic metabolite that causes pulmonary damage. In most pulmonary disposition studies, a gas or vapor is delivered via whole-body exposure (Paustenbach et al., 1983) or head-only exposure (Hafner et al., 1975). For aerosols, over 90% of a dose administered by mouth breathing is deposited in the oropharynx and swallowed. Consequently,

the disposition pattern reflects that of ingestion in combination with a small contribution from pulmonary metabolism. For determining the disposition of inhaled drugs by the pulmonary system alone, a dosimetric endotracheal nebulization technique (Leong et al., 1987, 1988) is useful. In this technique, microliter quantities of a radiolabeled drug solution can be nebulized within the trachea using a miniature air-liquid nebulizing nozzle. Alternatively, a small volume of liquid can be dispersed endotracheally using a microsyringe. In either technique, an accurate dose of a labeled drug solution is delivered entirely into the respiratory tract and lungs. Subsequent radioassay of the excreta thus reflects only the pulmonary disposition of the drug without complication from aerosols deposited in the oropharyngeal regions if the drug had been delivered by mouth inhalation. For example, in a study of the antiasthmatic drug lodoxamide tromethamine, the urinary metabolites produced by beagle dogs after receiving a dose of the radiolabeled drug via endotracheal nebulization showed a high percentage of the intact drug. However, metabolites produced after oral administration were mainly nonactive conjugates. The differences were due to the drug's escape from first-pass metabolism in the liver when it was administered through the pulmonary system. The results thus indicated that the drug had to be administered by inhalation to be effective. This crucial information was extremely important in the selection of the most effective route of administration and formulation of this antiasthmatic drug (Leong et al., 1988).

Cardiotoxicity of inhalant drugs should also be evaluated. For example, adverse cardiac effects may be induced by inhaling vapors of fluorocarbons, which are used extensively as propellants in drug aerosols. Inhalation of vapors of anesthetics also has been shown to cause depression of the heart rate and alteration of the rhythm and blood pressure (Merin, 1981; Leong and Rop, 1989). More important, inhalation of antiasthmatic aerosols of beta-receptor agonists delivered in a fluorocarbon propellant has been shown to cause marked tachycardia, electrocardiogram (ECG) changes, and sensitization of the heart to arrhythmia (Aviado, 1981; Balazs, 1981). Chronic inhalation of drug aerosols can also result in cardiomyopathy (Balazs, 1981). For detection of cardiotoxicity, standard methods of monitoring arterial pressures, heart rate, and ECGs of animals during inhalation of a drug, or at frequent intervals during a prolonged treatment period, should be useful in safety assessments of inhalant drugs.

Since the inhalation route is just a method for administering drugs, other nonpulmonary effects, such as behavioral effects (Ts'O et al., 1975) and renal and liver toxicity, should also be evaluated. In addition, attention should also be given to drugs that are not administered via the inhalation route, but that accumulate in the lungs where they cause pulmonary damage (Wilson, 1982; Hollinger, 1985).

22.8 PARAMETERS OF TOXICITY EVALUATION

Paracelsus stated over 400 years ago that "All substances are poison. The right dose differentiates a poison and a remedy." Thus, in safety assessments of inhaled drugs, the "dose," or magnitude of inhalation exposure, in relation to the physiological, biochemical, cytological, or morphological response(s), must be determined. Toxicity information is essential to establishing guidelines to prevent the health hazards of acute or chronic overdosage during therapy or of unintentional exposure to the bulk drugs and their formulated products during manufacturing and industrial handling.

22.8.1 The Inhaled "Dose"

Most drugs are designed for oral or parenteral administration in which the dose is calculated in terms of drug weight in milligrams (mg) divided by the body weight in kilograms (kg):

$$\text{Dose} = \frac{\text{drug weight (mg)}}{\text{body weight (kg)}} = \frac{\text{mg}}{\text{kg}}$$

For inhalant drugs, the inhaled "dose" has been expressed in many mathematical models (Dahl, 1990). However, the practical approach is based on exposure concentration and duration rather than on theoretic concepts. Thus, an inhaled "dose" is expressed in terms of the exposure concentration (C) in milligrams per liter (mg L^{-1}) or milligrams per cubic meter (mg m^{-3}) or parts per million (ppm) parts of air, the duration of exposure (t) in minutes, the ventilatory parameters including the respiratory rate (R) in number of breaths per minute and the tidal volume (T_v) in liters per breath, and a retention factor α (alpha), which is related to the reactivity and the solubility of the drug. The product of these parameters divided by the body weight in kilograms gives the dose:

$$\text{Dose} = \frac{CtRTv\alpha}{\text{body weight}} = \frac{\text{mg}}{\text{kg}}$$

In critical evaluation of the effect of a gas, vapor, or aerosol inhaled into the respiratory tract of an animal, the dosimetric method has been recommended (Oberst, 1961). However, due to the complexity of measuring the various parameters simultaneously, only a few studies on gaseous drugs or chemicals have employed the dosimetric method (Weston and Karel, 1946; Carpenter et al., 1949; Leong and MacFarland, 1965; Landy et al., 1983; Stott and McKenna, 1984; Dallas et al., 1986, 1989). For studies on liquid or powdery aerosols, modified techniques such as intratracheal instillation (Brain et al., 1976) or endotracheal nebulization (Leong et al., 1988) were used to deliver an exact dose of the test

material into the LRT, while bypassing the URT and ignoring the ventilatory parameters.

In routine inhalation studies, it is generally accepted that the respiratory parameters are relatively constant when the animals are similar in age, sex, and body weight. This leaves only *C* and *t* to be the major variables for dose consideration:

$$\text{"Dose"} = Ct = \text{mg min L}^{-1}$$

The product *Ct* is not a true dose because its unit is milligrams per minute per liter rather than milligrams per kilogram. Nevertheless, *Ct* can be manipulated as though it were a dose, an approximated dose (MacFarland, 1976).

The respiratory parameters of an animal will dictate the volume of air inhaled and hence the quantity of test material entering the respiratory system. Commonly used parameters for a number of experimental species and man are given in Table 22.1 to illustrate this point and include the AL surface area because this represents the target tissue for most inhaled materials. It can be seen that by taking the ratios of these parameters and comparing the two extremes, that is, the mouse and man, (i) a mouse inhales approximately 30 times its lung volume in 1 min, whereas a human at rest inhales approximately the same volume as that of his or her lung. This can increase with heavy work up to the same ratio as the mouse but is not sustained for long periods. This means that the dose per unit lung volume is up to 30 times higher in the mouse than man at the same inhaled atmospheric concentration. (ii) The minute volume of the mouse is in contact with five times less AL surface area than man; hence, the dose per unit area is up to five times greater in the mouse. (iii) The lung volume in comparison with the AL surface area in experimental animals is less than in humans, meaning that the extent of contact of inhaled gases with the AL surface is greater in experimental animals.

While it is possible, and common, to refer to standard respiratory parameters for different species in order to calculate inhaled dose and deposited dose with time, it is usually the case that inhaled materials influence the breathing patterns of test animals. The most common examples of this are irritant vapors, which can reduce the respiratory rate by up to 80%.

This phenomenon results from a reflexive pause during the breathing cycle due to stimulation by the inhaled material of the trigeminal nerve endings situated in the nasal passages. The duration of the pause and hence the reduction in the respiratory rate are concentration related, permitting concentration–response relationships to be plotted. This has been investigated extensively by Alarie (1981a) and forms the basis of a test screen for comparing quantitatively the irritancy of different materials and has found application in assessing appropriate exposure limits for human exposure when respiratory irritancy is the predominant cause for concern.

While irritancy resulting from the earlier reflex reaction is one cause of altered respiratory parameters during exposure, there are many others. These include other types of reflex response, such as bronchoconstriction, the narcotic effects of many solvents, the development of toxic signs as exposure progresses, or simply a voluntary reduction in respiratory rate by the test animal due to the unpleasant nature of the inhaled atmosphere. The extent to which these affect breathing patterns, and hence inhaled dose can only be assessed by actual measurement.

By simultaneous monitoring of tidal volume and respiratory rate, or minute volume, and the concentration of an inhaled vapor in the bloodstream and the vapor in the exposure atmosphere, pharmacokinetic studies on the *Ct* relationship have shown that the effective dose was nearly proportional to the exposure concentration for vapors such as 1,1,1-trichloroethane (Dallas et al., 1989), which has a saturable metabolism, and found that the steady-state plasma concentrations were disproportionately greater at higher exposure concentrations.

Acknowledging the possible existence of deviations, this simplified approach of using *C* and *t* for dose determination provides the basis for dose–response assessments in practically all inhalation toxicological studies.

22.8.2 The Dose–Response Relationship

The first principle of dose–response determination in inhalation toxicology is based on Haber’s rule, which states that

TABLE 22.1 Respiratory Parameters for Common Experimental Species and Man

Species	Body Weight (kg)	Lung Volume (mL)	Minute Volume (mL min ⁻¹)	Alveolar Surface Area (m ²)	Lung Volume % Surface Area	Minute Volume % Lung Volume	Minute Volume % Surface Area
Mouse	0.023	0.74	24	0.068	10.9	32.4	353
Rat	0.14	6.3	84	0.39	16.2	13.3	215
Monkey	3.7	184	694	13	14.2	3.77	53
Dog	22.8	1501	2923	90	16.7	1.95	33
Human	75	7000	6000	82	85.4	0.86	73

responses to an inhaled toxicant will be the same under conditions, where C varies in complementary manner to t (Haber, 1924), for example, if Ct elicits a specific magnitude of the same response, that is, $Ct = K$, where K is a constant for the stated magnitude of response.

This rule holds reasonably well when C or t varies within a narrow range for acute exposure to a gaseous compound (Rinehart and Hatch, 1964) and for chronic exposure to an inert particle (Henderson et al., 1991). Excursion of C or t beyond these limits will cause the assumption $Ct = K$ to be incorrect (Adams et al., 1950, 1952; Sidorenko and Pinigin, 1976; Andersen et al., 1979; Uemitsu et al., 1985). For example, an animal may be exposed to 1000 ppm of diethyl ether for 420 min or 1400 ppm for 300 min without incurring any anesthesia. However, exposure to 420 000 ppm for 1 min will surely cause anesthesia or even death of the animal. Furthermore, toxicokinetic study of liver enzymes affected by inhalation of carbon tetrachloride (Uemitsu et al., 1985), which has a saturable metabolism in rats, showed that $Ct = K$ does not correctly reflect the “toxicity value” of this compound. Therefore, the limitations of Haber’s rule must be recognized when it is used in interpolation or extrapolation of inhalation toxicity data.

22.8.3 Exposure Concentration Versus Response

In certain medical situations (e.g., a patient’s variable exposure duration to a surgical concentration of an inhalant anesthetic or the repeated exposures of surgeons and nurses to subanesthetic concentrations of an anesthetic in the operating theater), it is necessary to know the duration of safe exposure to a drug. Duration safety can be assessed by determining a drug’s median effective time (ET_{50}) or median lethal time (LT_{50}). These statistically derived quantities represent the duration of exposure required to affect or kill 50% of a group of animals exposed to a specified concentration of an airborne drug or chemical in the atmosphere.

The graph in Figure 22.2 is the probit plot of cumulative percentage response to logarithm of exposure duration. It shows 1000 mg m^{-3} for 10 h or 10 mg m^{-3} for 1000 h, each with a Ct (an approximated dose) of $\sim 10000 \text{ h mg m}^{-3}$. Similar to concentration–response graphs, the slopes indicate the differences in the mechanism of action and the margins of safe exposure of the three drugs. The ratio of ET_{50} over LT_{50} of two drugs indicates their relative toxicity, and the ratio of ET_{50} over LT_{50} of the same drug is the therapeutic ratio.

22.8.4 Product of Concentration and Duration (Ct) Versus Responses

To evaluate inhalation toxicity in situations where workers are exposed to various concentrations and durations of a drug vapor, aerosol, or powder in the work environment during manufacturing or packaging, a more comprehensive

FIGURE 22.2 Dose–response plot in terms of probit of cumulative percentage response to logarithm of exposure duration. A, B, and C indicate three exemplary curves.

determination of $E(Ct)_{50}$ or $L(Ct)_{50}$ values is used. The $E(Ct)_{50}$ or $L(Ct)_{50}$ values are statistically derived values that represent the magnitude of exposure, expressed as a function of the product of C and t , that is expected to affect or kill less than 50% and greater than 50% of the animals. The other curve represents exposures that kill 50% or greater than 50% of each group of animals (Irish and Adams, 1940).

The graph in Figure 22.3 illustrates inhalation exposures to a drug using various combinations of C and t that kill 50% of the animals. For example, a 50% mortality occurs when a

FIGURE 22.3 Dose–response plot in terms of logarithms of exposure concentration and durations. A and B indicate nonspecific example compounds A and B.

group of animals is exposed to drug A at a concentration of 1000mg m^{-3} for a duration of approximately 2h or at a concentration of 100mg m^{-3} for a duration of approximately 20h. Furthermore, the graph also illustrates that the inhalation toxicity of drug A is more than 1 order of magnitude higher than that of drug B. For example, an exposure to drug A at the concentration of 100mg m^{-3} for 100h kills 100% of the animals, whereas an exposure to drug B at the concentration of 1000mg m^{-3} for 100h does not kill any animals.

22.8.5 Units for Exposure Concentration

For gases and vapors, exposure concentrations are traditionally expressed in ppm. The calculation for the ppm of a gas or an vapor in an air sample is based on Avogadro's law, which states that "Equal volumes contain equal numbers of molecules under the same temperature and pressure." In other words, under standard temperature and pressure (STP), 1 g-molecular weight (mole) of any gas under a pressure of 1 atm (equivalent to the height of 760mm mercury) and a temperature of 273 K has the same number of molecules and occupies the same volume of 22.4L. However, under ambient conditions, the volume of 22.4L has to be corrected to a larger volume based on Charles' law, which states that at constant pressure the volume of gas varies directly with the absolute temperature. Thus, at a room temperature of 25°C , 1 mol of a gas occupies a volume of 24.5L:

$$22.4\text{L} \times \frac{298\text{K}}{273\text{K}} = 24.5\text{L}$$

Further correction of volume for an atmospheric pressure deviation from 1 atm may be done by applying Boyle's law, which states that the volume of a gas without change of temperature varies inversely with the pressure applied to it:

$$24.5\text{L} \times \frac{758\text{mmHg}}{760\text{mmHg}} = 24.4\text{L}$$

In practice, atmospheric pressure in most animal experimental environments usually varies only a few mmHg, so little or no correction is required.

Using the aforementioned principles, the volume of a vapor generated from a given weight of a liquid can be calculated. For example, 1 mol of water weighs 18g, while 1 mol of ethanol weighs 46g. When 1 mol of each liquid is totally vaporized, each will occupy the same volume of 24.5L at room temperature (25°C) and pressure (760mmHg). In an inhalation experiment, if the volume of test liquid and the rate of airflow being mixed in the animal exposure chamber are known, the vapor concentration in the chamber atmosphere can be calculated in ppm or milligrams per liter. A conversion table published by the US Bureau of Mines enables quick

conversion between ppm and milligrams per liter for compounds with molecular weights up to 300g (Fieldner et al., 1921; Patty, 1958).

For aerosols of nonvolatile liquid and powdery compounds, the concentration of the mist or dust atmosphere must be expressed in terms of milligrams per liter or milligrams per cubic meter (mg m^{-3}) of air. With advances in biotechnology, many pharmacological testing techniques are based on specific receptor bindings, in which the ratio of the number of molecules to those of the receptors is considered, in which case the exposure concentration may be more appropriately expressed in micromoles per unit volume of air ($\mu\text{mol m}^{-3}$).

22.9 INHALATION EXPOSURE TECHNIQUES

Many inhalation exposure techniques—such as the whole-body, nose-only, mouth-only, or head-only technique (Drew and Laskin, 1973; MacFarland, 1976; Leong et al., 1981; Smith et al., 1981; Phalen, 2009), the intranasal exposure technique (Elliott and DeYoung, 1970), the endotracheal nebulization technique (Leong et al., 1985, 1988; Schreck et al., 1986), and the body plethysmographic technique (Alarie, 1966; Thorne and Karol, 1989)—have been developed for inhalation toxicity studies. Table 22.2 provides a summary of the advantages and disadvantages of each of the major inhalation exposure methodologies.

The main criteria for the design and operation of any dynamic (as opposed to static) inhalation exposure system are the following:

- The concentration of the test atmosphere must be reasonably uniform throughout the chamber and should increase and decrease at a rate close to theoretical at the start or end of the exposure. Silver (1946) showed that the time taken for a chamber to reach a point of equilibrium was proportional to the flow rate of atmosphere passing through the chamber and the chamber volume. From this, the concentration–time relationship during the “run-up” and “run-down” phase could be expressed by the equation:

$$t_x = k \frac{V}{F}$$

where t_x = time required to reach $x\%$ of the equilibrium concentration, k = a constant of value determined by the value of x , V = chamber volume, and F = chamber flow rate. The t_{99} value is frequently quoted for exposure chambers, representing the time required to reach 99% of the equilibrium concentration and providing an estimate of chamber efficiency. Thus, at maximum efficiency, the theoretical value of k at t_{99} is 4.605, and the closer to this that the

TABLE 22.2 Advantages, Disadvantages, and Considerations Associated with Patterns of Inhalation Exposure

Mode of Exposure	Advantages	Disadvantages	Design Considerations
Whole body	Variety and number of animals	Messy	Cleaning effluent air
	Chronic studies possible	Multiple routes of exposure: skin, eyes, oral	Inert materials
	Minimum restraint	Variability of “dose”	Losses of test material
	Large historical database	Cannot pulse exposure easily	Even distribution in space
Whole body	Controllable environment	Poor contact between animals and investigators	Sampling
	Minimum stress	Capital-intensive	Animal care
	Minimum labor	Inefficient compound usage	Observation
		Difficult to monitor animals during exposure	Noise, vibration, humidity
Head only	Good for repeated exposure	Stress to animal	Air temperature
	Limited routes of entry into animal	Losses can be large	Safe exhaust
	More efficient dose delivery	Seal around neck	Loading
		Labor in loading/unloading	Reliability
Nose/mouth only	Exposure limited to mouth and respiratory tract	Stress to animal	Even distribution
	Uses less material (efficient)	Seal about face	Pressure fluctuations
	Containment of material	Effort to expose a large number of animals	Sampling and losses
			Air temperature, humidity
Lung only (tracheal administration)	Can pulse the exposure		Animal comfort
	Precision of dose	Technically difficult	Animal restraint
	One route of exposure	Anesthesia or tracheostomy	Pressure fluctuations
	Uses less material (efficient)	Limited to small numbers	Body temperature
Lung only (tracheal administration)	Can pulse the exposure	Bypasses nose	Sampling
		Artifacts in deposition and response	Air locking
		Technically more difficult	Animals’ comfort
		Anesthesia	Losses in plumbing/masks
Partial lung	Localization of dose	Placement of dose	Air humidity/temperature
	Can achieve very high local doses	Difficulty in interpretation of results	Stress to the animal
		Technically difficult	Physiologic support
	Unexposed control tissue from same animal	Possible redistribution of material within lung

results of evaluation of actual chamber performance fall, the greater the efficiency and the better the design of the chamber.

- Flow rates must be controlled in such a way that they are not excessive, which might cause streaming effects within the chamber, but must be adequate to maintain normal oxygen levels, temperature, and humidity in

relation to the number of animals being exposed. A minimum of 10 air changes per hour is frequently advocated and is appropriate in most cases. However, the chamber design and housing density also need to be taken into account, and some designs, such as that of Doe and Tinston (1981), function effectively at lower air change rates.

- The chamber or exposure manifold materials should not affect the chemical or physical nature of the test atmosphere.

The whole-body exposure technique is useful for acute and chronic toxicity studies of gases and vapors. For acute whole-body exposure, a few animals are exposed for 1–4 h to a gas, vapor, or aerosol of a drug or chemical in a simple glass jar. The gaseous drug is metered with a precision flow meter into the stream of filtered room air being drawn through the glass jar or chamber. For vapor generation from a volatile liquid, a stream of clean air is bubbled at a constant rate onto the walls of a temperature-regulated flask, which vaporizes the liquid droplets rapidly and continuously. In either method, the vapor emerging from the vaporizer is directed into the filtered airstream being drawn through the glass jar or chamber. For the generation of drug aerosols from liquids or powders, various types of atomizers or nebulizers and dust generators are available (Drew and Laskin, 1973; Drew and Lippmann, 1995; Leong et al., 1981; Phalen, 2009). For more critical and precision studies, an adequate number of animals per group are calculated by an appropriate statistical method (Gad, 2000), and the exposure is carried out in an elaborate dynamic air-flow chamber with precision control of the chamber airflow, temperature, and humidity.

Regardless of the exposure apparatus used, the most important aspect of an exposure study is that the generation of a constant concentration of the airborne drug vapor or aerosol in the chamber atmosphere has to be sampled (Drew and Lippmann, 1995) and analyzed using an appropriate analytical instrument, such as an infrared spectrophotometer for halogenated propellants or a gas chromatograph for other gases and vapors. The concentration of the drug as detected by the analyzer is the “analytical concentration.” For characterizing the aerosol atmosphere, particle sizing, in addition to concentration analyses, is essential. Because the breathing patterns of the experimental animals cannot be regulated, it is extremely important to generate aerosols of the appropriate size for bioavailability.

For critical laboratory studies on inhaled drugs, a mono-disperse aerosol of a specified range of MMAD should be used to increase the probability that the aerosol reaches the specified target area of the lungs. The Dautrebande aerosol generators (Dautrebande, 1962c) and the DeVilbiss nebulizer (Drew and Lippmann, 1995) are the classic single-reservoir generators for short-duration inhalation studies. For long-duration inhalation studies, the multiple-reservoir nebulizer (Miller et al., 1981) and the continuous syringe metering and elutriating atomizer (Leong et al., 1981) are frequently used. The nebulizers generate a polydisperse droplet aerosol either by the shearing force of a jet of air over a fine stream of liquid or by ultrasonic disintegration of the surface liquid in a reservoir (Drew and Lippmann, 1995). The aerosols emerging

from a jet nebulizer generally have MMADs ranging between 1.2 and 6.9 μm with GSDs of 1.7–2.2, and aerosols from an ultrasonic nebulizer have MMADs ranging between 3.7 and 18.5 μm with GSDs of 1.4–2.0 (Mercer, 1981).

For testing therapeutic formulations, the liquid aerosols are usually generated by the pressurized metered-dose inhaler (MDI) (Newman, 1984; Gad and Chengelis, 1998; Newton, 2000; Gad, 2006). The pressurized MDI generates a bolus of aerosols by atomizing a well-defined quantity of a drug that is solubilized in a fluorocarbon propellant. The aerosols, thus, consist of the drug particles with a coating of the propellant. As the aerosols emerge from the orifice, the mean particle size may be as large as 30 μm (Moren, 1981). After traveling through a tubular or cone-shaped spacer, the propellant may evaporate, reducing the MMADs to a range of 2.8–5.5 μm with GSDs of 1.5–2.2 (Hiller et al., 1978; Sackner et al., 1981; Newman, 1984) and making the aerosols more stable for inhalation studies. In a prolonged animal exposure study, multiple MDIs have to be actuated sequentially with an electromechanical gadget (Ulrich et al., 1984) to maintain a slightly pulsatile but relatively consistent chamber concentration.

For generating an aerosol from dry powders, various dust generators, such as the Wright dust feed, air elutriator or fluidized-bed dust generator, and air impact pulverizer, have been developed for acute and chronic animal inhalation studies and described in many articles (Hinds, 1980; Leong et al., 1981; Gad and Chengelis, 1998; Hext, 2009; Phalen, 2009; Brown et al., 2014). For generating powdery therapeutic agents, a metered-dose dry powder inhaler, Spinhaler or Rotahaler, is used (Newman, 1984). The particle size of the drug powder is micronized to a specific size range during manufacture, and the Spinhaler or the Rotahaler only disperses the powders.

More recently, another approach for administering dry powders to both humans and test animals has arisen. Dry powders, while less frequently used in nasal drug delivery, are becoming more popular. Powders can be administered from several devices, the most common being the insufflator. Many insufflators work with predosed powder in gelatin capsules. To improve patient compliance, a multidose powder inhaler has been developed which has been used to deliver budesonide. These devices can also be used for administration to test animal delivery, both in terms of amounts and aerodynamic size of the particles. While early dry powder inhalers such as the Rotahaler[®] used individual capsules of micronized drug which was difficult to handle, modern devices use blister packs (e.g., Diskus[®]) or reservoirs (e.g., Turbuhaler[®]). The dry powder inhalers rely on inspiration to withdraw drug from the inhaler to the lung, and hence the effect of inhalation flow rate through various devices has been extensively studied. The major problem to be overcome with these devices is to ensure that the finely micronized drug is thoroughly dispersed in the airstream. It has been recommended that patients inhale as

rapidly as possible from these devices in order to provide the maximum force to disperse the powder. The quantity of drug and deposition pattern varies enormously depending on the device, for example, the Turbuhaler produces significantly greater lung delivery of salbutamol than the Diskus. Vidgren et al. (1987) demonstrated by gamma scintigraphy that a typical dry powder formulation of SCG suffers losses of 44% in the mouth and 40% in the actuator nozzle itself.

It must also be emphasized that the major mass of a hetero-dispersed aerosol may be contained in a few relatively large particles, since the mass of a particle is proportional to the cube of its diameter. Therefore, the particle-size distribution and the concentration of the drug particles in the exposure atmosphere should be sampled using a cascade impactor or membrane filter sampling technique, monitored using an optical or a laser particle-size analyzer, and analyzed using optical or electron microscopy techniques.

In summary, many techniques have been developed for generating gas, vapor, and aerosol atmospheres for inhalation toxicology studies. By proper regulation of the operating conditions of the nebulizers and the formulation of MDIs, together with the use of spacer or reservoir attachments to MDIs, more particles within the respirable range can be generated for inhalation. An accurately controlled exposure concentration is essential to an accurate determination of the dose–response relationship in a safety assessment of an inhalant drug.

Finally, comparisons of various techniques for animal exposures indicate that the whole-body exposure technique is the most suitable for safety assessment of gases and vapors and permits simultaneous exposure of a large number of animals to the same concentration of a drug; however, this technique is not suitable for aerosol and powder exposures because the exposure condition represents the resultant effects from inhalation, ingestion, and dermal absorption of the drug (Gad and Chengelis, 1998; Phalen, 2009).

22.10 THE UTILITY OF TOXICITY DATA

Regardless of the type of test and the parameters to be monitored, the ultimate goal is to interpolate or extrapolate from the dose–response data to find a no-observable-adverse-effect level (NOAEL) or a no-observable-effect level (NOEL). By applying a safety factor of 1–10 to the NOAEL, a safe single-exposure dose for a phase I clinical trial may be obtained. By applying a more stringent safety factor, a multiple-exposure dose for a clinical trial may also be obtained. After the drug candidate has successfully passed all the drug safety evaluations and entered in the production stage, more toxicity tests may be needed for the establishment of a threshold limit value–time-weighted average (TLV–TWA). A TLV–TWA is defined as “the time weighted average concentration for a normal 8-h workday and a 40-h

workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect” (ACGIH, 2020). Using TLVs as guides, long-term safe occupational exposures during production and industrial handling of a drug may be achieved. Appropriate safety assessments of pharmaceutical chemicals and drugs will ensure the creation and production of a safe drug for the benefit of humans and animals. Further, inhalation toxicity data are needed for compliance with many regulatory requirements of the FDA, the Occupational Safety and Health Administration, and the Environmental Protection Agency (Gad and Chengelis, 1998).

22.11 FORMULATION AND POTENTIAL MUCOSAL DAMAGE

- Improved absorption involves interactions with the mucosal membrane.
- Proposed enhancement mechanisms are:
 - Extraction of membrane components
 - Penetration and fluidization of membrane
 - Loosening of tight junctions
 - Perturbation of nasal mucociliary clearance system
 - Simultaneous transport of environmental toxins
- Adverse effects have to be of short duration, mild, and rapidly reversible.
- Kinetics of lipid and protein extraction from the membrane are measures of the extent of damage evaluated by the measuring activity of membrane marker enzymes:
 - Lactate dehydrogenase: cytosolic enzyme, related to intracellular damage
 - 5'-Nucleotidase: membrane-bound enzyme, indicator of membrane perturbations
 - Alkaline phosphatase: membrane-bound enzyme, related to membrane damage
- Ideal characteristics of absorption enhancers include the following:
 - Pharmacological inertness
 - Nonirritant, nontoxic, and nonallergenic
 - Effect on nasal mucosa that should be transient and completely reversible
 - Potent in low concentrations
 - Compatible with other adjuvants
 - Has no offensive odor or taste
 - Inexpensive and readily available
- The factors influencing mucosal damage include the following:
 - Drug administration
 - Dose

- Frequency
- Interspecies difference
- Sensitivity toward absorption enhancers

22.11.1 Methods to Assess Irritancy and Damage

- Erythrocytes
 - Used to study the membrane activity of absorption enhancers
- Histology
 - Histological studies of nasal membranes
- Intracellular protein release
 - Index of cellular damage due to exposure to absorption enhancers
- Tolerability
 - These are subjective (double-masked) studies in which individuals report any effects due to the use of enhancers in the formulation.
- Cilia A function
 - Cilia beat frequency is obtained from tissue samples at sacrifice using video capture systems.
 - Tissues used for ciliary function studies include chicken embryo trachea, cryopreserved human mucosa taken from sphenoidal sinus, rat nasal mucosa, and recently human nasal epithelial cells.

More comprehensive descriptions and discussions on inhalation toxicology and technology may be found in several recent monographs, reviews, and textbooks (Willeke, 1980; Leong et al., 1981; Witschi and Nettekheim, 1982; Clarke and Pavia, 1984; Witschi and Brain, 1985; Barrow, 1986; McFadden, 1986; Leikauf, 2013; Salem, 1986; Gardner, 2006; Henderson, 2019; Gad and Chengelis, 1998; Hext, 2009; Brown et al., 2014; Gardner, 2006; Phalen, 2009; Salem and Katz, 2015).

US FDA regulation of new inhalation drug products is by the Division of Pulmonary, Allergy, and Rheumatology Products (DPARP). Like its counterpart for dermal route drugs (Dermal and Dental Products [DDP]), actual general/systemic toxicity testing must be performed using the drug in the intended clinical formulation to actually be given to man (FDA, 2002, 2008).

22.12 THERAPEUTIC DRUG DELIVERY BY THE DERMAL ROUTE

The dermal route has both some significant attractions and some significant drawbacks for use in drug administration. The ability to utilize the former and avoid (at least the relevance of) the latter is the key to successful development of new drugs administered by this route.

On the advantage side, dermal administration:

- Avoids first-pass metabolism
- Avoids acidic environment of the stomach
- Can be designed to deliver controlled amounts of drug over a prolonged period outside of a clinical setting
- Can be designed to achieve desired local tissue exposure to the therapeutic area while avoiding (or minimizing) systemic exposure

On the disadvantage side, dermal administration historically:

- Cannot be used for systemic delivery of large molecules (usually with molecular weights in excess of 1000)
- Achieves a lower systemic bioavailability than oral routes
- Uses formulation components which may irritate or damage the application site (Wilhelm, 2012) and are perceived as “messy” or aesthetically undesirable

New approaches to formulation or delivery systems (see Touitou and Barry, 2011) have overcome (or minimized) a number of the disadvantages and continue to evolve. For FDA, the division reviewing proposed new dermal products (DDP) requires that even systemic (general toxicology) studies be performed using intensely clinical formulation product, which presents a challenge to toxicologists. In addition to the traditional gels, lotions, and creams (for which new chemical permeation enhancers and vesicular carriers such as liposomes have and are being added), new technology such as iontophoresis, electrophoresis, and ultrasound is also evolving. Additionally, in some cases, the barrier layer in the skin (stratum corneum) can be bypassed (using such approaches as microneedles) or removed by tape stripping, laser, adhesion, and ballistic methods (such as those used for mass vaccine administration in the military).

Bioavailability is typically defined as the rate and extent at which a drug reaches the general circulation from an administered dosage form. Dermatological drug products include preparations which are designed to exert a local effect in diseased skin following topical application on the skin surface. The objective is to maximize drug concentration at the site of action within the skin with, ideally, a minimal systemic uptake. Thus, systemic availability may not properly reflect local cutaneous bioavailability (as it does for transdermal products which are designed to deliver drug into the systemic circulation). Moreover, topical doses tend to be so small (typically 2–5 mg of product per square centimeter) that serum and/or urine concentrations are often undetectable using conventional assay techniques. Further, complicating this is the lack of knowledge of the drug concentration needed at the skin target site (with the exception of antifungal and antibacterial agents whose target site is the subcutaneous [SC] surface). Topical bioavailability has been more properly defined as the temporal pattern of free drug, but this approach remains

largely theoretical due to the difficulty of quantifying drug within the skin. deHeer et al. (1999) present clear guidance on estimating dermal absorption of products.

Available options include estimating a drug’s permeability coefficient through human skin from the molecular weight and octanol–water partition coefficient. This information is not really sufficient to estimate topical bioavailability. The algorithms available are only able to approximate values for drug bioavailability (deHeer et al., 1999).

Alternatives include collecting samples by tape stripping or biopsy and then measuring the actual drug (and metabolites) present in the tissue samples. There are numerous complications to this and approaches to solving them (see Herkenne et al., 2008).

There are no direct guidance documents focused on non-clinical safety assessment for topical route drugs or on what

must be done before taking such a drug into clinical trials. Rather, the FDA regulatory expectations come from ICH/M4, the 2008 CDER reformulation document (CDER, 2008), and current practice (Jacobs and Loan, 2012). The results are summarized in Table 22.3. Regulatory preference as to a model for dermal systemic toxicology is solidly the minipig (McAnulty et al., 2012), though the rabbit and guinea pig still see use.

The CDER (2008) document presents that route-specific expectations for dermal include the following:

- Delayed hypersensitivity of any previously not evaluated topical drug or new formulation. In the United States, this means performing the local lymph node assay (LLNA), guinea pig maximization test (GPMT), or Buehler sensitization tests. As the Buehler is not accepted in Europe, use of one of the other two (see the

TABLE 22.3 Test Requirement Matrix for Topical Agents

Test Requirement	Species
<i>Initial clinical trial/IND requirements</i>	
1. Seven-day DRF toxicity two phase (single-dose MTD and non-GLP pilot in rodents)	R/M
2. Seven-day DRF toxicity two phase (single-dose MTD and non-GLP pilot in nonrodents)	D/S/P
3. Genotoxicity: bacterial mutagenicity (Ames) ^a	<i>In vitro</i>
4. Genotoxicity: <i>in vitro</i> clastogenicity (CHO chromosome aberration) (note that the ICH S2 guidance option 2 allows the use of alternative studies) ^a	<i>In vitro</i>
5. Genotoxicity: <i>in vivo</i> (mouse or rat micronucleus) ^a	R/M
6. Safety pharmacology: CV-hERG (recommended but not required) ^b	<i>In vitro</i>
7. Safety pharmacology: CV <i>in vivo</i> ^a	D/P/S
8. Safety pharmacology: FOB/Irwin ^a	R/M
9. Safety pharmacology: respiratory—rodent ^a	R
10. Pivotal/repeat dose in rodents (14–28-day intended route ^c)	R/M
11. Pivotal/repeat dose in nonrodents (14–28-day intended route ^c)	D/P/S
12. CYP induction/inhibition ^b	<i>In vitro</i>
13. Five-species microsomal metabolic panel ^b	<i>In vitro</i>
14. Develop bioanalytical for three species (man/rodent/nonrodent)	NA
15. Local irritation ^c (clinical formulation)	R
16. Of dermal—sensitization	G
<i>To support continued clinical development</i>	
17. Developmental toxicology (seg II)—rat and rabbit pilots and rat and rabbit studies	
18. Immunotoxicity ^c (if immune modulatory claim or there are findings in 14/28 dog studies)	
19. Pivotal/repeat dose in rodents (3/6-month oral)	
20. Pivotal/repeat dose in nonrodents (3/9–12-month oral)	
<i>To support marketing approval</i>	
21. Reproductive toxicity—seg I	
22. Reproductive toxicity—seg III	
23. Tumorigenicity/carcinogenicity—rat	
24. Tumorigenicity/carcinogenicity—mouse	

All studies described in the preceding text must be performed GLP.

Note: Species: R = rat, M = mouse, D = dog, S = pig, P = primate, B = rabbit, G = guinea pig, TBD = to be determined.

^aMay be required.

^bRecommended.

^cDermal/ophthalmic/vaginal/rectal.

chapter on immunotoxicology for details on these and their limitations) should be used.

- Photoirritation should be evaluated if the new formulation absorbs ultraviolet or visible radiation (290–700nm) and if the product is applied to sun-exposed skin. If the new formulation is a patch, then photoirritation should be considered if the patch is permeable to light and is applied to sun-exposed skin (see details in local tissue tolerance). A screen using 3T3 cells is acceptable in place of the traditional rabbit study for evaluation prior to investigational new drug (IND).
- If the new formulation contains an active ingredient that has not been used by the dermal route, the repeat-dose local toxicity study mentioned earlier should be conducted in a nonrodent species (preferably the minipig). This study should be of at least the same duration as clinical use (up to 9 months) and include both local and systemic evaluation. For new chemical entities (NCEs), repeat-dose studies in both rodents and nonrodents (preferably the pig) are required. In one of these (typically the rodent), it should be ensured that sufficient systemic exposure of the NCE is achieved usually by conducting such a study by the oral or a parenteral route.
- The administered skin dose from topically applied drug products can be orders of magnitude larger than the skin dose after systemic administration. Therefore, a dermal carcinogenicity study might be recommended for drugs with a chronic indication even if systemic carcinogenicity studies are available.
- The photocarcinogenic potential should be evaluated if the new formulation is used chronically on sun-exposed skin. Evaluation of photocarcinogenicity generally is not recommended for path products (see guidance for industry *photosafety testing*).
- Nonclinical dermal studies generally should be conducted with untreated control, vehicle control, and complete formulation groups.

A key point is if significant systemic exposure is or is not achieved. If it is not, then genotoxicity and safety pharmacology testing is not required. Such testing is required if it cannot be shown that systemic absorption is minimal or not detectable.

For the repeat-dose systemic toxicity studies, added to the usual details of study design is the need to evaluate local tissue effects of application sites and to collect tissue and histopathologically evaluate such sites.

As a last point, it should be added that topical administration is not limited to the dermal route. It also includes the body surfaces (vaginal and rectal) for which evaluation of irritation and hypersensitivity is required and for which systemic toxicology repeat-dose studies are performed by administration to

these sites (but there is no phototoxicity concern) and ocular for which it is expected that

- The dermal irritation and delayed contact hypersensitivity potential of the new formulation should be evaluated (because dermal exposure will occur with such drugs).
- The local tissue (eye) irritation must be evaluated.

SPECIAL CASE PRODUCTS: IMAGING AGENTS

23.1 INTRODUCTION

Special cases in the assessment of nonclinical safety arise from a variety of situations or for a number of reasons. We have already explored the major cases that arise as a result of different routes of administration (such as inhalation and topical routes with their variations). These are the most common variations from the general cases of oral and parenteral administration of drugs.

Likewise, the major case associated with different physical forms (small molecules, being the general case, the major variation being biotechnology-sourced materials) has also been discussed.

In this chapter, the first of the special cases which arise from the nature of the therapeutic use of these therapeutics are considered. These are imaging agents (a subset of *in vivo* diagnostic agents), with the second (being oncology drugs) being addressed in Chapter 24.

23.2 IMAGING AGENTS

Medical imaging agents used for the diagnosis or monitoring serve a variety of different modes of activity such as radiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), echo cardiology, and radionuclide imaging (Weissleder et al., 2010; Szabo, 2013; Wang et al., 2015). These imaging agents can be classified into at least two general categories contrast agents and diagnostic radiopharmaceuticals (Van Brocklin, 2008). Treated as drugs and regulated by either Center for Drug Evaluation and Research (CDER) (if small molecules) or Center for Biologics Evaluation and Research (CBER) (if biological immunochemistry-based entities) as the mechanisms of

therapeutic use (action) do not involve chemically or metabolically altering or interacting with the body, and thus would seem to be devices rather than drugs, but regulation by the drug centers has developed for historical reasons.

Historically, imaging agents (and the subset of radiopharmaceuticals) start as a real exception to the general case in that they do not require an Investigational New Drug (IND) before an initial clinical evaluation. Rather, under the Radioactive Drug Research Committee (RDRC—a special type of Institutional Review Board [IRB]) process as specified in Code of Federal Regulations (CFR) 21:36.1, single-dose studies may be conducted in one of a few academic medical centers with only RDRC review and with use limited to in a small number of individuals (up to 30) (CDER, 2000). A number of cardiovascular event-related deaths associated with imaging agent use (Health Imaging News, 2008) have led to greater scrutiny of the safety of the agents.

The RDRC is an institutional body that reviews research protocols for scientific and technical merit. An overview of the RDRC program from 1975 to 2004 has been recently reported (Van Brocklin, 2008). As of 2017, there were 205 RDRCs in the United States, 174 of them active.

In order to be generally regarded as safe (GRAS), a radiopharmaceutical is limited in terms of pharmacological and (if applicable) radiation dose. The mass associated with the radiopharmaceutical must “be known not to cause any clinically detectable pharmacological effect in human beings.” As a result of this limitation, first in human (FIH) studies must be limited to “microdosing” under an RDRC protocol. Typically, RDRCs require published human studies involving the tracer to be evaluated before approving a protocol at near therapeutic dose. The dose limitation requires that the smallest radiation dose needed to obtain meaningful data from the study be administered to the study subject. The maximum allowable

single dose to the whole body, blood-forming organs, lens of the eye, and gonads is 30 mSv (3 rem) with a maximum annual or total dose to all other organs of 50 mSv (5 rem). The maximum single dose and total annual dose to all other organs are 50 mSv (5 rem) and 150 mSv (15 rem), respectively. There is also a significant radiation dose limit on studies involving research subjects that are less than 18 years of age. The dose may not exceed 10% of the adult doses reported previously. Additionally, all radiation doses associated with the study must be included in the total study dose. This means that the CT dose from a positron emission tomography (PET)/CT study must be included in the total, and this total may not exceed the maximum limits set forth in the regulations.

The types of studies that may be conducted under an RDRC-approved protocol are also regulated. The research must be basic in nature and may include the evaluation of the radiopharmaceutical pharmacokinetic (PK), metabolism, and excretion. The distribution of a radiopharmaceutical to evaluate human physiology, pathophysiology, or biochemistry is permitted as long as the studies are not for diagnostic or therapeutic benefit. Safety and efficacy studies are not permitted under these regulations. An example of a study that is permissible under RDRC would be the brain distribution of [¹⁸F] fluorodopa relative to subject's age or neurodegenerative disease.

The RDRC may not approve protocols that require more than 30 subjects. If more than 30 subjects need to be studied and may be justified by the researcher, then a special summary form is submitted to the Food and Drug Administration (FDA) for review and a formal IND must be opened. A pediatric consultant to the RDRC must review the studies involving minors less than 18 years and a special summary must be submitted to the FDA. In addition, all adverse reactions "attributable to the use of the radioactive drug" must be reported immediately to the FDA. It is interesting to note, however, that over 30 years since the inception of the RDRC regulations with an estimated 60 000 subjects enrolled in the studies not one adverse event has been reported.

The regulations also stipulate the constitution of the RDRC with appropriate expertise to review the protocol applications. The committee must have at least five members. Three of those members must be a nuclear medicine physician, a qualified individual with radiopharmaceutical preparation experience, and a radiation dosimetry/radiation safety expert. The remaining members must have experience and qualifications in disciplines related to nuclear medicine.

23.2.1 Contrast Agents

As used in the guidance, a contrast agent is a medical imaging agent used to improve the visualization of tissues, organs, and physiologic processes by increasing the relative difference of imaging signal intensities in adjacent regions of the body. Types of contrast agents include, but are not

limited to (i) iodinated compounds used in radiography and CT; (ii) paramagnetic metallic ions (such as ions of gadolinium, iron, and manganese) linked to a variety of molecules and microparticles (such as superparamagnetic iron oxide) used in MRI; and (iii) microbubbles, microaerosomes, and related microparticles used in diagnostic ultrasonography.

23.2.2 Diagnostic Radiopharmaceuticals

As used in the 2004 CDER guidance, a diagnostic radiopharmaceutical is (i) an article that is intended for use in the diagnosis or monitoring of a disease or a manifestation of a disease in humans and that exhibits spontaneous disintegration of unstable nuclei with the emission of nuclear particles or photons or (ii) any nonradioactive reagent kit or nuclide generator that is intended to be used in the preparation of such an article. As stated in the preamble to FDA's proposed rules on regulations for *in vivo* radiopharmaceuticals used for diagnosis and monitoring, the agency interprets this definition to include articles that exhibit spontaneous disintegration leading to the reconstruction of unstable nuclei and subsequent emission of nuclear particles or photons (63 FR 28301 at 28303; May 22, 1998).

Diagnostic radiopharmaceuticals are generally radioactive drugs or biological products that contain a radionuclide that typically is linked to a ligand or a carrier. These products are used in nuclear medicine procedures, including planar imaging, single-photon emission computed tomography (SPECT), PET, or in combination with other radiation detection probes.

Diagnostic radiopharmaceuticals used for imaging typically have two distinct components:

1. A radionuclide that can be detected *in vivo* (e.g., technetium-99m, iodine-123, indium-111).
 - The radionuclide typically is a radioactive atom with a relatively short physical half-life that emits radioactive decay photons having sufficient energy to penetrate the tissue mass of the patient. The photons can then be detected with imaging devices or other detectors.
2. A nonradioactive component to which the radionuclide is bound that delivers that radionuclide to specific areas within the body.
 - This nonradionuclidic portion of the diagnostic radiopharmaceutical often is an organic molecule such as a carbohydrate, lipid, nucleic acid, peptide, small protein, or antibody.

As technology advances, new products may emerge that do not fit into these traditional categories (e.g., agents for optical imaging, magnetic resonance spectroscopy, combined contrast,

and functional imaging). It is anticipated that the general principles discussed here could apply to these new diagnostic products. Developers of these products should contact the appropriate reviewing FDA division for advice on product development.

23.2.3 Medical Imaging Agent Characteristics Relevant to Safety

The following sections discuss the special characteristics of a medical imaging agent that can lead to a more focused safety evaluation. Characteristics include its radiation-absorbed dose, mass dose, route of administration, frequency of use, biodistribution, and biological, physical, and effective half-lives in the serum, the whole body, and critical organs.

23.2.3.1 Mass Dose Some medical imaging agents can be administered at low mass doses. For example, the mass dose of a single administration of a diagnostic radiopharmaceutical can be small because device technologies can typically detect relatively small amounts of radionuclide (e.g., radiopharmaceuticals for myocardial perfusion imaging). When a medical imaging agent is administered at a mass dose that is at the low end of the dose–response curve, safety concerns are minimal.

23.2.3.2 Route of Administration Some medical imaging agents are administered by routes that decrease the likelihood of systemic adverse events. For example, medical imaging agents that are administered as contrast media for radiographic examination of the gastrointestinal tract (e.g., barium sulfate) can be administered orally, through an oral tube, or rectally. In patients with normal gastrointestinal tracts, many of these products are not absorbed, so systemic adverse events are less likely to occur. In general, nonradiolabeled contrast agents pose safety issues similar to therapeutic drugs generally should be treated with therapeutic agents for the purpose of conducting clinical safety assessments.

23.2.3.3 Frequency of Use Many medical imaging agents, including both contrast and diagnostic radiopharmaceuticals, are administered infrequently or as single doses. Accordingly, adverse events that are related to long-term use or to accumulation are less likely to occur with these agents than with agents that are administered repeatedly to the same patient. Therefore, the nonclinical development programs for such single-use products usually can omit long-term (i.e., 3 months duration or longer), repeat-dose safety studies. In clinical settings where it is possible that the medical imaging agent will be administered to a single patient repeatedly (e.g., to monitor disease progression), we recommend that repeat-dose studies (of 14–28 days duration) be performed to assess safety.

Biological medical imaging agents are frequently immunogenic, and the development of antibodies after intermittent, repeated administration can alter the pharmacokinetics, biodistribution, safety, and/or imaging properties of such agents and, potentially, of immunologically related agents. We recommend that studies in which repeat dosing of a biological imaging agent is planned to incorporate pharmacokinetic data, human antimouse antibody (HAMA), human antihumanized antibody (HAHA), or human antichimeric antibody (HACA) levels as well as whole body biodistribution imaging to assess for alterations in the biodistribution of the imaging agent following repeat dosing. Studies of immunogenicity in animal models are generally of little value. Therefore, we recommend that human clinical data assessing the repeat use of a biological imaging agent be obtained prior to application to licensure of such an agent.

23.2.3.4 Biological, Physical, and Effective Half-Lives Diagnostic radiopharmaceuticals often use radionuclides with short physical half-lives or that are excreted rapidly. The biological, physical, and effective half-lives of diagnostic radiopharmaceuticals are incorporated into radiation dosimetry evaluations that require an understanding of the kinetics of distribution and excretion of the radionuclide and its mode of decay. We recommend that biological, physical, and effective half-lives be considered in planning appropriate safety and dosimetry evaluations of diagnostic radiopharmaceuticals.

23.2.4 Performance of Nonclinical Safety Assessments

FDA recommends that the nonclinical development strategy for an agent be based on sound scientific principles, the agent's unique chemistry (including those of its components, metabolites, and impurities), and the agent's intended use. Because each product is unique, we encourage sponsors to consult with us before submitting an IND application and during product development. The number and types of nonclinical studies recommended would depend in part on the phase of development, what is known about the agent or its pharmacologic class, its proposed use, and the indicated patient population. If it is determined that nonclinical pharmacology or toxicology studies are not needed, FDA is prepared to grant a waiver under 21 CFR 312.0 if adequate justification is provided.

In the discussion that follows, a distinction is made between drug products and biological products. Existing specific guidance for biological products is referenced but not repeated here (see Section III.B.2 of CDER, 2004).

23.2.4.1 Nonclinical Safety Assessments for Nonbiological Drug Products

- Timing of Nonclinical Studies Submitted to an IND Application

TABLE 23.1 Timing of Nonclinical Studies for Nonbiological Imaging Agents Submitted to an IND

Study Type	Before Phase I	Before Phase II	Before Phase III	Before NDA
Safety pharmacology	Major organs, ^a and organ systems the drug is intended to visualize			
Toxicokinetic/pharmacokinetic	As part of repeat-dose GLP study in P2			
Expanded single-dose toxicity	Expanded acute single-dose ^b two species			
Short-term (2–4 weeks) multiple-dose toxicity		Repeat-dose toxicity ^c		
Special toxicology	Conduct as necessary based on route irritancy, blood compatibility, protein flocculation, misadministration, and extravasation			
Radiation dosimetry	If applicable <i>in vitro</i> ^d		May be needed based on molecular structure, biodistribution pattern, class concern, or clinical or nonclinical signal	
Genotoxicity Immunotoxicity			Needed or waiver obtained ^d	
Reproductive and developmental toxicity				
Drug interaction				As needed
Other based on data results				As needed

^aSee the guidances *S7A Safety Pharmacology Studies for Human Pharmaceutical* and *S7B Safety Pharmacology Studies for Assessing the Potential for Delayed Ventricular Repolarization (QT Interval Prolongation) by Human Pharmaceuticals* (note that S7B allows for phase evaluation of the required studies).

^bSee the guidance *Single-Dose Acute Testing for Pharmaceuticals*.

^cWhen repeat-dose toxicity studies have been performed, but single-dose toxicology studies have not, dose selection for initial human studies will likely be based on the results of the no-observed-adverse-effect level (NOAEL) obtained in the repeat-dose study. The likely result will be a mass dose selection for initial human administration that is lower than if the dose selection had been based on the results of acute, single-dose toxicity studies.

^dSee radiopharmaceutical discussion in CDER (2000).

- FDA recommends that nonclinical studies be timed so that they help facilitate the timely conduct of clinical trials (including appropriate safety monitoring based on findings in nonclinical studies) and reduce the unnecessary use of animals and other resources. The recommended timing of nonclinical studies for medical imaging drugs is summarized in Table 23.1. The allograft for converting nonclinical animal doses to human dose equivalents is presented in Table 23.2.
- Contrast Agents
 - Because of the characteristics of contrast drug products (e.g., variable biologic half-life) and the way they are used, FDA recommends that nonclinical safety evaluations of such drug products be made more efficient with the following modifications:
 - Long-term (i.e., >3 months), repeat-dose toxicity studies in animals usually can be omitted. (Exceptions are products with long residence time, e.g., >90 days.)
 - Long-term rodent carcinogenicity studies usually can be omitted.
 - Reproductive toxicology studies required under Section 312.23(a)(8)(ii)(a) often can be limited to an evaluation of embryonic and fetal toxicities in rats and rabbits and to evaluations of reproductive organs in

TABLE 23.2 Factors Used for Milligram per Kilogram to Milligram per Square Meter Conversions

Species	Conversion Factor
Mouse	3
Rat	6
Guinea pig	7.7
Hamster	4.1
Rabbit	11.8
Dog	20
Monkey	12
Human (60 kg)	37

other short-term toxicity studies. If you determine that such reproductive studies are not needed, we are prepared to grant a waiver under Section 312.10 if you provide adequate justification.

FDA recommends that studies be conducted to address the effects of large mass dose and volume (especially for iodinated contrast materials administered intravenously); osmolality effects; potential transmetalation of complexes of gadolinium, manganese, or iron (generally MRI drugs); potential effects of tissue or cellular accumulation on organ function (particularly

if the drug is intended to image a diseased organ system); and the chemical, physiological, and physical effects of ultrasound microbubble drugs (e.g., coalescence, aggregation, margination, and cavitation).

23.2.4.2 Diagnostic Radiopharmaceuticals (Nonbiological Products) Because of the characteristics of diagnostic radiopharmaceuticals and the way they are used, FDA recommends that nonclinical safety evaluations of these drugs be made more efficient by the following modifications:

- Long-term, repeat-dose toxicity studies in animals typically can be omitted.
- Long-term rodent carcinogenicity studies typically can be omitted.
- Reproductive toxicology studies can be waived when adequate scientific justification is provided.
- Genotoxicity studies should be conducted on the non-radioactive component because the genotoxicity of the nonradioactive component should be identified separately from that of the radionuclide. Genotoxicity studies can be waived if adequate scientific justification is provided.

FDA recommends that special safety considerations for diagnostic radiopharmaceuticals include verification of the mass dose of the radiolabeled and unlabeled moiety; assessment of the mass, toxic potency, and receptor interactions for any unlabeled moiety; assessment of potential pharmacologic or physiologic effects due to molecules that bind with receptors or enzymes; and evaluation of all components in the final formulation for toxicity (e.g., excipients, reducing drugs, stabilizers, antioxidants, chelators, impurities, and residual solvents). It is recommended that

the special safety considerations include an analysis of particle size (for products containing particles) and an assessment of instability manifested by aggregation or precipitation. It is also recommended that an individual component be tested if specific toxicological concerns are identified or if toxicological data for that component are lacking. However, if toxicological studies are performed on the combined components of a radiopharmaceutical and no significant toxicity is found, toxicological studies of individual components are seldom required.

SPECIAL CASE PRODUCTS: DRUGS FOR TREATMENT OF CANCER

24.1 INTRODUCTION

While cancer is not the most frequent disease cause of death in the United States and developed world (generally it is second behind cardiovascular disease, though Covid-19 has risen to second place in 2020/2021, with only 606 520 US deaths attributed to cancer in 2020 (American Cancer Society, 2020)), it is easily the most feared. Treatment options have progressed from surgery to radiation to chemotherapy to use of targeted biological therapies and most recently serial combinations of these (Mukherjee, 2010; Oh et al., 2017; McCormick, 2017). Drug, biologic, and drug/biologic agents with multiple agents being used in each of these stages. The best approaches are (as with antibiotics for multiresistance bacterial infections) combinations of these, usually in a staged manner.

The most common NME drugs entering development—fully one-third of all Investigational New Drugs (INDs)—are for oncology. Many reach approval (see Table 24.1), but oncology drugs also have the highest failure rates in all stages of development (Hay et al., 2014; DiMasi et al., 2015). The largest portions of drugs reaching clinical development are cancer drugs. Success rates (determined by 5-year survival rates after diagnosis) have improved with better understanding of specific Adverse Outcome Pathways (AOPs) for specific cancers, and increased use of biomarkers to better select and govern the use of treatments. Even up to 2013 (when the last comparative data is available from National Cancer Institute [NCI], see Table 24.1) steady improvements have been made yearly in the United States and other developed nations (EMA, 1997). New approved oncology drugs for 2019–2021 are listed in Table 24.2.

Traditional oncology drugs now have a specific Food and Drug Administration (FDA) and International Conference on

Harmonization (ICH) guidance for their nonclinical safety assessment requirements (ICH S9 R1, 2018), reflecting what have been the accepted (and expected) practices and approaches for the assessment of this largest portion of new drugs undergoing development (fully one-third of all new drugs). The newest (2018) version of ICH S9 makes clear that the guidance is also intended to apply to adjunctive drugs.

These drugs are intended for use in individuals with a serious and life-threatening disease. Initial clinical trials are conducted not in volunteers, but rather in patients who have already failed other forms of therapy, not volunteers. Requirements for entry into initial clinical trials for new cancer agents are on a sliding scale, depending on frequency of drug administration to patients (as shown in Table 24.3). For an oncology drug with only one administration a month, a single-dose study in each of two species would be sufficient. Note, however, that data (not wishful thinking) must be provided to support the projected frequency of administration (especially if said administration is projected to be infrequent). Because of this, as summarized in Tables 24.4 and 24.5, the requirements are not as strenuous as the general case because of the high number of deaths attributed to the disease. Indeed, genotoxicity and safety pharmacology are usually not required (Baguley and Kerr, 2002) (see Table 24.6).

The other unusual feature in such trials, whether the drug is a small or large (protein) molecule, is that clinical dosing regimens are rarely daily but rather in accordance with a schedule set as much by tradition and clinical operations in hospitals as by drug pharmacokinetics. While drug pharmacodynamics are initially established in mouse models (though a new trend of evaluation of efficacy in companion animal dogs with cancer is developing), only later in clinical development is an understanding of these sufficient to guide clinical practice. In a 2011 reorganization, FDA recognizing that cancer is a

TABLE 24.1 Common Cancers: How 5-Year Survival Rates Have Changed Over Time

Cancer	1975 Survival Rate (%)	2013 Survival Rate (%)	Notes
Prostate cancer	66.3	98	We now catch nearly 70% of prostate cancers at the localized stage
Non-Hodgkin's lymphoma	46	75.8	One of the least common cancers on this list
Lung cancer	11.5	22.1	One in five cancer deaths in the United States are attributable to lung cancer
Brain cancer and other nervous system cancers	23	35.8	The cost of treatment is the highest of any cancer
Leukemia	33.4	67.2	In 2018, an estimated 459 000 people were living with leukemia
Bladder cancer	71.9	78.8	An estimated 83 730 people will be diagnosed with this cancer in 2021
Colorectal cancer	48.9	66.3	Screening rates have slowed since 2010
Melanoma	81.9	95.8	83% of melanomas are caught early in routine screening
Breast cancer	75.3	91.8	It remains the most common form of cancer in the United States
Pancreatic cancer	3.1	12.1	Hardly any of these cancers are found early; the mortality rate remains high
Uterine cancer	88	82.5	This receives the least research funding of any disease on this list

TABLE 24.2 New Drug and Biologic Agents Approved to Treat Cancer, 2021, 2020, and 2019

Drug Name	Approval Date	Active Ingredient	FDA Approved Use on Approval Date
Cytalux	11/29/2021	Pafolacianine	To help identify ovarian cancer lesions
Scemblix	10/29/2021	Asciminib	To treat Philadelphia chromosome-positive chronic myeloid leukemia with disease that meets certain criteria
Tivdak	9/20/2021	Tisotumab vedotin-tftv	To treat recurrent or metastatic cervical cancer with disease progression on or after chemotherapy
Exkivity	9/15/2021	Mobocertinib	To treat locally advanced or metastatic nonsmall cell lung cancer (NSCLC) with epidermal growth factor receptor exon 20 insertion mutations
Rylaze	6/30/2021	Asparaginase erwinia chrysanthemi (recombinant)-rywn	To treat acute lymphoblastic leukemia and lymphoblastic lymphoma in patients who are allergic to <i>Escherichia coli</i> -derived asparaginase products, as a component of a chemotherapy regimen
Truseltiq	5/28/2021	Infigratinib	To treat cholangiocarcinoma whose disease meets certain criteria
Lumakras	5/28/2021	Sotorasib	To treat types of nonsmall cell lung cancer
Pylarify	5/26/2021	Piflufolostat F-18	To identify prostate-specific membrane antigen-positive lesions in prostate cancer
Rybrevant	5/21/2022	Amivantamab-vmjw	To treat a subset of nonsmall cell lung cancer
Zynlonta	4/23/2021	Loncastuximab tesirine-lpyl	To treat certain types of relapsed or refractory large B-cell lymphoma
Jemperli	4/22/2021	Dostarlimab-gxly	To treat endometrial cancer
Fotivda	3/10/2021	Tivozanib	To treat renal cell carcinoma
Pepaxto	2/26/2021	Melphalan flufenamide	To treat relapsed or refractory multiple myeloma (RRMM)
Cosela	2/12/2021	Trilaciclib	To mitigate chemotherapy-induced myelosuppression in small cell lung cancer
Ukonniq	2/5/2021	Umbralisib	To treat marginal zone lymphoma and follicular lymphoma
Tepmetko	2/3/2021	Tepotinib	To treat nonsmall cell lung cancer
Orgovyx	12/18/2020	Relugolix	To treat advanced prostate cancer
Margenza	12/16/2020	Margetuximab (anti-HER2 mAb)	To treat HER2+ breast cancer
Gallium 68 PSMA-11	12/1/2020	Gallium 68 PSMA-11	For detection and localization of prostate cancer

(Continued)

TABLE 24.2 (Continued)

Drug Name	Approval Date	Active Ingredient	FDA Approved Use on Approval Date
Danyelza	11/25/2020	Naxitamab-gqgk	To treat high-risk refractory or relapsed neuroblastoma
Gavreto	9/4/2020	Pralsetinib	To treat nonsmall lung cancer
Detectnet	9/3/2020	Copper Cu 64 dotatate injection	To help detect certain types of neuroendocrine tumors (NETs)
Blenrep	8/5/2020	Belantamab mafodotin-blmf	To treat multiple myeloma
Monjuvi	7/31/2020	Tafasitamab-cxix	To treat relapsed or refractory diffuse large B-cell lymphoma
Zepzelca	6/15/2020	Lurbinectedin	To treat metastatic small cell lung cancer
Cerianna	5/20/2020	Fluoroestradiol F18	Diagnostic imaging agent for certain patients with breast cancer
Qinlock	5/15/2020	Ripretinib	To treat advanced gastrointestinal-stromal tumors
Retevmo	5/8/2020	Selpercatinib	To treat lung and thyroid cancers
Tabrecta	5/6/2020	Capmatinib	To treat patients with nonsmall cell lung cancer
Trodelyv	4/22/2020	Sacituzumab govitecan-hzjy	To treat adult patients with metastatic triple-negative breast cancer who received at least two prior therapies for metastatic disease
Pemazyre	4/17/2020	Pemigatinib	To treat certain patients with cholangiocarcinoma, a rare form of cancer that forms in bile ducts
Tukysa	4/17/2020	Tucatinib	To treat advanced unresectable or metastatic HER2-positive breast cancer
Sarclisa	3/2/2020	Isatuximab	To treat multiple myeloma
Tazverik	1/23/2020	Tazemetostat	To treat epithelioid sarcoma
Ayvakit	1/9/2020	Avapritinib	To treat adults with unresectable or metastatic gastrointestinal stromal tumor (GIST)
Enjertu	12/20/2019	Fam-trastuzumab deruxtecan-nxki	To treat metastatic breast cancer
Padcev	12/18/2019	Enfortumab vedotin-ejfv	To treat refractory bladder cancer
Brukina	11/14/2019	Zanubrutinib	To treat certain patients with mantle cell lymphoma, a form of blood cancer
Ga-68-DOTATOC	8/21/2019	Ga-68-DOTATOC	For use with positron emission tomography (PET) for localization of somatostatin receptor positive neuroendocrine tumors (NETs)
Inrebic	8/16/2019	Fedratinib	To treat adult patients with intermediate-2 or high-risk primary or secondary myelofibrosis
Rozlytrek	8/18/2019	Entrectinib	To treat adult patients with metastatic nonsmall cell lung cancer (NSCLC) whose tumors are ROS1-positive To treat adult and pediatric patients 12 years of age and older with solid tumors
Turalio	8/2/2019	Pexidartinib	To treat adult patients with symptomatic tenosynovial giant cell tumor
Nubeqa	7/30/2019	Darolutamide	To treat adult patients with nonmetastatic castration resistant prostate cancer
Xpovio	7/3/2019	Selinexor	To treat adult patients with relapsed or refractory multiple myeloma (RRMM)
Polivy	6/10/2019	Polatuzumab vedotin-piiq	To treat adult patients with relapsed or refractory diffuse large B-cell lymphoma
Piqray	5/24/2019	Alpelisib	To treat breast cancer
Balversa	4/12/2019	Erdafitinib	To treat adult patients with locally advanced or metastatic bladder cancer

Source: FDA (2021)/U.S Department of Health and Human Services/Public Domain.

ALL, acute lymphoblastic leukemia; EGFR, epidermal growth factor receptor; GIST, gastrointestinal stromal tumor; GnRH, gonadotropin-releasing hormone; HER, human epidermal growth factor; HSCT, hematopoietic stem cell transplantation; IND, investigational new drug application; mTOR, mammalian target of rapamycin; NDA, new drug application; VEGF, vascular endothelial growth factor.

TABLE 24.3 Examples of Treatment Schedules for Anticancer Pharmaceuticals to Support Initial Clinical Trials

Clinical Schedule	Examples of Nonclinical Treatment Schedule ^{a-e}
Once every 3–4 weeks	Single dose
Daily for 5 days every 3 weeks	Daily for 5 days
Daily for 5–7 days, alternating weeks	Daily for 5–7 days, alternating weeks (two-dose cycles)
Once a week for 3 weeks, 1 week off	Once a week for 3 weeks
Two or three times a week	Two or three times a week for 4 weeks
Daily	Daily for 4 weeks
Weekly	Once a week for 4–5 doses

^aTable 24.1 describes the dosing phase. The timing of the toxicity assessment(s) in the nonclinical studies should be scientifically justified based on the anticipated toxicity profile and the clinical schedule. For example, both a sacrifice shortly after the dosing phase to examine early toxicity and a later sacrifice to examine late onset of toxicity should be considered.

^bThe treatment schedules described in the table do not specify recovery periods.

^cThe treatment schedules described in this table should be modified as appropriate for molecules with extended pharmacodynamics effects, long half-lives, or potential for anaphylactic reactions. In addition, the potential effects of immunogenicity should be considered (see ICH, 2011).

^dFor nonrodent studies, dose groups usually consist of at least three animals per sex per group, with an additional two per sex per group for recovery, if appropriate. Both sexes should generally be used, or justification should be given for specific omissions.

^eA common approach for many small molecules is to set a start dose at 1/10 the severely toxic dose in 10% of the animals (STD₁₀) in rodents. If the nonrodent is the most appropriate species, then 1/6 the highest nonseverely toxic dose (HNSTD) is considered an appropriate starting dose. The HNSTD is defined as the highest dose level that does not produce evidence of lethality, life-threatening toxicities, or irreversible findings.

TABLE 24.4 Special Case: Oncology Agents (Cytotoxic)

Test Requirement	Species
<i>Initial clinical trial/IND requirements</i>	
1. Acute toxicity in rodents (IV)	R/M
2. Acute toxicity in nonrodents (IV)	D/S/P
3. 7-day DRF toxicity in rodents (IV)	R/M
4. 7-day DRF toxicity in nonrodents (IV)	D/S/P
5. Safety pharmacology: CV-hERG ^a	<i>In vitro</i>
6. Pivotal/repeat dose in rodents (14–28 day IV)	R/M
7. Pivotal/repeat dose in nonrodents (14–28 day IV)	D/P/S
8. CYP induction/inhibition ^a	<i>In vitro</i>
9. Five species microsome metabolic panel ^a	<i>In vitro</i>
10. Develop bioanalytical for three species (man/ rodent/nonrodent)	NA
<i>To support continued clinical development</i>	
11. Pivotal/repeat dose in rodents (3-month maximum requirement under ICH S9)	R/M
12. Pivotal/repeat dose in nonrodents (3 maximum requirement under ICH S9)	D/P/S
<i>Marketing approval</i>	
13. Unless issues arise, other requirements are generally varied	

Note: Species: R = rat, M = mouse, D = dog, S = pig, P = primate, B = rabbit; TBD = to be determined. All studies described previously must be performed GLP.

^aRecommended but not required regulatory unless there are indications of potential toxicity in nonclinical studies.

TABLE 24.5 Special Case: Oncology Agents (Protein-Targeted Molecules) and Immunotherapies

Test Requirement	Species
<i>Initial clinical trial/IND requirements</i>	
1. Acute toxicity in rodents (IV)	R/M
2. Acute toxicity in nonrodents (IV)	D/S/P
3. 7-day DRF toxicity in rodents (IV)	R/M
4. 7-day DRF toxicity in nonrodents (IV)	D/S/P
5. Safety pharmacology: CV <i>in vivo</i>	D/P/S
6. Safety pharmacology: FOB/Irwin	R/M
7. Safety pharmacology: respiratory-rodent	R
8. Pivotal/repeat dose in rodents (14–28 day IV)	R/M
9. Pivotal/repeat dose in nonrodents (14–28 day IV)	D/P/S
10. CYP induction/inhibition ^a	<i>In vitro</i>
11. Five species microsome metabolic panel ^a	<i>In vitro</i>
12. Develop bioanalytical for three species (man/rodent/nonrodent)	NA
<i>To support continued clinical development</i>	
13. Developmental toxicity (segment II)—rat and rabbit pilots and rat and rabbit studies	R/B
14. Immunotoxicity	TBD
15. Pivotal/repeat dose in nonrodents (3/6 months oral)	D/P/S
<i>To support marketing approval</i>	
16. Reproductive toxicity—segment I	R
17. Reproductive toxicity—segment III	R

Note: Species: R = rat, M = mouse, D = dog, S = pig, P = primate, B = rabbit; TBD = to be determined. All studies described previously must be performed GLP.

^aRecommended.

TABLE 24.6 Pre-IND Nonclinical Safety

Systemic toxicity	Two species, TLD In case of episodic (1/3–4 week) usage, a single dose may be sufficient to evaluate
Genotoxicity	Not required
Safety pharmacology	Generally only
Reproductive/developmental	Generally not required
Carcinogenicity	Not required
Scaling	By body surface area allometry
Dosing coverage	Day for day within cohort

diverse family of diseases and that this presents the need to evaluate efficacy and safety (both clinical and nonclinical) in different ways, better relevance to the known differences, an Office of Oncology Diseases (OOD) was established with five separate divisions. Classification (listed below) is based on the specific nature (and target tissue) of the cancer to be treated:

1. Division of Oncology 1 (DO1)
2. Division of Oncology 2 (DO2)
3. Division of Oncology 3 (DO3)
4. Division of Hematologic Malignancies 1 (DHM1)
5. Division of Hematologic Malignancies 2 (DHM2)

The divisions vary in approach and pursuing more than one cancer may lead to the need for more than one IND.

Administrations are usually once or twice a week on a 3- or 4-week sequence of repeat dosing followed by a period without dosing. It is a normal practice for an initial clinical tolerance trial to be conducted with the dose level being escalated in each 3- or 4-week dosing series (Baguley and Kerr, 2002; Teicher and Andrews, 2004; Hidalgo et al., 2010). The 28-day two species nonclinical safety assessment studies have historically been the most common to enable INDs allowing maximum flexibility to clinicals when the margins of safety (MOS) are low. This has changed as there is more confidence in optimizing dosing regimens prior to clinical trials, a result of better data, for the entire multiseries set of administrations and allow for the most flexible coverage of changed needs in clinical development.

Dose scaling as we now practice it across the range of pharmaceuticals arose from the practice of oncology. Clinicians in this therapeutic area think of dosing in terms of mass of drug per square meter, which leads to the need to perform conversions of the expression of dose in safety studies (milligrams per kilogram) to the dose in the per body surface area (BSA) form. In general, the highest dose administered in nonclinical studies does not set an upper limit on the dose escalation in clinical studies—such doses can be advanced to yet higher doses in the face of a lack of toxic-limited dose (TLD) findings in patient populations. Doses

for earlier introduced cytotoxic drugs were/are quite high, but levels have come down as there has come to be better treatment specifics.

The toxicity of the traditional cytotoxic or antimetabolite anticancer drugs correlates more closely with BSA than with body weight (BW). Thus, it is a standard practice to administer and compare such drugs on the basis of BSA. To interconvert between units of milligrams per kilogram and milligrams per square meter, it is necessary to know either BSA or BW. Accurate values for BW are easy to obtain. In contrast, BSA is difficult to measure and therefore is usually calculated from a known BW. The relationship between BW and BSA is described by the formula: $BSA(m^2) = b \times [BW(kg)^{-1}]^{2/3}$, where b is a species-specific factor derived from empirical data. In practice, the values for b vary between laboratories (e.g., values for b for the mouse have been found to vary from 0.090 to 0.096). Confusion and miscommunication can occur as a result of the use of different species-specific factors. For example, difficulties have arisen during the dose selection process for a novel cytotoxic anticancer agent with a sleep dose–response curve. In this case, if different investigators use b values as varied as 0.099, 0.101, and 0.111, then animal BSA values for a 10kg dog will likewise vary, depending on the choice of b (0.926, 0.945, and 1.038 mg, respectively, for a 2 mg m^{-2} dose). The use of a single set of species-specific factors by all investigators is proposed as it would be beneficial in removing confusion from discussions of study designs and results. Such a proposal has an even more immediate benefit in the case of compounds with very steep dose–response curves, where even small variations in dosing can profoundly influence the results obtained and their interpretation. Requirements for initiating an IND and for market approval are different from the “General Case” (ICH M3(R2)) and generally provide a shorter and less-expensive path.

24.1.1 Animal Models

While other species are occasionally used in carcinogenicity (“carc”) studies, hamsters, and dogs, for example, rats and mice are overwhelmingly utilized for the traditional two-year exposure studies, with the use of mice gradually falling out of favor. For these customary studies, rat strains used are the Fischer F344, Sprague Dawley, and Hans Wistar, with use of the later increasing in incidence. Mouse strain are one or another substrain of the Swiss-Webster being most common and the B6C3F1 also being used. For all of these, the availability of historical data being a critical consideration. A number of strains of transgenic mice have been validated and used in 6-month mouse studies, but the nas H2 and the p53 have come to be the only strains used. In both cases, a 90-day range finder study conducted in the same strain (from the same source) as that to be used in the actual 6-month study is essential.

24.1.2 Statistical Analysis of Study Results

The results of a carcinogenicity study are based on comparative test groups versus concurrent control incidences of neoplasticity in specific tissues or organs with consideration of mortality. Increased rates of mortality will decrease the time that test animals are “at risk,” which must be adjusted for analyses. While other parameters (BWs, clinical chemistry, and clinical pathology) are measured and statistically analyzed, use of these data are to understand causality but not used to determine outcomes in terms of the principal question (whether the test drug presents the potential risk of causing cancers in patient detailed discussion of the issues and means for analyzing study results appropriately can be found in Gad, 1999 and Rousseaux et al., 2022).

24.2 HOW ONCOLOGY IS DIFFERENT

Safety assessments’ requirements and testing for primary oncology drugs is fundamentally different than most other (general case) drugs. As set forward in ICH S9 (2018) for small molecule cancer drugs, the diseases being treated are fatal (generally over a few years at most) and the drugs themselves have some degree of toxicity; for small molecules, usually are potentially very toxic with only small MOS. Dosing regimens are more complex, and therapeutic doses are traditionally defined in terms of quantity per m^2 of BSA. Initial studies are performed in patients, not volunteers, with days (or weeks) between doses to allow recovery of patients from drug toxicity while also not allowing the remaining population(s) of neoplastic cells to recover and develop resistance to the drug. Oncology trials for orphan drugs are also different, primarily due to the low numbers of available patients. (Kesselheim et al., 2011)

The initial cycle of treatment (several administrated at a single-dose level at a dose level called the highest nonseverely toxic dose (HNSTD), derived from the results of nonclinical studies) serves to qualify continued repetitions of the treatment cycle at a series of increased dose levels. Each cycle (say 4 or 5 weeks of once-a-week dosing) is continued for either a pre-determined period or until reversible adverse effects are seen in (usually) two or more patients. The series of cycles with increasing dose usually continues until a serious adverse effect is identified. While not intended to evaluate efficacy, if such is seen, the initial trail can be extended for opening an IND, and therefore, a clinical trial, the safety assessment program is more limited than the general case as described in ICH M3. In general, such a program requires:

- 28-day (or four to five repetitions of dosing, each reported by 5–7 day) studies in two appropriate species (rodent and nonrodent). Most commonly, dose-range

finding studies are performed to optimize dose levels and dosing regimens for use in the 28-day studies.

- Cardiovascular respiratory and central nervous system (CNS) safety pharmacology studies.
- If the drug is to be added to an existing standard of care regimen, a study must also be done to evaluate if the joint effort of the candidate and the standard of care jointly have a higher level of adverse effects. This is commonly a 2-week non-good laboratory practices (GLP) study performed in mice.
- If the route is something other than oral, the route-specific local tissue tolerance studies must also be done.

Subsequent to phase I, additional required safety studies include embryo fetal development studies in rats and rabbits, and a 3-month repeat dose study in a rodent and nonrodent species. If the patient population has disease-related organ function adversities already, appropriate additional safety pharmacology studies for the organs of concern should also be conducted.

24.3 DOSE CONVERSIONS: PERSPECTIVE

Dosages of pharmaceuticals are typically calculated on the basis of BW interspecies comparisons of toxicological effects of drugs, and chemicals are commonly based on exposures normalized with respect to BW or systemic exposure (i.e., area under the curve [AUC] and C_{max} values).

24.3.1 The Use of the $mg\ m^{-2}$ Dose Unit

In clinical oncology, doses are preformed on the day of treatment and are prepared on a basis of BSA derived from BWs using a nomogram to convert to patient BSA. Converting data from nonclinical studies (which will be in mass/BW, most commonly in $mg\ kg^{-1}$) to clinical dose equivalents is done using an arithmetic procedure. This is not used in non-clinical studies, but subsequently is used in INDs, investigators brochures, and in clinical protocols.

24.3.2 Calculations of Drug Dosages for Treatment

Cytotoxic anticancer drugs are typically administered in dose units of milligrams per square meter. However, BSA is difficult to measure. In contrast, values for height and BW are easy to obtain. Two solutions present themselves:

1. In clinic, estimates of BSA can be accomplished from height and weight data using established nomograms.
2. In the toxicology laboratory, BSA can be calculated from animal BW data using the appropriate formula.

24.3.3 Conversion of mg kg^{-1} BW Doses to Units of mg m^{-2}

Conversions from milligrams per kilogram BW to milligrams per square meter occur often in the design of toxicity studies, in the interpretation of data from a number of different studies, including old studies, and in comparisons of animal and human data where dose units are not similar. Two solutions are commonly used.

Another unusual feature in oncology is that the maximum utilized clinical dose is not based on a no-observable-adverse effect level (NOAEL), but rather the TLD. Patient's doses are typically titrated to overt toxicity, and actual clinical treatment practice doses patients up to a frankly toxic dose.

Somewhat in parallel, what constitutes a dose-limiting adverse effect in a nonclinical study (a TLD) is usually taken to be a frank toxicity and not a simple intolerance (such as sporadic emesis).

Additionally, it is frequently the case that even initial clinical trials will be done with the investigative agent being administered along with another agent and possibly also radiation. In these cases, such initial clinical trials will also require that at least an additional short study, usually 14 days in a rodent (and not necessarily GLP), be done to establish the safety of the actual combined intended clinical treatment.

24.4 DOSE SETTING IN ONCOLOGY AND NONINFECTIOUS IMMINENTLY FATAL DISEASES: STD_{10} AND HNSTD

24.4.1 Determination of First in Human Dose Levels Based on Pivotal Toxicology Study Data

Starting dose levels for First in Human (FIH) studies comes from data from the most sensitive species (usually the non-rodent). Such studies most commonly determine (and in the report, declare) a NOAEL. In oncology, however, more severe levels of adverse effect are sought because in treatment one wants to use the highest not life-threatening dose in the clinic to achieve the maximum safe daily oral dose.

For setting initial clinical doses for oncology and noninfections imminently fatal diseases, you will calculate STD_{10} (1/10th of the severely toxic dose) usually in rodents, and HNSTD. Both of which are defined and discussed in ICH S9. See Hansen et al. (2015) for further information.

PEDIATRIC PRODUCT SAFETY ASSESSMENT (2006 GUIDANCE, INCLUDING JUVENILE AND PEDIATRIC TOXICOLOGY)

25.1 INTRODUCTION

Two of the “special” or especially susceptible populations at the top of all lists of concern as to drug toxicity are the young and the old. There remain no guidelines or specific requirements for assessing the special risks of drugs to the elderly (geriatrics), but there are now requirements and guidelines for the nonclinical assessment of risks of drugs to pediatric and juvenile populations (FDA, 2006; EMEA, 2008; JMHLW, 2012; ICH, 2014). These nonclinical studies are the front end of the Pediatric Investigation Program (PIP) required of most new drugs. Pediatric Research Equity Act (PREA) (FDA, 2003) requires that all sponsors have in place a plan to assess pediatric risks of new drugs (or a waiver for such) prior to entering phase 3 trials. While existing studies required to evaluate reproductive effects evaluate prenatal and early postnatal effects, the FDA remains concerned that effects on juveniles, such as growth retardation (FDA, 1998), may not be adequately screened for. Juvenile animal studies (JAS) are intended to generate meaningful data and identification of risk that can’t be generated by available clinical or nonclinical studies applicable to pediatric and juvenile population for which direct exposure to the drug is plausible. Assessment performed in such studies should be made at the beginning and end of dosing at a minimum in both genders of test animals.

Designing and conducting relevant evaluation programs present a number of difficulties. Start with modeling the continuing process of anatomical, physiological, and metabolic developments as neonates progress from birth through childhood and adolescence in humans. These changes are accompanied with continuous major changes on the absorption, distribution, metabolism, and elimination/clearance of both endogenous and exogenous molecules

(Table 25.1). The changes cannot be simply extrapolated from adult situations, dosing, pharmacodynamics, or pharmacokinetics (as was attempted in the past), and no single species of

TABLE 25.1 Drugs that Exhibit Differences in Toxicity Between Adult and Pediatric Patients

Acetaminophen	Acute acetaminophen toxicity is a classic example of how maturation can affect the toxicity profile of a drug. Young children are far less susceptible to acute acetaminophen toxicity than adults because children possess a higher rate of glutathione turnover and more active sulfation. Thus, they have a greater capacity to metabolize and detoxify an overdose of acetaminophen when compared to adults.
Valproic acid	In contrast to acetaminophen, young children treated with valproic acid appear disproportionately vulnerable to fatal hepatotoxicity.
Chloramphenicol	Chloramphenicol is associated with mortality in newborns because exposure is increased due to a longer half-life ($t_{1/2} = 26$ h) compared to adults ($t_{1/2} = 4$ h).
Inhaled corticosteroids	Inhaled corticosteroids have been found to decrease growth velocity in children, an irrelevant end point in adults (FDA, 1998)
Aspirin	Aspirin should not be used to treat children with influenza or varicella infections because of their increased risk of developing Reye’s syndrome, a complication not seen in adults.
Lamotrigine	Children are at a greater risk for developing hypersensitivity-type reactions, including Stevens–Johnson syndrome, when treated with lamotrigine.

animal can serve as the most appropriate model for developing humans for all drugs. Species selection must be carefully considered through 85% of all studies are performed in rats only. Nonhuman primates should be used only for biologics (SOT, 2020; Yao, 2020).

Studies must be designed to support specific classes of drugs and clinical trials, mimicking what is to be done in such trials. Included in considerations must be the human age at the time of the pediatric trial, the duration of dosing relative to the phases of development and growth in pediatric and juvenile animals, what is known about potential target organs (one must remember that except in very rare cases, juvenile/pediatric trials are conducted after primary adult toxicity studies, providing some broad knowledge as to potential target organs), and the potential differences in toxicodynamic and pharmacodynamic profiles in developing and mature organisms.

The stage of development in animals being studied must be comparable to those in humans, a comparison summarized in Figure 25.1. The range of utilized model species is more restricted than for general toxicity studies, mirroring available knowledge on developmental specifics.

It is thought that organ systems at highest risk for drug toxicity are those that undergo significant postnatal development. Thus, evaluation of postnatal developmental toxicity is a primary concern. The structural and functional characteristics of many organ systems differ significantly between juveniles and adults as a result of the growth and development that takes

place during postnatal maturation, and the same is the case for model species. Examples include the following:

- Brain, where neural development continues through adolescence (Rice and Barone, 2000).
- Kidneys, where adult levels of function are first reached at approximately 1 year of age (Radde, 1985).
- Lungs, where most alveolar maturation occurs in the first 2 years of life (Burri, 1997).
- Immune system, where adult levels of IgG and IgA antibody responses are not achieved until about 5 and 12 years of age, respectively (Miyawaki et al., 1981).
- Reproductive system, where maturation is not completed until adolescence (Zoetis and Walls, 2003).
- Skeletal system, where maturation continues well into adulthood for 25–30 years (Zoetis and Walls, 2003).
- Gastrointestinal systems, which may have direct consequences on bioavailability, clearance, and biotransformation of drugs, are functionally mature by about 1 year of age (Walthall et al., 2005).

Studies in juvenile animals may be useful in the prediction of age-related toxicity in children, as shown in the following examples:

- The effects of phenobarbital on cognitive performance in children were predicted by experimental studies

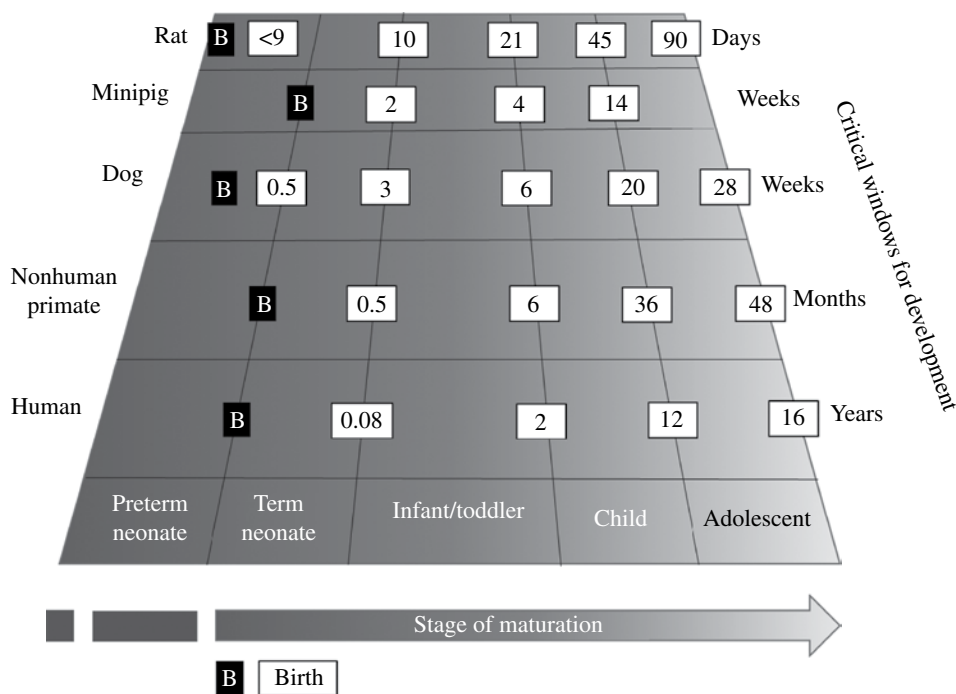

FIGURE 25.1 Comparative stages of development for neonatal and juvenile toxicity studies. Source: Beulke-Sam (2003).

examining the effects of this drug on the developing rodent nervous system (Fonseca et al., 1976; Diaz et al., 1977; Farwell et al., 1990).

- The vulnerability of human neonates to hexachlorophene neurotoxicity was modeled in developing rats and monkeys (Towfighi, 1980).
- The increased susceptibility of infants to verapamil-induced cardiovascular complications would be expected based on animal studies demonstrating a greater sensitivity of the immature heart to calcium channel blockade (Boucek et al., 1984; Skovranek et al., 1986).
- An increased risk of convulsions in young children treated with theophylline was predicted by studies of the preconvulsant effects of this agent in developing rodents (Mares et al., 1994; Yokoyama et al., 1997).

Examples of drug-induced postnatal developmental toxicity demonstrated in animals include the following:

- Neurobehavioral impairment in adult rats following early postnatal exposure to methamphetamine (Vorhees et al., 1994).
- The effects of methylphenidate on growth and endocrine function in young rats (Greeley and Kizer, 1980; Pizzi et al., 1987), particularly given the wide use in children with ADD and frequent polypharmacy in such cases with other drugs such as clonidine.
- Apoptotic neurodegeneration in neonatal rats treated with NMDA receptor antagonists (Ikonomidou et al., 1999).
- Decreased myelination and axonal damage induced in preweaning rats by vigabatrin (Sidhu et al., 1997).
- Long-term changes in serotonergic innervation in rats exposed to fluoxetine during early juvenile life (Wegerer et al., 1999).
- Chondrotoxicity in immature animals treated with fluoroquinolones (Stahlmann et al., 1997).

Potential ages and routes for juvenile studies are shown in Figure 25.1.

25.1.1 Scope of Nonclinical Safety Evaluation

The nonclinical safety evaluation of pediatric therapeutics should primarily focus on their potential effects on growth and development that have not been studied or identified in previous nonclinical and clinical studies. Juvenile animal testing may be useful in assessing potential developmental age-specific toxicities and differences in sensitivity between adult and immature animals. Although the toxicological assessment should focus primarily on the active moiety, testing the inactive ingredients in the clinical formulation can also be important, particularly when a drug's pharmacodynamics or distribution is altered by the inactive ingredients or

when uncharacterized excipients are present. The toxicological assessment should include local and systemic analyses of effects on postnatal growth and development in the anticipated pediatric population. The known pharmacological and toxicological properties of the drug relative to the proposed patient population (Yaffe and Aranda, 2005) should be considered. Any concerns for postnatal developmental toxicity can be addressed either in JAS or by modified study designs (e.g., modification of Segment III reproductive toxicity studies to include animals of similar developmental status as the pediatric population of concern). JAS are especially relevant when a known target organ toxicity occurs in adults in tissues that undergo significant postnatal development. The extent and timing of nonclinical safety studies will depend on the available new pediatric indication for an approved product used in adults that may be quite different from the information needed to support pediatric use of a new molecular entity because of the postnatal developmental safety concerns in the later population. These concerns will be considered for their particular clinical indications on a case-by-case basis within the drug review divisions.

25.1.2 Timing of Juvenile Animal Studies in Relation to Clinical Testing

Specific recommendations regarding the timing of nonclinical toxicology studies are available in the International Conference on Harmonization (ICH) guidance for industry *M3 Nonclinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals* (ICH M3 safety studies guidance). The recommendations presented here for JAS may assist in identifying postnatal developmental toxicities that are not adequately assessed in general toxicity studies with mature animals and that may not be adequately and safely tested in pediatric clinical trials.

25.1.2.1 Long-Term Exposure in Pediatric Subjects Most clinical studies in pediatric subjects do not involve long-term exposure to a therapy because they are generally of short-term duration (<6 months). This is especially true when the trials are intended to determine pharmacokinetics rather than efficacy. As a result, long-term exposure during postnatal developmental periods is not usually addressed in pediatric clinical trials. If the drug is indicated for chronic use, then some assessment of the long-term developmental effects of the drug in animals should be made before marketing. However, in those cases when pediatric clinical studies do involve long-term exposure, we recommend conducting JAS *before* initiation of the long-term clinical studies. When designing JAS, the age of the pediatric population for which the drug is intended is important. Neonates, infants, and older children are at very different developmental stages, and appropriate nonclinical data should support the drug's use in the intended pediatric population.

25.1.2.2 Short-Term Exposure in Pediatric Subjects

Depending on the indication and use of the drug, safety concerns, and the number of subjects exposed, there may be a need for JAS in conjunction with clinical studies even if the trials are designed for short-term exposure. Because JAS may identify potential hazards and these hazards may have relevance to human safety, it may be more useful to complete JAS before conducting clinical studies so that appropriate monitoring can be incorporated into the clinical trial design to limit human risk.

25.1.2.3 Insufficient Clinical Data to Support Initiation of Pediatric Studies

Typically, pediatric subjects are included in clinical trials after there has been considerable experience in the adult population. When there is insufficient clinical data or experience because of minimal prior adult and pediatric experience, completed JAS are needed before initiation of pediatric clinical trials regardless of whether the clinical trials involve long-term exposures. Similarly, when there have been reports of adverse effects with off-label use in pediatric patients, and there are inadequate data to evaluate the relationship between the drug and the adverse effects, completed JAS are needed before initiation of pediatric clinical studies. The timing of JAS relative to clinical testing of therapeutics indicated for serious or life-threatening pediatric conditions will be considered on a case-by-case basis by the review division.

25.2 ISSUES TO CONSIDER REGARDING JUVENILE ANIMAL STUDIES

It is important for juvenile animal toxicology studies to be designed efficiently using the least number of animals to identify potential pediatric safety concerns. Whenever feasible, we recommend designing an initial study to address end points of concern for multiple potential pediatric populations. In all cases, studies using juvenile animals are appropriate when adequate information cannot be generated using standard nonclinical studies or from clinical trials. The following issues are specific to studies in juvenile animals for assessing toxicity.

25.2.1 Developmental Stage of Intended Population

Consideration should be given to the age of the intended population and thus the stage of postnatal development. The condition to be treated may also influence the type, extent, and timing of testing considered appropriate. Selection of appropriate end points in the nonclinical studies to address concerns for the specific pediatric populations is important.

Recommendations regarding specific age ranges of pediatric subpopulations are discussed in the ICH guidance for

industry *E11 Clinical Investigation of Medicinal Products in the Pediatric Population*.

25.2.2 Evaluating Data to Determine When Juvenile Animal Studies Should Be Used

Evaluation of the available data is important when considering the need for studies in juvenile animals. Toxicity studies in juvenile animals may be appropriate when available nonclinical or clinical data are insufficient to support reasonable safety of a therapeutic for pediatric patients. Gaps in the age ranges of rodent and nonrodent species used in standard toxicity testing are widely acknowledged. These age gaps can affect assessment of nervous system toxicity end points in particular because of the extended process of maturation. Standard toxicity studies with adult animals cannot assess all the relevant end points, especially growth present in the immature animal. In other circumstances, however, JAS might not be necessary when (i) data from similar therapeutics in a class have identified a particular hazard and additional data are unlikely to change this perspective, (ii) there are adequate clinical data and adverse events of concern have not been observed during clinical use, and (iii) target organ toxicity would not be expected to differ in sensitivity between adult and pediatric patients because the target organ of toxicity is functionally mature in the intended pediatric population and younger children with the functionally immature tissue are not expected to receive the drug.

Most drugs that are intended for use in pediatric patients have established efficacy and safety profiles in adult humans. Some data may also be available from pediatric patients aged 12 years or older. For some drugs, a preponderance of clinical data will be obtained from children, as in the case of inhaled corticosteroids (FDA, 1998). For approved drugs that have already undergone extensive clinical testing, substantial nonclinical pharmacology and toxicology data will have already been performed. The toxicology assessment generally includes studies of general toxicity, reproductive toxicity, genetic toxicity, carcinogenicity, and special toxicities, as well as studies in juvenile animals, if available. Target organs of toxicity of the drug both in humans and animals should have been identified in these studies. A thorough evaluation of these data should enable scientists to (i) judge the adequacy of the nonclinical information, (ii) identify some of the potential safety concerns for the intended population, and (iii) identify any gaps in the data that might be addressed by testing in juvenile animals.

25.2.3 Considering Developmental Windows When Determining Duration of Clinical Use

Based on the observation that embryo–fetal development is especially sensitive to perturbation during organogenesis,

tissues that undergo significant postnatal development in pediatric patients and juvenile animals may also have greater sensitivity to certain drug-induced toxicities than mature tissues. Organ systems identified as undergoing considerable postnatal growth and development include the nervous, reproductive, pulmonary, renal, skeletal, gastrointestinal, hepatobiliary, and immune systems. Given the variable rate of postnatal development during different periods of childhood, the definition of long-term treatment can vary by pediatric population. Intended treatment of several weeks may not be considered long term in early adolescence but might involve considerable development for the neonate given the duration of some developmental windows.

25.2.4 Timing of Exposure

The timing of the intended use of the drug as it relates to periods of rapid postnatal growth and development is important. If the drug is intended for use in children undergoing phases of rapid overall growth and development, it is important to evaluate an animal model undergoing a corresponding growth phase. Organ systems mature at specific times in specific species. Human-to-animal comparisons of developmental periods for the nervous, reproductive, skeletal, pulmonary, immune, renal, cardiac, and metabolic systems are presented in Section VII of FDA (2006) at the end of this guidance. These can be used as general guides to appropriate periods of treatment to assess the development of specific systems in various animal models. Immature animals have accelerated chronological development compared to humans, which can facilitate evaluation of long-term effects following acute or chronic exposure using well-defined end points (e.g., assessment of reproductive or nervous function).

25.2.5 Selection of Study Models

In addition to consideration of models and end-point assessments based on the intended pediatric human use, target organs for toxicological and pharmacological activities identified in adults need special consideration. It is important that organ systems identified as specific targets of drug toxicity in adults and that undergo significant postnatal development be studied in juvenile animals for those specific effects, even when the primary postnatal developmental period in humans does not coincide with the intended treatment phase. This is based on the observation that development is generally a continuous event. Additionally, a therapeutic target tissue may be developmentally regulated by other tissues or organ systems. In such cases, it may be advisable to examine the effects of the drug during the stages of development relevant to all of those tissues/organs in a test species.

25.3 GENERAL CONSIDERATIONS IN DESIGNING TOXICITY STUDIES IN JUVENILE ANIMALS

Modified repeat-dose toxicity studies can provide a more general screen for potential hazards in some instances. However, we recommend that such studies modify the animal age at the study initiation, duration of treatment, and end points assessed to address the specific concerns. Modification of standard ICH studies designed to address developmental stages C–F (ICH, 1994) would include ensuring adequate exposure in juvenile animals during the postnatal period and assessment of developmental end points appropriate for the intended pediatric population. Assessment of developmental end points not usually included in standard repeat-dose toxicity studies also may be appropriate. In addition to ensuring adequate exposure to the drug, histopathologic examinations and effects on specific growth parameters and functionally immature tissues in the juvenile animal would be important. In these modified designs, dosing can be initiated with animals younger than usual and extended until the developmental period for the intended pediatric population has been completed in the animal species in accordance with the age of the pediatric patients who would use the drug. Information from such studies can be compared with the findings from treated adults of the same species to evaluate whether the effects are specific to juvenile animals.

If one has knowledge of the toxicodynamics/pharmacodynamics of the compound of interest, there is a wealth of information available on comparative developmental end points (see FDA, 2006), including on enzymatic metabolism (see Table 25.2).

25.4 STUDY DESIGNS AND CONSIDERATIONS

As a starting place, it must be noted that one cannot generally initiate dosing of animals immediately at birth—their chances of survival are very adversely affected. Table 25.3 summarizes currently accepted guidance on earliest dosing start dates for different routes according to model species. Second, there are several approaches to assigning animals in separate litters (for rodents) to different test groups (see Table 25.4).

For nonrodents, the complications of small litter (and acceptable) group sizes in primates (Table 25.5), dogs (Table 25.6), and minipigs (Table 25.7) must be considered.

Generally, the use of a single species is considered sufficient to evaluate juvenile toxicity subsequent to evaluation of adult systemic toxicity.

It is critical that those designing, conducting, and analyzing juvenile toxicity studies be very knowledgeable about the developmental biology of the model species being employed.

TABLE 25.2 Enzymatic Metabolism Development (Humans, Rats, and Rabbits)

Developmental Modulation of Phase I/II Metabolism			
Maturation of Enzyme Activity

TABLE 25.5 Juvenile Nonhuman Primate Model

Advantages	Disadvantages
Physical size facilitates collection of multiple biologic specimens	Procurement of appropriately aged animals
Postnatal development of many organ systems well characterized	Not practical to test full span of postnatal development
Potentially less immunogenic than other species	Limited reference or historical control data for some end points
Standardized tests available	More expensive (vs. rodent)
• Neurobehavioral testing	Limited appropriate technical expertise/experience
	Statistical analysis

TABLE 25.3 Earliest Starting Day Based on Dosing Routes

	Rat	Mice	Rabbit	Dog	Minipig
Oral gavage	PND 1	PND 4	PND 14	PND 1	PND 1
Subcutaneous	PND 1	PND 1	PND 6	PND 1	PND 1
Intramuscular	PND 1	PND 1	PND 6	PND 1	PND 1
IV bolus (repeated)	PND 4	PND 7	PND 6	PND 1	PND 7 ^a
IV infusion	PND 21	PND 21	PND 28	PND 56	PND 7 ^a
Inhalation (whole body)	PND 4	PND 4	PND 6	PND 10	PND 2–7
Inhalation (nose only)	PND 21	PND 21	PND 28	PND 4 ^b	PND 4 ^b
Dermal ^c	PND 21	PND 21	PND 28	PND 42	PND 28

Source: Hoberman and Lewis (2012) and Parker (2014).

^aDifficult because there are no easily accessible veins (vascular implant port can be surgically installed after PND 7).

^bMasks can be fit as young as PND 4, but restraint issues arise.

^cNot recommended in preweaning animals.

TABLE 25.4 Litter Composition Study Design Options

Within-litter design	Each litter has all treatment groups.
Split litter design	Each litter has some of the treatment groups.
Between-litter design	Each litter has the same treatment group.
Fostering design	Each litter is composed of pups from other litters without using any siblings. All pups within new litter receive the same treatment.
One pup per sex per litter design	Self-explanations.

Note: Each method has its advantages and disadvantages (logistically, cross-contamination possibility, IACUC issues, and statistically).

TABLE 25.6 Juvenile Dog Model

Advantages	Disadvantages
Provides model of immaturity	Long time to sexual maturity limits assessment of reproductive development
Postnatal development of many organ systems well characterized	Limited reference or historical control data for some end points
Physical size facilitates collection of multiple biologic specimens	Learning and memory tests not well developed
Samples can be collected with minimum restraint and without anesthesia	Potential immunogenic response
Techniques for handling and treating puppies well established	Pharmacological relevance may not have been previously characterized
Ability to procure appropriate numbers of animals, even for early-age assessments	Statistical analysis

TABLE 25.7 Juvenile Minipig Model

Advantages	Disadvantages
High pregnancy rate and synchronization of mating possible	Limited pharmacological relevance
Gestation length shorter than NHP	Neurobehavioral tests not well developed
Similarity of organ system anatomy, size, and physiology to humans	Potential immunogenic response
Availability of reference data for juvenile organ development	Limited labs available with experience
Piglets are easily accessible for handling and dosing and allow frequent blood sampling	Sexual maturity at 6.5–7.5 months ^a
Sexual maturity at 4–5 months	

^aTortereau et al. (2013).

TABLE 25.8 Data Interpretation

Toxicity	Any new toxicity findings. Any increased sensitivity. Clinical signs can be different in preweanlings (dehydration, hair coat, teeth should all be interpreted with caution), i.e., increased skin turgor is not necessarily dehydration in weanling Organ weights are changing during study, not necessarily synchronized, allometric, and isometric growth. Background incidence is higher for some histological endpoints (kidneys) and variation of normal can be greater at different ages—pathologist experience in juvenile animals can be critical. Clinical path “reference ranges” don’t necessarily apply. These are not screened animals prior to study start.

USE OF IMAGING, IMAGING AGENTS, AND RADIOPHARMACEUTICALS IN NONCLINICAL TOXICOLOGY

26.1 INTRODUCTION

Rather than split these into three separate chapters, here the aim is to integrate these interrelated subjects into a single cohesive unit, with the goal of a coverage that better relays the power (and challenges) of the use of available imaging technologies and how contrast agents and radiopharmaceuticals fit into this utilization, followed by a review of current regulatory nonclinical safety requirements for the use of those two classes of drugs.

Imaging and radiopharmaceutical techniques for diagnostic use all share the goal of using a growing toolbox of methodology to evaluate drug targeting and effects. In recent years, these methodologies have become available for use in model species in toxicology, from larger nonrodents (dogs, swine, and primates) to rodents (rats and mice) (Kiessling and Pichler, 2011).

The first section seeks to provide an overview of the methods and their potential use. The next two sections will address consideration of how to evaluate the nonclinical safety of actual agents (regulated as drugs).

The available methods for imaging cover a broad range of possibilities:

- X-rays
- Positron emission tomography (PET)
- Computed tomography (CT)
- Magnetic resonance imaging (MRI)
- Optical imaging
- Ultrasound (US)
- Radiopharmaceuticals
- Nanoparticle-assisted imaging

Others are likely to join the list; terahertz imaging (based on wavelengths between infrared and microwaves) is now being pursued for cancer detection (Jacoby, 2015).

The development of therapeutic agents and modalities spans a period of 5–15 years leading to current approaches (and is still ongoing). The most recent technique available for real-time cellular, tissue, and molecular imaging (MI) of organisms and the disposition of drug in living body provides a powerful means to identify whether a drug candidate hits the target and effects tissues in laboratory animals in early stages of drug development, improving the quality of selection of molecules entering development.

Unlike the more purely energy-driven imaging technologies (also discussed here), MI technology provides not only visualization and characterization but also measurement of biological processes at the molecular and cellular levels in humans and other living systems. MI technologies are increasingly recognized as important preclinical and clinical research tools to speed up the long timelines of drug development process (Hargreaves, 2008; Rogge and Taft, 2010; Weissleder et al., 2010; Kiessling and Pichler, 2011), with a focus on utilizing noninvasive techniques to visualize the anatomic structures and physiologic activity in nonclinical and clinical research and in clinical practice. Modern imaging assessments provide information about tissues by penetrating the living body via physical phenomena. These imaging modalities have been reengineered for use with laboratory animals by pushing the resolution and sensitivity of each modality to the physical limit. The improved high resolution and sensitivity make the imaging technology highly translational in the preclinical drug development process.

These technologies are able to provide evidence of *in vivo* biodistribution of imaging probes and agents, confirm on-target

biological activity, discern disease mechanism, and potentially provide proof of concept for the therapeutic in question. Several excellent review articles (Bruggen and Roberts, 2002; Willmann et al., 2008) and one book (Weissleder et al., 2010) have been published on the general role of MI on the process of both preclinical and clinical drug development.

26.1.1 Multimodality Imaging Techniques

MRI, SPECT, PET, CT, US, and optical imaging all generate sectional images that can be reconstructed into two-dimensional (2-D) or three-dimensional (3-D) images. For nonclinical evaluations, the imaging technique must have spatial resolution that is adequate for small animals and sensitivity to detect biochemical events. Each technique has certain advantages and limitations, with platform selection being dependent upon which techniques best serve the need of answering a particular nonclinical question. Combining imaging techniques (multimodality) in the same animal, such as using PET/CT, SPECT/CT, and PET/MRI coregistration, we can provide temporal pathophysiological information such as development of structural and functional changes, progression and resolution during disease treatment, and the drug-related on-target- and even off-target-related toxicities (Cali et al., 2012).

26.1.1.1 Agents, Probes, and Biomarkers MI probes are agents used to visualize, characterize, and measure biological processes in living systems. MI instrumentation, including MRI, CT, US, optical imaging, SPECT, and PET as shown in Figure 26.1 and are tools that enable the visualization and quantification in space and over time of signals from MI probes. In nonclinical research, diagnostic probes or imaging agents are administered in trace amounts and typically do not induce any physiological response or significant pharmaceutical effect in living systems (Schwaiger et al., 2013).

Imaging probes include radiolabeled contrast agents, biologics, nanoparticles, and different cell types. A radiotracer can be defined as a specific radiolabeled molecule that monitors the *in vivo* behavior of a functional molecule and can be used to provide biological information in a living system. The synthesis of a radiotracer generally includes radiolabeling of the molecule of interest, purification of final product, resting specific activity, and analysis of *in vivo* stability. The commercially available imaging probes and customized radiotracers for PET or SPECT imaging can be used to detect such functional changes as cerebral blood flow, myocardial perfusion, glucose metabolism, infection, bone lesion, kidney function, apoptosis, angiogenesis, thyroid dysfunction, tumor detection, gene expression, neuroreceptor binding, and cell trafficking process (Cai and Chen, 2021; Morone and Betterhauser, 2015).

26.1.2 Dynamic Molecular Imaging Techniques

The radiotracer approach used for PET and SPECT functional imaging is especially valuable at early stages of drug discovery, where researchers can directly label a therapeutic candidate to see where it localizes in laboratory animals. If the drug candidate does not distribute to its intended physiologic target, as desired, it can be excluded from further development at an early stage. In addition, PET and SPECT imaging experiments can reveal molecular changes in targeted and nontargeted tissues brought about by the drug and its side effect caused within the laboratory animals. This can be extremely important since changes on the molecular level occur long before becoming visible in any anatomic imaging. Such approaches allow the rank ordering of development candidates based on relevant physiologic processes very early in drug development.

In vivo imaging techniques such as PET and SPECT provide a means to perform pharmacokinetic (PK) and pharmacodynamic (PD) studies in animal models without terminating the animal, allowing for serial time samples. With the introduction of dynamic and static imaging approaches, it is now possible to obtain high-resolution PET and SPECT images of “motion-frozen” time points in PK and PD studies and be able to quantify the amount of drug in the target organs of interest in the same laboratory animal over a period of time during the drug evaluation process.

26.2 X-RAY

This is the oldest and most generally familiar technology for visualizing structures *in vivo* and noninvasively. It generally does not require use of an imaging agent, though in some cases.

Instruments (crude ones are easy to build—the author and his brother built one for a science fair project in high school) with electrical energy and generally any radiation in a wavelength ranging from 0.01 to 10 nm by electrons cause a metal anode to release photons. These wavelengths are shorter than UV or visible light and carry more energy. These waves pass through most objects—certainly through living tissues—with varying degrees of absorption. Capturing the “scanned” region onto a suitable receptor (originally film, now electronic detectors) provides an image (“radiograph”) of internal structures.

The difficulty is that X-ray photons carry (and can transmit/transfer) enough energy to ionize atoms and harm the tissues they transit.

Contrast (imaging) agents are used to increase the sharpness and clarity of images in a specific region of interest in the body.

Fluoroscopy is a form of X-ray imaging used to obtain real-time mobile images of structures within the body. It may

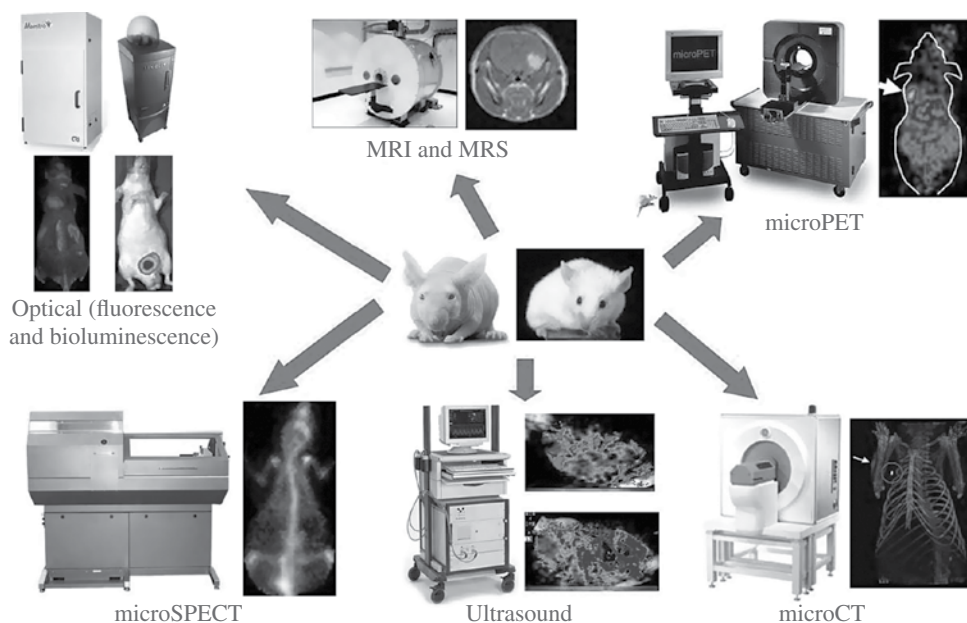

FIGURE 26.1 Multimodality imaging instrumentations. The modern molecular imaging equipment includes magnetic field/radiofrequency (magnetic resonance imaging (MRI)), X-ray (computed tomography (CT)), high-frequency sound waves (ultrasound (US)), optical (bioluminescence/fluorescence), gamma rays (single-photon emission computed tomography (SPECT)), and annihilation twin photons from beta emission (positron emission tomography (PET)). *Source:* National Institutes of Health.

also be used by surgeons to allow a proper placement of devices such as catheters.

26.2.1 Angiography

Angiography, utilizing X-rays to image coronary vasculature and blood flow in discrete regions during a study, has become a standard tool for evaluating effects on vascular function (including blockage, revascularization, and angiogenesis) when such are concerns or desired outcomes of treatment. The performance of such investigations is usually restricted to dogs and swine, where it is a valuable tool for evaluating vascular/flow functional effects.

26.3 POSITRON EMISSION TOMOGRAPHY (PET)

In PET imaging, a compound (small-molecule drug or biological molecule) labeled with a positron-emitting radioisotope is injected into the subject in a nonpharmacological trace quantity. A positron ejected by a radionuclide combines with an electron in adjacent tissues to emit a pair of photons (511 keV) resulting from annihilation of a positron-electron pair. The PET scanner uses the annihilation coincidence detection (ACD) method to obtain projection images of the localization and quantification of the radiolabeled compound in a living subject (Wang and Maurer, 2005). PET imaging technology can be used for drug distribution, organ

perfusion, cell trafficking, tumor targeting, tumor metabolism/proliferation, tumor angiogenesis, tumor hypoxia, tumor apoptosis, tumor volume, anticancer therapeutic response, bone growth/healing, and mechanism studies in animal models of central nervous system (CNS) and autoimmune diseases. Advantage of this technique includes high molecular sensitivity (nanomolar) with almost unlimited depth penetration. Disadvantages of PET include radiation safety and relatively high cost. PET functional imaging is often combined with either micro-CT or animal MRI for better identification of functional change in deep tissue against anatomical structure in an *in vivo* animal model.

26.4 SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY (SPECT)

SPECT camera images individual high-energy photons—gamma rays, resulting from radionuclide decay. The technique requires injection of a gamma-emitting radioisotope into the laboratory animal for research or patient in clinical practice. Radioisotopes can be coordinated to a test article (ligand) to allow for the evaluation of the binding properties of the test article *in vivo*. The combination of radioisotope and the ligand will bind to a place of interest in the body of the living subject to be seen by the gamma ray detectors, thus producing an image by CT. For example, an imaging agent with affinity for areas of growing bone can be utilized

to evaluate potential impact of a test article on the process of ossification.

The single-photon emission radiates from the source in all directions with equal probability. Because of this, an aperture composed of highly attenuation material is required to identify the path of origin of each emission prior to being able to create an image with a gamma camera. In preclinical SPECT imaging, the most recently developed multipinhole collimator technology achieves submillimeter high resolution in small laboratory animals.

SPECT can be used to complement any gamma imaging studies. Biodistribution, tumor imaging, infection, bone imaging, and cardiac gated imaging can also be performed with SPECT. SPECT (Wernick and Aarsvold, 2004) offers radiolabeled image resolution and sensitivity that can translate from mouse to human. It also can provide both qualitative and quantitative measurement of physiologic processes. The isotopes used for SPECT imaging (i.e., ^{123}I , ^{125}I , $^{99\text{m}}\text{Tc}$, ^{111}In) are readily available and relatively inexpensive, with longer half-lives than those commonly used in PET imaging. The extended half-life of these isotopes translates to longer scan times and/or scanning periods without the need for secondary isotope administration. These characteristics of SPECT imaging results in a reduction in the isotope quantity needed, as well as the total number of animals utilized in preclinical studies—more data using fewer animals over a longer investigational period. SPECT imaging/isotopes also provide the ability to simultaneously image multiple radiopharmaceuticals with different energies (i.e., $^{99\text{m}}\text{Tc}$ vs. ^{125}I). Micro-SPECT functional imaging is able to coregister with a high-quality CT imaging framework for anatomical imaging comparison.

One characteristic of SPECT imaging is the infrastructure and instrumentation cost, as well as the need for radioactive material handling and dosimetry. This platform requires the investigators' multidisciplinary knowledge and experience to ensure that the study design provides an adequate data set to meet their objectives. Although the molecular sensitivity of SPECT is almost one order of magnitude lower in sensitivity than PET, SPECT imaging continues to be widely used in both clinical practice and preclinical research due to its advantages of a relatively lower operating cost, dual-labeled compounds, and a valuable long half-life radionuclides, which allow for lengthier monitoring periods of *in vivo* biological process compared to PET imaging.

26.5 COMPUTED TOMOGRAPHY (CT)

CT is an application of X-ray imaging that provides a 3-D anatomical image. In CT scan, X-rays are emitted from an X-ray source rotating around the subject placed in the center of the CT scanner. A detector opposite the X-ray source senses X-rays that are not absorbed by the tissue; this absorption is inversely related to the density of the tissue

structures. The X-ray absorption profile is then used to reconstruct high-resolution (roughly 6–50 μm with no depth limit) tomographic anatomical images. Micro-CT can be used for bone studies, developmental and reproductive toxicology (DART) studies, fetal skeletal evaluations vascular studies, and lung studies. The use of contrast media (see Table 26.1) enables soft tissue segmentation and some functional imaging, for example, in kidney function studies. The disadvantages of micro-CT include low soft tissue contrast, use of radiation, and limited molecular-level applications. Micro-CT is able to provide a high-quality anatomical framework for functional imaging techniques, particularly in PET and SPECT imaging data analysis.

26.6 MAGNETIC RESONANCE IMAGING (MRI)

MRI relies mainly on the detection of hydrogen nuclei in water and fat to construct high-resolution images. The contrast in these images results from different T_1 and T_2 relaxation times for hydrogen nuclei in different tissue environments. MRI is based on the same principles as liquid-state nuclear magnetic resonance (NMR)—that is, the behavior of nuclei in a magnetic field under the influence of radiofrequency (RF) pulses—but the hardware, pulse sequences, and data processing are somewhat different. Improvements in electronics and computers since the mid-1990s have given MRI resolution capabilities in intact organisms down to approximately 3 mm and therefore tremendous potential as a tool for studying the mechanisms of toxicology. MRI techniques provide detailed information on the response of specific organs to toxicants and can also be used to monitor xenobiotic metabolism *in vivo*. In addition, they could reduce the number of animals required for toxicology studies, as a single animal can be followed over an extended period to monitor internal changes.

MRI utilizes NMR, and the signal is derived primarily from the hydrogen nuclei (protons) of water molecules. The technique uses a powerful magnetic field to align the magnetization of atoms in the organism and a pulse of RF to alter the alignment of this magnetization. The scanner then detects the rotating magnetic field to produce an image of the scanned area. Unlike radiography or CT, no ionizing radiation is used. Intravenous contrast agents are used to enhance the signal and/or help delineate vessels or tumors. MRI is most useful for imaging soft tissues, especially those with little density contrast, such as the liver or brain, and is most frequently used to provide anatomical images and delineate lesions such as tumors or areas of necrosis in living animal models. Magnetic resonance microscopy (MRM) is MRI with resolutions better than 100 μm^3 . An advantage of this technique is high resolution (roughly 10–100 μm with no limit of depth) and high soft tissue contrast. MRI contrast agents include chemical exchange saturation transfer (CEST) agents, paramagnetic

TABLE 26.1 Classification of X-Ray Contrast Media for Small-Animal CT Imaging

Iodinated Extracellular Fluid CM (Urographic Water-Soluble CM)	Vascular Space CM (Blood Pool Agent)	Hepatocellular CM (Tissue-Specific CM)	Gastrointestinal CM
Monomeric nonionic CM	Macromolecular CM	Iodine-containing lipid	Iodinated CM
Iopromide	Dysprosium–DTPA–dextran CM	Iopromide liposomes	Diatrizoate (ionic CM)
Iohexol	Oil emulsions of ethiodol and iodine	Iodixanol liposomes	Iopromide-370 (nonionic CM)
Iopamidol		Cholesteryl ioponate	
Ioversol		Polyiodinated triglyceride emulsion (ITG-LE)	Barium sulfate
		Fenestra DC	
Iopentol	Iodine-containing micelles	Dysprosium EOB DTPA	
Iomeprol	MPEG–iodolysine micelles

metal chelates, iron oxide particles, ¹⁹F-containing agents, and hyperpolarized molecules. The disadvantage includes limited molecular applications and long scanning times. Functional information can be gathered in a related technique known as magnetic resonance spectroscopy (MRS), which provides information either on the concentration and distribution of magnetic nuclear isotope-labeled drugs in tissues of laboratory animal or on particular endogenous biochemical (metabolites) since a specific pattern of metabolites can be associated with certain diseases and tumors.

26.7 OPTICAL IMAGING

A variety of different kinds of optical imaging techniques have been developed for biomedical applications. They include various microscopy methods such as confocal microscopy, two-photon microscopy, and coherent anti-Stokes Raman scattering (CARS) microscopy for *in vitro* and *ex vivo* applications. These techniques are combined with a number of methods for *in vivo* applications such as

various types of microscopic imaging, bioluminescence imaging (BLI), fluorescence imaging, diffused optical tomography, and optical coherence tomography. Over the last decade, the various modes of optical imaging have grown in popularity and sophistication. Today, optical imaging has a wide variety of applications in genomics, proteomics, cell biology, and drug discovery and development. Optical imaging has emerged as a real-time, sensitive, and noninvasive modality for visualization, localization, and measurement of bioactive molecules and molecular processes *in vivo*.

Even though optical imaging cannot compete with PET, SPECT, MRI, and CT in clinical applications today, the advantages of optical imaging (i.e., convenience, sensitivity, cost-effectiveness, and nonradioactive material safety) have made it very popular among the traditional imaging modalities for MI in preclinical studies. Optical imaging of receptors, enzymes, gene expression, live cells, and tumors *in vitro* and *in vivo* has deepened our understanding of disease progression and therapeutic response at the molecular, cell, tissue, and whole-animal levels.

In vivo optical imaging includes fluorescence and bioluminescence imaging. Both techniques are highly sensitive (picomolar) at limited depths of a few millimeters, are quick and easy to perform (with a high-throughput capability), and in general do not require costly instrumentation. This character makes it particularly suited to the drug development and validation process.

Fluorescence¹ imaging uses high-intensity illumination² of a certain wavelength to excite fluorescent molecules in a sample. When a molecule absorbs photons at the appropriate wavelength, electrons are excited to a higher-energy level. As these excited electrons “relax” back to the ground state, vibrational energy is lost and, as a result, the emission spectrum is shifted to longer wavelengths. Fluorescence imaging causes excitation of certain fluorophores in a living system by using external light and then detects fluorescence emission with a sensitive CCD camera. The fluorophores can be endogenous molecules (such as collagen or hemoglobin), exogenous fluorescent molecules such as green fluorescent protein (GFP), or small synthetic optical contrast agents.

A limitation of *in vivo* fluorescence imaging is from light attenuation and scattering by adjacent living tissues. Light in the near-infrared (NIR) range (650–900 nm) instead of visible light can improve the light penetration within laboratory animal. It can also minimize the autofluorescence of some endogenous molecules such as hemoglobin, water, lipids, and other biomacromolecules. In a whole mouse illumination experiment, photon counts in the NIR range (670 nm) are about four orders of magnitude higher compared to those in the green light range (530 nm) under similar conditions. NIR fluorescence imaging has provided an effective solution for improving the imaging depth along with sensitivity and specificity. Therefore, fluorophores with emission maxima in the NIR region are important for successful *in vivo* optical imaging and future clinical applications. Commercially available fluorophores,³ with well-defined excitation and emission spectra, can be used to “stain” specific structures or molecules in a specimen. Proper selection of fluorophores allows the identification of multiple targets as long as emission spectra can be cleanly separated and distinguished from autofluorescence.

26.8 ULTRASOUND

The principles of US imaging are founded in the basic physical interaction of sound waves with living tissues of

various densities (Szabo, 2013). It is extensively used in small-animal (dogs and cats) veterinary care (Mattoon and Nyland, 2015). Ultimately, the results of these interactions are displayed as an image. Doppler-based modes can also be utilized to evaluate fluid dynamics, primarily velocity, of the circulatory system, or within specific organs. Ultrasonography can be used to evaluate both structural and functional end points of multiple target organs within various species, including small and large animals. Contrast agents, such as microbubbles, can be functionalized with specific molecules, such as monoclonal antibody, thus improving image quality (Lindner, 2004). Micro-US is a useful tool for measurement of internal volumes.

Ultrasonography is practiced in various formats such as brightness mode (B-mode), motion mode (M-mode), Doppler (including both color flow and spectral Doppler), and contrast-enhanced imaging. A distinct advantage to the utilization of ultrasonography is simply the many applications that can be practiced in preclinical development. Subjects can be imaged at multiple time points within a given study, and multiple targets can be evaluated. A disadvantage is the lack of high-resolution capabilities, as well as the need for an experienced imaging expert to obtain the acceptable images for analysis. Poor image capture will ultimately lead to unsatisfactory data sets. Ultrasonography represents a noninvasive imaging solution that can be utilized to provide quantitative structural and functional data sets. Investigators have many options available through the application of ultrasonography to match the imaging format to the specific needs of their research projects.

26.8.1 Echocardiography

Echocardiography is the use of US technology to assess various aspects of cardiac function and morphology (Kaddoura, 2017). By using different echo windows (i.e., standard placements of the echo probe) and types of US propagation, qualitative information can be obtained regarding indices of cardiac size, systolic function, diastolic function, and hemodynamics. Furthermore, certain parameters are a reflection of an integrated input of cardiac functions and can be used to provide a global impression of cardiac function (Table 26.2).

In the present studies, the parameters measured varied due to differences in heart size, anatomy, species, movement artifacts, and the equipment used. However, certain parameters are constant across all studies, and these are used for comparative purposes. Two such parameters (or surrogates) are also those used in the Common Terminology Criteria for Adverse Events (CTCAE), v3, an adverse event rating which is used for assessing adverse events during clinical trials. These parameters include an assessment of the left ventricular ejection fraction and fractional shortening of the left ventricle. A glossary of the terms used, how these reflect

¹Fluorescence is the phenomenon where absorption of light of a given wavelength by a molecule is followed by the emission of light at longer (visible) wavelengths.

²Microscope illumination is the radiation incident to a specimen.

³A molecule or part of a molecule that emits fluorescence following excitation with light.

TABLE 26.2 Glossary of Echocardiographic Terms and Changes Associated with a Decreased Cardiac Function

Parameter	Effect	Change in Cardiac Function
Heart size	A decrease is associated with a decrease in cardiac function, as there is a reduced volume	LVIDd: left ventricular internal diameter at end diastole (mm) LAD: left atrial diameter (mm)
Systolic function	FxS: fractional change in left ventricular diameter (%)	A decrease is associated with decreased cardiac function, reflecting reduced systolic contraction
	FxArea: fractional change in left ventricular area (%)	A decrease is associated with decreased cardiac function, reflecting a reduced area of systolic contraction
	LVIDs: left ventricular internal diameter at end systole (mm)	An increase is associated with decreased cardiac function, reflecting reduced systolic contraction
	PEP/LVET: ratio of the pre-ejection period to left ventricular ejection time	An increase is associated with deficits in contractility or high afterload, a relatively shortened period of systolic contraction
Diastolic function	VCFm: mean velocity of circumferential fiber shortening (circ s ⁻¹)	A decrease is associated with decreased cardiac function, reflecting a reduced rate of systolic contraction or reduced contractility
	IVRT: left ventricular isovolumic relaxation time (ms)	An increase is often associated with impaired myocardial relaxation
Hemodynamics	Heart rate (bpm) VTI: velocity time integral of aortic flow profile (mm)	Related to stroke volume decreased with a decrease in cardiac function
	VTI×HR: proportional to cardiac output (mm×min)	Decreased with a decrease in cardiac function
	AoVel: peak aortic velocity (mm s ⁻¹)	Decreased with a decrease in cardiac function
Global function	EPSS: separation of the mitral leaflets from the septal wall during the early wave of mitral flow (mm)	Increased with a decrease in cardiac function, may be associated with mitral regurgitation

indices of cardiac function, and how changes in these parameters reflect decreases in cardiac function are listed in Table 26.2.

26.9 NANOPARTICLE CONTRAST AGENTS

Nanoparticles have been found to be useful in a wide range of therapeutic applications. Used as devices, they can be used to target and treat (by selectively absorbing energy or delivering an anticancer agent) cancer. They can also be used, particularly in small animals, as contrast agents in micro-CT for small animals (Ashton et al., 2015).

26.10 RADIOPHARMACEUTICALS

Radioactive pharmaceutical agents (such as technetium) can be used as diagnostics or to enhance imaging (allowing evaluation of the functioning of tissues such as the brain, heart, lungs, thyroids, liver, kidney, gallbladder, and tumors) or as therapeutics (Kowalsky and Falen, 2011).

Another common use is in studying the metabolism of drugs in development. A small batch of a drug can be synthesized containing one or more radioactive atoms at selected locations in the structure. This allows qualitative and quantitative evaluation of the distribution, metabolism, and excretion of the drug molecules and their metabolites.

26.11 APPLICATIONS OF PRECLINICAL IMAGING IN LABORATORY ANIMALS

26.11.1 Molecular Imaging as an ADME Platform in Drug Screen

Traditional nonclinical studies on absorption, distribution, metabolism, and excretion (ADME) are currently conducted either by “cold” chemistry or by introducing a radiolabeled drug candidate into laboratory animals, usually rodents, and then sacrificing a certain number of the animals at times following dosing that represent each step in the ADME process. The animals are then either necropsied or sectioned and examined, and radioactivity is quantitated with scintillation counters or using quantitative whole-body autoradiography (QWBA), respectively, to demonstrate where the drug is distributed in high resolution, and how it is cleared from the body. This traditional approach to ADME is a labor-intensive process that requires several groups of animals, with three to five animals per group (if rodents) and five to ten groups, to capture temporal and dose-related changes in the data.

PET, SPECT, QWBA, fluoroscopy, high-resolution US, optical imaging, and other imaging techniques offer numerous benefits in ADME studies. The coregistration of PET/CT and SPECT/CT imaging enables the measurement of rapid kinetic processes in real time and can therefore generate a more accurate picture of the ADME profile. Many of these imaging technologies allow the use of mice as animal models, thereby

reducing costs. *In vivo* imaging also provides biodistribution information in real time, as compared to the extensive postmortem evaluation procedures required for more traditional approaches (Wang et al., 2015).

In nonclinical imaging studies, animals can be imaged with the same radioisotopes as used in the clinic for humans but at dose levels adapted to the smaller subjects. As a result, successful preclinical studies in animals quickly translate to clinical studies on humans. Provided that small-animal imagers are indeed able to image small subjects with the same utility as humans in the clinic, the ability to use the same tracer in clinical trials as those used in nonclinical studies can result in significant efficiency improvements and time and cost savings when translated into humans in clinical practice.

As a result of these new imaging modalities being available for preclinical development, PET and SPECT imaging have important roles to play in both the nonclinical and clinical stages leading up to submission of a prospective therapeutic to the FDA for marketing approval. *In vivo* MI permits earlier determination of whether a given group of drug candidates will work or not in animal models. By using imaging to look at responses earlier in animal, safety can be further ensured, and resources can be saved by abandoning drugs that do not translate to the human model in favor of those that do by early “go/no go” decisions.

Microscopic imaging methods are also increasingly being recognized as a valuable tool in ADME testing, which can be employed in both *in vitro* and *in vivo* nonclinical studies. Microscope images can reveal multiple pieces of information on the cellular response to drug compounds in one experiment. This might include the simultaneous acquisition of data on drug–receptor binding and any morphological effects of drug treatment. The ability to use multiple protein-specific fluorescent probes in a single experiment is a key enabling technique in high-content imaging. Fluorescence microscopic imaging allows molecules beyond the resolution limit of the light microscope to be visualized (Giepmans et al., 2006). Fluorescence microscopy is a key technique in clinical diagnostic as well as research settings. Confocal⁴ fluorescence microscopy, in particular, has become an essential tool central to the study of structural and molecular dynamics in living cells. Time-lapse imaging can be used to monitor downstream drug effects and, ultimately, excretion from the cell. Once images have been digitally captured, it is also possible to examine the data retrospectively in response to new questions about the drug compound. Microscopy images have the advantage that they are easily machine readable with appropriate image analysis software. This makes microscopy amenable to medium- to high-throughput analysis. Motorized and computer-controlled microscopes are essential for automated

⁴Confocal microscopy is an imaging technique that eliminates out-of-focus light in specimens and enables 3-D imaging of thick specimens.

image capture and for incorporation into medium- to high-throughput environments.

Bioluminescent probes have also been used for ADME evaluation. There have been several reports in the literature published describing the synthesis and utility of bioluminescent probes that are substrates of CYP family of enzymes. CYPs are a critical focus of drug development efforts because they are the dominant drug-metabolizing enzymes. CYPs predominantly facilitate drug clearance and, in certain cases, activation of prodrugs into active compounds. The identification of CYP oxidation sites on newly designed drug molecules might guide redesign efforts so as to minimize breakdown by the CYP family enzymes while retaining its activity. Klaubert and colleagues presented a series of CYP-specific luminescent probes that could help uncover specific CYP functions against a background of multiple CYPs in samples such as liver microsomes and cultured hepatocytes.

It is ideal to have an imaging agent that selectively targets the target tissue, organ, or pathophysiologic lesions for best imaging contrast and diagnostic accuracy *in vivo*. Nevertheless, most of the dyes themselves are not target-specific. The *in vivo* performance of an imaging agent or probe can be complicated by its interactions with many biomolecules, membranes, and related cellular permeability or tissue penetration as well as PK processes including ADME. Therefore, it has been challenging to discover and develop an optimal imaging agent for *in vivo*, namely, targeted imaging.

26.11.2 Preclinical Imaging in Oncology

Cancer drug development has the lowest to market success rate of any therapeutic class and is protracted due to the nature of current efficacy markers. Many imaging techniques have been routinely used in the drug discovery process to directly monitor the therapeutic in blood and tumor tissues to evaluate the effects of the drug treatment in the context of tumor. Imaging recently emerges with increasing popularity as it can be used to monitor the changes at the molecular level *in vivo*, and it can help in evaluating treatment efficacy much earlier than traditional clinical end point. For example, FDG PET imaging is one of the most powerful MI techniques available for clinical use to detecting, staging, monitoring, and evaluating the prognosis of cancer (Reske and Kotzerke, 2001). In clinical practice, ¹⁸F-FDG could offer adequate contrast and tumor detection in several cancers, such as lung, colon, and breast cancers and lymphoma. However, the clinical result is not satisfying in other cancers, such as renal, head and neck, prostate, and pancreatic cancers. Therefore, new imaging probes are needed for early tumor detection in both preclinical and clinical research. Recently, one tumor imaging study aims at verifying the capability of ⁶⁴Cu-radiolabeled (a positron emitter; half-life, 12.7h) bevacizumab, an anticancer therapeutic antibody-targeting tumor angiogenesis, in detecting different types of

tumors in early stage of tumor model and comparing with the gold standard ^{18}F -FDG. The project used a different strategy from ^{18}F -FDG in order to accurately detect tumors in earlier stage and effectively decrease the nontumor-related hot spots in the background of the ^{18}F -FDG PET imaging. This preliminary imaging result illustrates that ^{64}Cu -bevacizumab would have superior properties as a new generation of tumor detection probe compared to ^{18}F -FDG probe in preclinical imaging study.

The imaging techniques can also be used to evaluate efficacy and therapeutic response of anticancer drug candidate in the same tumor model to minimize the subject-to-subject variability and reduce the number of animals required by more traditional methods. One efficacy imaging study represents a powerful way for tracking adoptively transferred T cells and studying their *in vivo* distribution and therapeutic effect in DUC18/CMS5 tumor model by micro-PET imaging. In the efficacy study, the anti-Thy1.2 antibodies conjugated to 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) and radiolabeled with ^{64}Cu were administered to three groups of BALB-Thy1.1 mice on days 4, 7, or 14 post-DUC18 T-cell transfer. The imaging probe successfully detected the transferred cells in tumor tissue and imaged the size and shape of the tumors in the same living subject for therapeutic evaluation. Information obtained from the *in vivo* T-cell trafficking studies could aid in designing protocols that would enhance the efficacy of tumor-specific T cells. The cutting-edge imaging technology helps us further understand the area of trafficking behavior of adoptively transferred tumor-specific T cells and improve efficacy study with much fewer animal numbers since the same animal can be repeatedly imaged in different days posttreatment when tumor grows or be ablated during the treatment.

On the other hand, various optical imaging techniques can be used in combination, either simultaneously or sequentially, to provide information from cancer cells and tumor tissues in living animal models. Among them, both fluorescence and bioluminescence imaging techniques have found wide applications for *in vivo* tumor optical imaging in mouse models. These approaches afford the collection of convenient, frequent visualization and measurement of tumor biomarkers in a real-time, sensitive, and noninvasive way.

One of the most successful imaging modes for preclinical imaging study is optical imaging technique which has been largely exploited to monitor the progress of practically all strategies for gene and cell therapy, regardless of vector or indication. The ability to image host responses to both vector administration and therapeutic interventions provides crucial data for clinical translation. By using a combination of bioluminescence and fluorescence, the efficacy of gene transfer as well as therapeutic response can be monitored simultaneously. A variety of vector studies which include viral vectors and plasmids have been combined with bioluminescence for analyzing and understanding the effect of gene transfer to a

variety of tissues and of physiological conditions such as tumors, autoimmune disorders, neurological conditions.

One of the earliest uses of optical imaging probes for MI purposes involved the use of bioluminescent reporter probes. The fusion gene reporter system is an indirect imaging strategy where two or more genes are fused together under the control of a single common promoter giving rise to a single polypeptide or transcript. The output of fusion reporter genes is often in the form of fluorescence from a light-emitting gene such as GFP or RFP as well as other reporters such as the luciferase reporter which generates fluorescence upon addition of a substrate such as luciferin. This system provides the ability to noninvasively obtain molecular information in systems ranging from a single live cell to the multicellular environment of an animal which holds tremendous potential for studying cancer metastasis, efficacy of drug therapy, and many other applications in a preclinical imaging in laboratory animal. They can also be used for imaging of other disease models such as inflammation as demonstrated by Yaghoubi et al. (2007) using a mouse model of arthritis-induced inflammation; the authors were able to successfully image migration of T cells into the inflamed paws. Another use of reporter genes is the ability to study drug-protein interactions. A drug can activate a specific protein whose expression can be analyzed by optical reporters. Enzymes are a class of proteins, whose expression levels in various diseases models can be easily monitored by use of fusion reporters. Ray et al. developed a multimodality sensor that comprised of a bioluminescent, a fluorescent, and a PET reporter gene linked together by a four-amino acid spacer (DEVD), a classical caspase 3 cleavage site. The activation of the caspase 3 through regulators of apoptosis could be easily visualized by all the three modalities including bioluminescence and fluorescence. This system could be used for screening of apoptosis activators/inhibitors in a preclinical drug development.

Activatable probes as described earlier are an interesting class of MI probes. These probes are designed to generate a signal in response to specific biological stimuli. The signal generated is amplified and observed by use of optical imaging agent, which is one of the most popular modalities utilized. Most activatable probes are based on fluorescence activation methods. The idea is that in close proximity, a donor (fluorophore) and a quencher (acceptor) silence each other optically because of a variety of quenching phenomena such as fluorescent resonance energy transfer (FRET), dark-quenching mechanisms, and nanoparticle-based surface energy transfer. These probes often described as “molecular beacons” are activated in the presence of specific biomolecules or chemical stimuli, which generate an amplified fluorescence signal. The distance between the donor and acceptor molecules thus plays an important role when designing useful imaging probes.

Proteases (used as probes for cancer imaging) are enzymes which can break down proteins by hydrolyzing the peptide

bonds that link the amino acids in the polypeptide chains making up the protein. Proteases are known to be overexpressed under different pathologic conditions including cancer. To date, various activatable probes have been developed to detect and image representative cancer-related proteases, such as matrix metalloproteinases (MMPs), cathepsins, and caspases. A dual-labeled MMP-7 activatable peptide probe was designed for potential use in imaging MMP-7 activity in tumors. It comprised of a quencher NIRQ820 linked to a donor Cy5.5 through a linker (GVPLSLTMGC polypeptide chain) which is a well-known substrate for MMP-7. Another class of quenchers used for design of activatable probes involves use of dark quenchers which have no known fluorescence from the visible to the NIR spectrum. Black Hole Quencher (BHQ) dyes are one of the commercially available dark quenchers and are able to permit efficient quenching. Studies have demonstrated that the synthesis of an MMP-13 activatable peptide probe was designed using a combination of the known MMP-13 substrate GPLGMRGLGK and Cy5.5 and BHQ-3. The study showed a 32 times increase in the optical signal following incubation with MMP-13. The specificity of the peptide substrate was also observed following a decrease in optical signal when cotreated with an MMP-13 inhibitor. Tsien and colleagues developed a similar probe called as activatable cell-penetrating peptide. This system allows for the intracellular transportation of the probe following hydrolysis by extracellular peptidases. The transportation of the probe only occurs following protease-specific activation.

Apoptosis or programmed cell death plays an important role following cancer treatment. Noninvasive approaches to monitor apoptosis will allow for determining the efficacy of existing as well new antitumor therapies in a preclinical and clinical setting. Caspase families of enzymes are known mediators of apoptosis.

Activation of imaging probes linked with caspase target polypeptides could allow for imaging of apoptosis in cells.

Macromolecules such as polymer-based systems, dendrimer, and antibodies have been used for development of MI agents for cancer and other disease models. Enzyme incubation leads to a 12-fold increase in signal under *in vitro* conditions. Dendrimer and other macromolecules such as chitosan-based polymers have been used in a similar manner for MI of cathepsin as well as caspases under *in vitro* as well as *in vivo* conditions. Antibodies have also been studied for developing imaging moieties to specific targets in cancer. Antibody imaging can provide a sensitive, noninvasive means for characterizing cell surfaces. Kobayashi and colleagues have developed a series of antibody-conjugated optical imaging agents. Indocyanine green (ICG) was conjugated to a variety of monoclonal antibodies targeted toward a variety of receptors such as anti-CD25, antiepidermal growth factor receptor 1 (EGFR1), and antihuman epidermal growth factor receptor 2 (anti-HER2). These conjugates are nonfluorescent as the fluorescence is quenched because of the proximity of the antibody

and the fluorescent dye. But intracellular uptake of the antibody by tumor cells and further breakdown allows for fluorescence recovery of the dye for imaging tumor cells. This methodology has been used successfully to image tumors overexpressing certain markers under *in vivo* conditions. Integrins are class of proteins which have a wide variety of functions in mediating cell–cell communication and cell–extracellular matrix interactions. They have wide variety of roles including promoting angiogenesis, cell migration, and cell survival. They have been implicated in a wide variety of cancers such as glioblastomas, melanomas, breast cancer, and head and neck tumors, among others. The most extensively studied integrin is the $\alpha\beta3$ integrin. It is known to bind to a specific ligand, a 3-amino acid polypeptide chain, consisting of arginine–glycine–aspartic acid (RGD). This polypeptide is associated with many receptors such as vitronectin, fibronectin, and thrombospondin that have been associated with many cancers such as brain, ovarian, breast, prostate. Imaging of $\alpha\beta3$ integrin can provide a lot of information about the tumor at the structural, functional, and even molecular level. *In vivo* studies demonstrated high tumor contrast of the targeted probe and good delineation of the tumor. Subsequent studies have shown the use of a wide variety of contrast agents conjugated with the cRGD peptide for imaging a variety of tumor models. Molecular modeling studies have identified preferential interaction of the cRGD sequence with the $\beta3$ subunit of integrins relative to the αv subunit, suggesting that most probes mainly target the $\beta3$ integrin but not the heterodimer $\alpha\beta3$. RGD peptides have also been used for imaging of ischemia in mouse models. In the cardiovascular setting, angiogenesis is triggered by hypoxia and ischemia, and its major consequence in tissues is the restoration of perfusion and oxygenation. RGD dendrimers have been developed for multimodal imaging of limb ischemia in mice (Sinusas et al., 2008). The newer research focuses on developing multimeric compounds for imaging tumors including multivalent ligand–receptor interactions for improved MI. Similar approach has been used for imaging other overexpressed biomarkers such as folate receptors for image-guided resection of ovarian cancer. Van Dam et al. reported the development of folate receptor-targeted fluorescent probe (van Dam et al., 2011). The folate molecule was conjugated to FITC for image of folate receptor-positive tumors (FR +ve). The newly designed MI probe was used under intraoperative conditions for identification of folate-positive tumor cells for possible resection. In the pilot study, the injected probe was found to be safe and offer specific and sensitive real-time identification of tumor tissue during surgery in patients with ovarian cancer and the presence of FR- α -positive tumors.

The use of targeted fluorescent agents could provide a paradigm shift in surgical imaging as it allows an engineered approach to improving tumor staging and the technique of cytoreductive surgery, thereby improving the outcome in various cancers.

Nanoparticles have also been utilized for developing agents for fluorescence imaging of cancer and other modalities. Metal-based nanoparticles such as quantum dots (QDs) and gold nanoparticles (AuNPs) have been investigated extensively as agents for optical imaging. These possess unique characteristics such as high photostability, low-quenching properties, and high luminosity. QDs are a class of nanoparticles made from semiconductor metals which based on size and composition can generate light over wide spectrum ranging from visible to NIR.

An interesting concept would be to attach multiple fluorescent dyes on the surface of the QDs. The increasing number of the fluorescence molecules proportionally enhances the overlap integral between the QD and the fluorophore acceptor and can reduce their PL emission. The linker between the QD and fluorophore can be specifically designed to be the substrate of an enzyme of interest. Addition of the enzyme will lead to fluorescence recovery allowing for imaging of specific biomarkers. Antibodies conjugated to QDs have also been used for detection of tumors. Nie and colleagues have synthesized QDs targeted toward prostate cancer cells by use of antibodies recognition of the prostate-specific membrane antigen (PSMA). The fluorescence imaging indicated the high tumor targeting after the injection of QD-PSMA Ab conjugates. But there are issues with poor penetration and high autofluorescence following injection of the conjugates. Other approaches for MI involve use of bioluminescence-based detection and fluorescent proteins conjugated to QDs. Bioluminescence resonance energy transfer (BRET)-based imaging moiety was developed by Rao and colleagues. The authors' conjugated Renilla luciferase mutant (Luc8) fused with an MMP-2 substrate polypeptide sequence to QDs. The addition of MMP-2 to this preassembled QD-substrate-Luc8 reduced the BRET ratio and enabled the detection of MMP-2 activity with high sensitivity. QDs have also been used for mapping of sentinel lymph nodes, a site for metastatic tumorigenic cells following primary tumor development. Frangioni and Bawendi first reported the use of NIR QDs in labeling lymph nodes in living subjects. Experiments performed in small and large animals such as mouse and pigs allowed for high-resolution imaging of sentinel lymph nodes using NIR CdTe/CdSe QDs. The mapping allowed for resection of the lymph node up to a 1 cm depth indicating the usefulness of SLN mapping for fluorescence-based resection of tumorigenic lymph nodes. Peptide conjugated to QDs have allowed for active targeting and subsequent imaging of tumors. Ruoslahti and colleagues have reported the discovery of novel peptides targeting the endothelium and lymphatic vessels surrounding the tumor. Peptides such as CGFECVRQCPCRC (denoted as GFE) which binds to membrane dipeptidase on the endothelial cells and KDEPQRRSARLSAKPAPPKPEPKP KKAPAKK (denoted as F3) preferentially bind to blood vessels and tumor cells in various tumors. The peptide CGNKRTRGC

(denoted as LyP-1) which recognizes lymphatic vessels and tumor cells in certain tumors conjugated with QDs has shown to be extremely encouraging for fluorescence-based imaging of various types of tumors. Chen et al. have shown the use of cadmium- as well as noncadmium-based integrin $\alpha\beta3$ -targeted QDs for imaging of gliomas in mice models. These QDs showed high concentration in tumor sites, and immunofluorescence studies confirmed that the majority of the QD fluorescence signal in the tumor colocalized with the tumor vessels. The high efficiency of conjugation for the synthesis of QDs and peptides along with the good sensitivity and specificity of these conjugates to image tumors warrants the further development of such agents for *in vivo* molecular diagnosis of tumor, including early detection as well as image-guided resection of tumor via surgery.

AuNPs have been shown to be promising candidates for biomedical applications (Gad et al., 2012; Stern et al., 2015). They are biocompatible and easily functionalized for attachment of a variety of ligands such as DNA, peptides, proteins, and antibodies for developing target-specific agents. Their unique surface plasmon resonance absorbance allows for distinctive optical properties which can be used for sensing and imaging biomolecules. It has been noted in the literature that attachment of fluorescent molecules to the AuNP surface allows for unique interactions leading to the development of a highly quenched state. These have led to the development of a number of AuNP-based imaging probes. The construct was based on an MMP-2-sensitive peptide sequence conjugation Cy5.5, a fluorescence dye and AuNP. The quenching of Cy5.5 was accomplished through NSET interactions with the AuNPs as well as self-quenching through FRET. Incubation with the enzyme MMP-2 under *in vitro* conditions caused the cleavage of the peptide leading to fluorescence recovery. The probe showed similar results under *in vivo* conditions in mice bearing MMP-2-positive SCC7 tumors. Carbon nanotubes have also found use as potential optical imaging agents. Robinson et al. were one of the first to report the use of carbon nanotubes as potential dual imaging as well as therapeutic agent for cancer imaging and therapy. SWCNT distribution within tumors was tracked at a high spatial resolution due to their intrinsic optical properties. This was one of the first reported uses of carbon nanotubes as candidates for image-guided photothermal treatment of cancer. Magnetic nanoparticles functionalized with fluorophore Cy5.5 and loaded with siRNA have allowed for sensitive detection of siRNA delivery in animal models with both optical imaging and MRI. MRI also allows for monitoring of long-term therapeutic efficacy following injection of the nanoparticles. Other nanoparticle platforms such as polymeric nanoparticles, silica nanoparticles, and liposomal formulations have all been reported for preclinical optical imaging of cancer, CNS, inflammation, cardiac diseases, and other disease states.

26.11.3 Preclinical Imaging of CNS Disease

Neurodegenerative diseases, such as Alzheimer's disease (AD) and Parkinson's disease (PD), are becoming an increasingly urgent public health concern, particularly among aging populations. PET and SPECT imaging of brain functions help illustration on mechanism and progress of AD and PD in molecular level.

PD is associated with nigral degeneration and striatal dopamine deficiency and is not known to occur in any species other than humans. Therefore, the most widely used animal model for this disease is the toxicity induced in the nigrostriatal pathway of C57BL6 mice following the administration of 1-methyl-4,1,2,3,6-tetrahydropyridine (MPTP). The ^{18}F -FDG PET reveals reduced lentiform nucleus glucose metabolism. Noninvasive functional imaging of dopaminergic change in the striatum was assessed by using PET to visualize and quantify the uptake of ^{18}F -dopamine in the brain of PD animal model.

Showing striatal dopamine terminal dysfunction with PET supports the diagnosis and rationalizes the use of dopaminergic medications. PET imaging can detect changes in striatal dopamine levels after ^{18}F -dopamine administration and correlate these functional changes to motor responses.

The neurobiologic processes support the use of metabolic imaging technique, namely, ^{18}F -FDG PET imaging, in the study of AD as brain perfusion imaging. Amyloid imaging has been used in studies seeking to elucidate the natural history of AD and early detection and monitoring of the treatment of AD.

One of the applications of optical imaging includes cell tracking following transplantation in cases of neurological disorders and stroke by use of bioluminescence. Kim et al. (2004) used BLI to track murine C17.2 NPCs after transplantation in a murine model of stroke. Their aim was not only to follow migration but also to study possible proliferation and quantification of the transplanted cells. It was found that the maximum photon emission was observed at the site of experimental injury. The signal was maintained for 7 days following injection of the cells. Migration was observed to the ischemic site following injection. This migration was not seen in healthy animals indicating clearance of the cells from the animals. QDs have also been used for stem cell trafficking with good success. Kawabori et al. have demonstrated the use of QDs with NIR fluorescence for *in vivo* tracking of cells within the brain. Using a permanent model of middle cerebral arterial occlusion in rats, the authors tested the potential of bone marrow stromal cells for functional recovery when transplantation occurred 7 days poststroke via two different delivery routes. Intracerebral transplantation of cells was found to be the best mode of transplantation as fluorescence was detected for 7 days following transplantation. No fluorescence was observed following intravenous transplantation. The fluorescent probes mentioned earlier need to be excited by an external light source, which makes the excitation of deeply transplanted cells difficult. Two-photon or multiphoton excita-

tion techniques have been proposed in the literature to overcome this issue. Chronic neurodegenerative diseases have also been imaged at a preclinical level using fluorescent agents. Beta-amyloid peptides were labeled with Cy5.5 and used for imaging transport in normal as well as P-glycoprotein/ABCB1 and BCRP/ABCG2 pump-deficient mice. The increased accumulation of beta-amyloid peptides is correlated with AD patients and elder nondemented patients. Such studies could be useful in evaluating kinetics of brain elimination of intracerebrally injected compounds for a variety of diseases.

26.11.4 Preclinical Imaging of Autoimmune Disease

Autoimmune diseases are a heterogeneous class of diseases characterized by chronic inflammation of the target organ and often requiring lifelong treatment. One of the most important progress in the study of autoimmune diseases is the development of modern MI techniques by the production of specific radioactive probe which contributes to the identification of immune process responsible for various autoimmune diseases, such as rheumatoid arthritis (RA), age-related muscular degeneration (AMD), type 1 diabetes mellitus (IDD), and Crohn's disease. These imaging studies described a novel detection system for determining the localization patterns of arthritogenic anti-GPI IgG in the joints of normal healthy mice, using rodent-scale PET (micro-PET). The micro-PET R4 scanner permits dynamic noninvasive high-resolution imaging of radiolabeled GPI-specific IgG in mice at multiple time points. The dynamic PET imaging results illustrated that anti-GPI IgG rapidly localized within minutes to distal joints of the front and rear limbs and remained there for at least 24 h.

The fluorescence imaging can be used for monitoring immune responses and demonstrating the tissue specificity of the construct in laboratory animal models. A similar approach was used for detection of reactive oxygen species (ROS) found commonly in patients with RA and malignant tumors. Under these conditions, there is also an overexpression of hyaluronidase which degrades hyaluronic acid (HA). Park et al. have demonstrated a probe to measure the ROS generation by conjugating an NIR fluorophore to a thiolated HA which can be attached to AuNPs. The newly synthesized nanoparticle allowed for ROS detection in laboratory animal models of RA and metastatic ovarian cancer. The signal intensity derived from the abnormal tissues was significantly higher than other systemic organs.

26.11.5 Imaging Animal Model of Infectious Disease

Infectious diseases are the second leading cause of death worldwide. As age progresses, the immune system undergoes numerous changes that may affect our susceptibility to infection. Laboratory animal imaging has become an important research tool in studies of infectious diseases and has

significantly contributed to both our understanding of pathogenesis and preclinical investigations on drug development.

The mouse model of *infectious disease* has been extensively investigated worldwide. An important caveat to the epidemiological studies is that they usually combine several different routes of infection. Some studies have indicated that the route of infection with *Francisella* is an important determinant of bacterial dissemination as well as disease progression and outcome. In a PET study, $^{64}\text{Cu}(\text{II})\text{-PTSM}$, a tracer for detecting hypoxia, was used to radiolabel *Francisella tularensis* and to evaluate the bacteria trafficking of different routes in mice. PET imaging study shows the dissemination of *F. tularensis*, the cause of tularemia, when administered intranasally (i.n.), intratracheally (i.t.), intragastrically (i.g.), intradermally (i.d.), intraperitoneally (i.p.), or intravenously (i.v.) in mice. The results demonstrated that *Francisella* rapidly disseminates within hours to multiple tissues via most routes of administration, although different trafficking patterns were observed. Infection via the pulmonary routes resulted in rapid spread to the lung and gastrointestinal (GI) tract. In fact, this direct radiolabeling and imaging strategy can be used for study of various laboratory animals of infectious diseases since the noninvasive imaging techniques permit enhanced information through longitudinal studies of the same animal during the infection process. The future development of multimodality MI studies for investigating the pathogenesis of infection will provide researchers multiple tools to have a positive impact on treatment of infectious diseases.

26.11.6 Preclinical Imaging of Cardiac Disease

Imaging-based approach on noninvasive evaluation of myocardial function plays more and more important role for preclinical imaging research and clinical practice, such as for myocardial metabolism, congestive heart failure, atherosclerosis, thrombosis, and stem cell therapy in myocardial infarction. PET and SPECT/CT imaging are most effective if motion artifacts can be filtered out. This is typically performed by using physiological monitoring equipment to introduce “gating” tags to the raw acquisition data, indicating the start of the cardiac and respiratory cycles by ^{201}Tl - and $^{99\text{m}}\text{Tc}$ -labeled radioactive probes.

In the use of a combination of bioluminescent cells and fluorescent probes, Weissleder et al. (2010) have been able to image the beating of heart cells at a cellular level in live mice. Combined with the intravital microscopy and multiphoton imaging, the authors demonstrate the *in vivo* optical sectioning and dual-channel time-lapse fluorescence imaging of cardiac ischemia. The NIRF imaging has also been used for imaging of plaques in coronary arteries. Weissleder et al. (2010) have developed an NIRF catheter for intravascular imaging of protease activity. The catheter used for the study was of clinical grade and allowed for efficient visualization of plaques in a rabbit model using a commercially available

NIRF agent called ProSense[®]. This study allows for the theranostic use of NIRF imaging of plaques in high-risk patients, thus potentially reducing incidences of acute coronary syndrome with interventional pharmaceutical or mechanical interventions.

Optical imaging technology has also played an important role in the risk minimization and improved clinical translation. The idea is to select fluorescent molecules that will allow for the maximum possibility of long-term clinical success. This will allow for accelerated use of fluorescence-based methodologies in humans. Besides camera-based fluorescence imaging methods, advanced photonic approaches including multispectral optoacoustic tomography (Ntziachristos and Razansky, 2010) or fiber-based confocal methods can further improve the theranostic and diagnostic potential of optical MI in laboratory animal models of human cardiovascular diseases and thus translate to future clinical practice.

All the techniques described to this point are considered and regulated as medical devices. Radiopharmaceuticals and imaging agents, which are injected parenterally into the body or administered orally (in the case of GI tract contrast agents such as barium), are considered to be and are regulated as drugs. As such, we will now consider required nonclinical safety evaluation.

26.12 NONCLINICAL SAFETY ASSESSMENT FOR IMAGING AGENTS

As our tour of imaging modalities and some of the established classes of imaging agents should make clear, this group of molecules covers a diverse range of structures. All are not intended to chemically or metabolically interact with the body to achieve their desired function, but nevertheless can have toxicity.

Characteristics which are considered relevant to potential safety include the following:

1. Mass dose—How much is administered?

Doses of imaging agents are usually small, though larger for a contrast agent than for a radiodiagnostic agent. As in all of toxicology, the lower the dose, the less likely are adverse events.

2. Route of administration

Imaging agents are administered by routes that best deliver them to their target tissues or regions of the body.

While this most commonly means a parenteral, some are administered by routes that decrease the likelihood of systemic adverse events (such as barium sulfate as contrast medium to the GI tract). Routes determine the potential for off-target hits or physiologic and

immunologic effects which greatly influence the potential for toxicity.

3. Frequency of use

Most imaging agents are administered once or infrequently over a period of time, limiting the possibility of either cumulative/chronic effects or of inducing adaptive immune responses. That is, decreasing the CT concentration and time aspect of dose as a metric of systemic exposure.

Accordingly, the nonclinical safety assessment programs need not include longer-term (3-month or longer) repeat-dose studies. When repeat administration of an imaging agent is possible in clinical use (such as when being used to monitor disease or recovery progression), preclinical repeat-dose studies of 14–28-day duration should be performed (FDA, 2004).

Biologic imaging agents are frequently immunogenic with repeat intermittent administration leading to development of antibodies which can alter safety, pharmacokinetics, and performance (Awe et al., 2021). Such studies should evaluate standard systemic toxicity parameters as well as pharmacokinetics and the formation of appropriate antibodies as well as whole-body distribution of same at the completion of repeat dosing. Human clinical data should also be assessed following repeat-dose clinical studies of biologic imaging (or diagnostic) agents but prior to application for licensure (FDA, 2004; Awe et al., 2021).

4. Biological, physical, and effective half-lives

As should be expected, it is possible that there are several half-lives to be considered. Radionuclides generally have short physical half-lives, which limit their effective half-lives. Persistence (PK) half-life may be different than effective half-life, which will also be the case for potential biologic effect half-life.

For our purposes here, imaging agents will be considered to include both contrast agents and diagnostic radiopharmaceuticals.

Contrast agents serve to improve our ability to visualize tissues, organs, and cells and physiologic/biochemical processes by sharpening the differences in imaging signal intensities between these and surrounding portions of an organism.

Diagnostic radiopharmaceuticals are intended for use in the diagnosis or monitoring of a disease, in whole or in terms of some monitorable part or manifestation of it.

These act by spontaneous disintegration of unstable nuclei emitting a photon or other nuclear particle. These usually are composed of a radionuclide component (technetium-99, iodine-123, indium-111, or such) and a nonradioactive component that is found to the radionuclide and serves to deliver it to a specific target cell, tissue, organ, or region of the body.

Generally, to open an IND for a nonbiologic imaging agent, the requirements are less extensive than for most drugs:

1. Safety pharmacology—Cardiovascular, respiratory, and central nervous system, plus any organ system that the agent is intended to visualize (Gad, 2015).
2. Expanded acute single-dose studies in two species (at least one nonrodent).
3. *In vitro* genotoxicity through conducting the complete three-assay battery as per ICH S2(R1) is advised.
4. Tissue tolerance and special studies as dictated by the route of administration.

Table 26.3 presents the current complete program up to NDA approval. Note that longer (>90-day) -term repeat-dose studies, carcinogenicity studies, and reproductive/developmental studies can be omitted. If larger doses are administered, osmolarity effects should be considered.

Diagnostic radiopharmaceuticals are recommended to have the following modifications due to their special characteristics and the way that they are used:

- Long-term repeat-dose toxicity studies in animals typically can be omitted.
- Long-term rodent carcinogenicity studies typically can be omitted.
- Reproductive toxicology studies can be waived when adequate scientific justification is provided (ICH S2A).
- Genotoxicity studies should be conducted on the non-radioactive component because the genotoxicity of the nonradioactive component should be identified separately from that of the radionuclide. Genotoxicity studies can be waived if adequate scientific justification is provided (ICH S2B).

There are special safety considerations for diagnostic radiopharmaceuticals, including verification of the mass dose of the radiolabeled and unlabeled moiety; assessment of the mass, toxic potency, and receptor interactions for any unlabeled moiety; assessment of potential pharmacologic or physiologic effects due to molecules that bind with receptors or enzymes; and evaluation of all components in the final formulation for toxicity (e.g., excipients, reducing drugs, stabilizers, antioxidants, chelators, impurities, and residual solvents). Specific safety considerations include an analysis of particle size (for products containing particles) and an assessment of instability manifested by aggregation or precipitation. We also recommend that an individual component be tested if specific toxicological concerns are identified or if toxicological data for that component are lacking. However, if toxicological studies are performed on the combined components of a radiopharmaceutical and no

TABLE 26.3 Timing of Nonclinical Studies for Nonbiological Products Submitted to an IND

Study Type	Before Phase 1	Before Phase 2	Before Phase 3	Before NDA
Safety pharmacology	Major organs ^a and organ systems the drug is intended to visualize			
Toxicokinetic and pharmacokinetic	See ICH guidances			
Expanded single-dose toxicity	Expanded acute single dose ^b			
Short-term (2–4-week) multiple-dose toxicity		Repeat-dose toxicity ^c		
Local tissue tolerance and special	Conduct as necessary based on route irritancy, blood compatibility, protein flocculation, misadministration, and extravasation			
Radiation dosimetry	If applicable			
Genotoxicity	<i>in vitro</i> per ICH S9	As per ICH S9		
Immunotoxicity			May be needed based on molecular structure, biodistribution pattern, class concern, or clinical or nonclinical signal	
Reproductive and developmental toxicity			Needed or waiver obtained	
Drug interaction				As needed
Other based on data results				As needed

^aSee the guidances S7A (“Safety Pharmacology Studies for Human Pharmaceuticals”) and S7B (“Safety Pharmacology Studies for Assessing the Potential for Delayed Ventricular Repolarization (QT Interval Prolongation) by Human Pharmaceuticals”) (note that S7B allows for phase evaluation of the required studies).

^bSee the guidance “Single Dose Acute Toxicity Testing for Pharmaceuticals.”

^cWhen repeat-dose toxicity studies have been performed, but single-dose toxicology studies have not, dose selection for initial human studies will likely be based on the results of the no-observed-adverse-effect level (NOAEL) obtained in the repeat-dose study. The likely result will be a mass dose selection for initial human administration that is lower than if the dose selection had been based on the results of acute single-dose toxicity studies.

significant toxicity is found, toxicological studies of individual components are seldom required.

Additionally, sufficient data must be submitted from non-clinical and clinical studies to facilitate reasonable calculation of both whole-body and critical organ radiation absorbed dose (see 21 CFR 312.33(a)(10)(ii)).

If the radiopharmaceutical is intended for pediatric use, the radiation absorbed dose should be provided for each of the age groups for which use is intended (neonate, 1-year-old, 5-year-old, 10-year-old, and 15-year-old are potential use classes) using appropriate anthropomorphic phantoms established in the literature (e.g., by the Medical Internal Radiation Dose (MIRD) Committee of the Society of Nuclear Medicine).

26.13 RADIOPHARMACEUTICALS

In research uses, both imaging agents and radiopharmaceuticals are generally excluded from IND requirements (21 CFR 361.1). If, however, there is an intention to use these clinically immediately for diagnosis or treatment, an IND is

required, and the nonclinical safety testing requirements laid out in this chapter are operative.

Therapeutic radiopharmaceuticals not only have the receptor interaction toxicodynamics concerns already addressed for nonradioactive molecules in this volume but also carry concerns for potential late (delayed) radiation toxicity effects. The FDA has promulgated a specific guidance (FDA, 2011) for the assessment of these concerns. Radiobiologics are specifically excluded from coverage by this guidance and indeed currently have no specific assessment guidances rather than those applying to biologics in general.

Therapeutic radiopharmaceuticals are typically administered systemically to treat cancer. For cancer therapy with curative intent, the radiation-absorbed doses delivered by therapeutic radiopharmaceuticals are comparable to those delivered with external beam radiotherapy (XRT) and are orders of magnitude higher than doses delivered by diagnostic radiopharmaceuticals. At therapeutic doses of radiation, the late radiation toxicities commonly associated with XRT (e.g., renal, pulmonary, neurologic, late bone marrow failures) can also be seen with therapeutic radiopharmaceuticals. With XRT, if the total dose given to an organ is less than its tolerance

dose, the probability of symptomatic late radiation toxicity to that organ will be minimal (Halperin et al., 2013). This type of toxicity should not be confused with the radiation-induced secondary malignancies for which the risk is known and accepted as unavoidable. The tolerance doses of most human organs for conventionally fractionated XRT are known and are routinely used to direct the administration of XRT at a dose and schedule that minimizes late toxicity. In the FDA's experience, however, there are few clinical data from which to estimate organ tolerance doses for therapeutic radiopharmaceuticals.

Organ tolerance doses for systemically administered therapeutic radiopharmaceuticals can differ significantly from the published tolerance doses for conventionally fractionated high-dose-rate XRT. With XRT, the dose received by an organ is determined by its proximity to the primary radiation beam and the tumor. Organs within the primary radiation beam and in close proximity to the tumor are at greatest risk. In the case of systemically administered radiopharmaceuticals, the dose received by each organ is determined primarily by the pharmacokinetics and biodistribution of the radiopharmaceutical agent. In addition, the range and type of the radiations emanating from the source organ are critical.

Radiolabeled drug-based therapy is an emerging and complex field with many potential dose-modifying factors such as dose rate and fractionation. Experience with external beam therapy demonstrates that with therapeutic doses of radiation, a relatively small percentage change in total dose could lead to a large change in the probability of complications after the tolerance limit of an organ has been reached. The organ tolerance doses for XRT are based on conventionally fractionated high-dose-rate therapy. Fractionation allows for repair of radiation damage between fractions. In contrast, therapeutic radiopharmaceuticals usually deliver a single dose of radiation at a low dose rate, where damage and repair of that damage occur simultaneously as competing processes. Therefore, organ tolerance doses for systemically administered therapeutic radiopharmaceuticals are not directly comparable to those for XRT. Radiation toxicity has been observed with therapeutic radiopharmaceuticals at estimated organ doses that were below the XRT tolerance doses for the target organs. The entity of low-dose hypersensitivity may account for this discrepancy, as well as could local region concentration of active emitters. Ionizing radiation causes injury to cells and tissues mainly by damaging nuclear DNA (Hall, 2018), although non-DNA targets have been described (Coppes et al., 2005). Most damaged cells continue to function normally until they die while attempting to undergo mitosis. Thus, the time frame in which radiation injury becomes clinically apparent is determined in part by cell turnover time.

In organs with a rapid cell turnover (early reacting normal tissue) (e.g., bone marrow, epidermis, small intestine, and oropharyngeal mucosa), symptoms of radiation injury (e.g., bone

marrow failure, desquamation, nausea, vomiting and diarrhea, and oral mucositis) appear within days to weeks of an acute dose of radiation. Radiation injury to these organs is called early or acute radiation toxicity and is often self-limiting and reversible. However, in organs with a slow cell turnover rate (late-responding normal tissue) (e.g., the brain, spinal cord, heart, lungs, liver, kidneys, bone, and bladder), symptoms of radiation injury (e.g., brain necrosis, paralysis, pericardial and myocardial fibrosis with left ventricular failure, interstitial pneumonitis and pulmonary fibrosis, liver or kidney failure, osteoradionecrosis, and hemorrhagic cystitis) do not occur until after a latency period of several months to years during which relatively normal organ function continues. Radiation injury to these organs is referred to as late radiation toxicity and is usually progressive and irreversible (Halperin et al., 2013).

Because acute radiation toxicity becomes apparent within a short time period after administration, proximity in time to radiation exposure can be used as an important criterion in determining whether the radiopharmaceutical is the cause of a particular complication or adverse effect. Such toxicities will become apparent early in a clinical trial, and the trial can be revised or terminated, as appropriate. In contrast, late radiation toxicity in organs such as the kidneys and liver or CNS will not become apparent until months or years after treatment, necessitating longer-term follow-up of treated patients.

With XRT, radiation injury is often limited to organs within the radiation beams, because more distant organs receive much lower doses. With radiopharmaceutical therapy, the risk of radiation injury to an organ is determined by both its intrinsic radiosensitivity and the concentration time–activity curve of the agent in that organ. For example, late radiation effects can occur if the kidneys receive a significant radiation absorbed dose from radiopharmaceuticals that are removed from the systemic circulation by glomerular filtration. The kidneys are known to have a relatively low radiation tolerance dose (23 Gray (Gy) for conventionally fractionated XRT); therefore, late radiation nephritis may be a dose-limiting toxicity for many therapeutic radiopharmaceuticals. Although the bladder tolerance dose is considerably higher (65 Gy), hemorrhagic cystitis can occur as a late effect unless the bladder is adequately irrigated to reduce residency time.

26.14 NONCLINICAL LATE RADIATION TOXICITY STUDIES

26.14.1 Study Goals

For treatment with therapeutic radiopharmaceuticals with curative intent, radiation-absorbed doses comparable to doses delivered by XRT must be delivered to the tumor. Because similarly high doses may be unavoidably delivered to normal

tissue, radiation toxicities commonly associated with XRT may also be seen with radiopharmaceutical therapy. Because the prescribed radioactivity is given with a small mass dose of the carrier, radiation toxicity, rather than pharmacological toxicity associated with the cold (nonradioactive) drug substance (formulation), is often dose limiting. Historically, non-clinical toxicity studies have been conducted mainly with the cold formulation. Although these studies usually have shown that the no-observed-adverse-effect levels (NOAELs) are many times the clinical mass dose, such studies assess the toxicity of the cold formulation only. Therefore, to assess the potential risk of late radiation toxicity in humans, it is important to conduct late radiation toxicity studies in animals. Such studies may allow the sponsor to

- Perform controlled experiments that are not ethically feasible in humans
- Identify organs at risk for late radiation toxicity
- Establish a NOAEL for late-occurring, irreversible radiation effects in an appropriate animal species to help select the clinical doses
- Compare the biological effects and tolerance doses of radiation delivered with radiopharmaceutical therapy to those of radiation delivered by XRT in specific organs
- Examine the pathologic changes and possible mechanism of injury
- Distinguish the toxicity of radiopharmaceutical therapy from that of other concomitant therapies
- Determine the amount of organ sparing that could be obtained by fractionating the radiopharmaceutical dose

26.15 STUDY DESIGN

There are challenges associated with the design and conduct of nonclinical late radiation toxicity studies. Therapeutic doses of radiopharmaceuticals require the administration of large amounts of radioactivity. The animals and animal waste will be radioactive, requiring radiation precautions to protect personnel and the general public. Precautions will also be necessary for the disposal of radioactive waste. Despite these challenges, such studies have been conducted and are recommended to optimize dosing and thus ensure safe clinical trials and patient care. Before initiating late radiation toxicity studies, the sponsor should discuss the specifics of the study design with the applicable review division and consider the following factors.

26.15.1 Good Laboratory Practices

Late radiation toxicity studies conducted for the safety evaluation of a radiopharmaceutical drug product should be conducted in accordance with preexisting requirements under

the regulations for good laboratory practices (21 CFR part 58) and the Animal Welfare Act (7 U.S.C. 2131 et seq.).

26.15.2 Species Selection

The sponsor should take into consideration the similarity in dosimetry, biodistribution, and PK profile of the radiopharmaceutical in the selected species and in humans. Suitable animal models to study late radiation toxicity are available. Rats have been shown to develop late radiation nephropathy and pulmonary fibrosis after external beam irradiation. Radiation-induced myocardial fibrosis has been shown to occur in rabbits and dogs. The sponsors should discuss with the applicable review division alternative developmental programs when appropriate animal models are not available to study late radiation toxicity.

26.15.3 Timing of Study

We recommend that the animal studies be scheduled to facilitate the conduct of clinical trials, including the selection of appropriate safety monitoring methods based on findings in such studies. To select the most appropriate species, human dosimetry and PK data using tracer doses should be obtained before initiation of the late radiation toxicity study. Several factors should be considered when assessing the relevance and the timing of the nonclinical studies: (i) the availability of human data following sufficient long-term follow-up in treated patients that might obviate the need for such studies and (ii) the recognition that therapeutic radiopharmaceuticals are sometimes developed to treat patients with no other viable treatment options or for patients who will not survive long enough to be affected by late radiation toxicity. Ideally, the studies should be completed before the start of phase II dose-escalation clinical trials, because late radiation toxicity may not be seen in the first dose cohort until after the entire trial has been completed. However, a phase II trial can, based on risk/benefit considerations, be initiated before completion of the late radiation toxicity study.

26.15.4 General Study Design

The study design should capture acute (occurring within the first few weeks after irradiation) as well as delayed (occurring after a prolonged latency) radiation effects. Clinically, late radiation toxicity is not observed until at least several months to years following the radiotherapy. In animals, late radiation toxicity usually occurs on a shorter time scale than in humans. For example, the latent period for radiation nephritis in rats ranges from 3 to 7 months. In dogs, renal dysfunction is observed by 10 months. Therefore, to obtain a reasonable estimate of the incidence of specific adverse effects, animals should be monitored for late radiation toxicity for at least 1 year after dosing.

To the extent feasible, the nonclinical study design should closely mimic the design of the anticipated clinical trials including similar amount of injected radioactivity, number of doses, frequency of dosing, and dosing interval, as well as the relative tissue turnover rate and the relative biodistribution and pharmacokinetics in the animal species and human. If both single and fractionated dosing will be studied in clinical trials, a two-arm study design evaluating late radiation toxicity after single as well as fractionated dosing may be necessary. If planned radiation doses in humans will require hematopoietic growth factor support or bone marrow rescue, it may be necessary to support or rescue the irradiated animals so that they will survive comparable doses to allow for late radiation toxicity observations.

Parameters that should be monitored are similar to those evaluated in expanded single- or repeat-dose toxicity studies. These parameters include clinical observations, food consumption, body weight, ophthalmologic examination, hematology, clinical chemistry, urinalysis, and postmortem investigations (e.g., necropsy, organ weights, macroscopic and microscopic examinations).

26.15.5 Dose Levels

Late radiation toxicity studies in animals should include at least four dose levels to identify the NOAEL and dose-related mild-to-severe late radiation toxicity. The study should also include the cold formulation (ideally, the cold isotope equivalent to the highest mass dose) as a control group to distinguish specific radiation effects from potential pharmacological effects of the cold formulation. The dose-limiting toxicities will be severe but are usually reversible (e.g., acute radiation toxicity related to the GI tract and bone marrow). Therefore, the highest dose selected should produce acute radiation toxicity. This dose should be at least twice the maximum planned human dose or radiation tolerance dose for the critical organ (TD5/5 external beam radiation) identified as a possible dose-limiting factor in clinical trials. The dose multiples should be expressed in terms of body surface area and radiation absorbed dose to the critical organs, when critical organs have been identified. The number of animals in each group should be sufficient to ensure survival of an adequate number to perform proper analysis at the completion of study.

26.15.6 Clinical Pathology

Hematology, urinalysis, and clinical chemistries should be performed before dosing, 2 weeks after dosing, then once every 3 months afterward, and at termination. In addition to a standard battery of hematology and clinical chemistry parameters, the study should also include the assessment of relevant biomarkers, if available, to identify late radiation toxicity for the target organ. For example, urinary gluta-

thione *S*-transferase isoenzyme levels can be monitored in addition to blood urea nitrogen and creatinine levels as markers for renal injury. We recommend that the study design be developed in consultation with the FDA to ensure that appropriate long-term toxicity indices are monitored.

26.15.7 Necropsy and Histopathology

Necropsy, including organ weights and macroscopic examination of various organs, should be performed for all animals in the study, including those that died during the study observation period. Detailed histopathologic and microscopic evaluation should be performed at termination.

27

OCCUPATIONAL TOXICOLOGY IN THE PHARMACEUTICAL INDUSTRY

27.1 INTRODUCTION

Most of the assessment of toxicology and safety of therapeutics is focused on the patients who are to benefit from the new medicine. However, there are two other groups of individuals (each of which has different exposure profiles) that one must be concerned about—the healthcare providers (nurses, pharmacists, and physicians) who provide and/or administer the drugs and the individuals involved in manufacturing them. The concerns here are in the realm of occupational toxicology.

Modern toxicology has its roots in the occupational environment. The earliest recorded observations relating exposure to chemical substances and toxic manifestations were made about workers. These include Agricola's identification of the diseases of miners and Pott's investigation of scrotal cancer incidence among chimney sweeps. Occupational toxicology, as its name implies, concerns itself with the toxicological implications of exposure to chemicals in the work environment (EEC, 1992; ACGIH, 2015).

Here we will examine occupational toxicology as it applies to and is currently practiced in the pharmaceutical industry and its support services. This industry, which by definition involves biologically active compounds, has been a driving force in the development of the science of toxicology. The need for a thorough safety evaluation of potential therapeutics prior to marketing approval has driven the continued evolution of toxicological testing methods and the identification of mechanisms of toxic action. The area of occupational toxicology gained great momentum in the pharmaceutical industry from the early 1980s into the twenty-first century including participation in developing TLVs (ACGIH, 2015). This is made clear by the increased number of companies that have implemented occupational toxicology programs during this period.

Yet, occupational-related activities generally represent only a small fraction of activity in safety assessment in the pharmaceutical and biotechnology industries. It is difficult to gauge the level of activity in this occupational area due to the paucity of publications on the subject (Teichman et al., 1988). This is probably the result of the fact that most occupational toxicologists' function in an administrative environment and thus experience less pressure to publish and that they in general deal with information relating to new chemical processes that may not be protected by patents. The lack of general knowledge about the function of the occupational toxicologist that has resulted could lead one to conclude that (i) the thorough evaluation of drugs to obtain marketing approval makes an investigation of their potential hazards to manufacturing employees unnecessary and (ii) because they are used therapeutically, pharmaceutical agents are safe under any and all circumstances in occupational settings.

27.2 OCCUPATIONAL TOXICOLOGY VERSUS DRUG SAFETY EVALUATION

While pharmaceutical products are indeed created to treat disease, they cannot necessarily be considered nonhazardous in all situations. The clinician must evaluate the benefits to the patient in light of any side effects or adverse reactions that may be associated with drug usage and any other toxicological properties uncovered in animal studies. Examples range from antibiotics, which have clastogenic properties in mice (for which, to the patient, its activity in suppressing life-threatening infections presents a clear and overriding benefit), to an antineoplastic, which has extreme renal toxicity, but which effectively kills established tumors. The occupational toxicologist must look at pharmaceutical agents

in a completely different light. These same risk/benefit analyses do not apply in an occupational setting. Even agents with minimal clinical adverse reactions and whose pharmacological activity could be considered generally beneficial in the clinical setting may present certain employees with health hazards in the manufacturing or healthcare provider settings.

Table 27.1 presents some of the basic differences in the way preclinical and occupational toxicologists must approach their work. Preclinical development of a pharmaceutical product requires exhaustive testing of drug candidates under the requirements of the US Food and Drug Administration (FDA) or equivalent national agency to help predict and evaluate clinical findings and to preclude serious or chronic hazards that would not ordinarily be observed in clinical studies limited in duration and population (FDA, 1990). By contrast, the occupational toxicologist must evaluate the potential of a compound to cause toxicity from unintended exposures via a variety of routes of administration and a wide range of exposure levels of varying lengths and from the perspective that in those that make and administer the drugs, there is no benefit and therefore any biological effect is undesirable. In drug safety evaluations, studies are designed to approximate the clinical setting, particularly in terms of routes of administration and dosage. Thus, most preclinical studies generally focus on oral and/or parenteral administration with dosages that either are comparable to or exceed therapeutic levels. However, neither oral nor parenteral administration is a likely route of exposure among employees. Rather, during manufacturing operations employees are more likely to be exposed via inhalation or direct contact with the skin or eyes. In addition to the route of exposure itself, the effects occurring following direct contact or inhalation exposure may be of a nature not predictable by the studies undertaken for preclinical safety evaluation. Most important among these effects are irritation and sensitization. Dermal, ocular, and respiratory irritation potential generally cannot be predicted from preclinical studies utilizing oral or parenteral administration. Similarly, sensitization, which has the potential to significantly add to the difficulty of conducting manufacturing operations safely, is difficult to evaluate even with current specific methods and models. For most pharmaceu-

tical agents, testing to ascertain the potential to induce dermal sensitization reactions is not conducted during a typical preclinical development program.

Other important differences lie in the length of treatment and the dosages involved. Therapeutic use of pharmacological agents may be of acute or limited duration, such as in the administration of anti-infectives, or chronic, as with antihypertensive agents. Occupational exposure may also be of varying length, limited by shift or batch manufacturing methods. It is possible, however, that the manufacture of certain high-volume products such as antibiotics may result in daily exposure, if only in limited doses, over a significant portion of a working lifetime. The levels to which employees may be exposed are, in general, potentially lower than those that are used therapeutically, although exposures will vary with the type of operations performed.

The area of occupational toxicology has received a great deal of attention in the chemical industry. Historically, the chemical industry has focused on the occupational environment and developed many of our current toxicological methods to address health and safety concerns. However, since the mid-1970s the chemical industry has increasingly become subject to testing requirements relevant to the protection of the environment and the public at large, as mandated by Environmental Protection Agency (EPA) regulations in the United States (EPA, 1976, 1979, 2016). Data development for occupational health hazard evaluation has seldom been sought by the Occupational Safety and Health Administration (OSHA). Consequently, few new test methods have been developed, and those in current use are generally modifications of methods introduced in the 1930s and 1940s. Some of the differences in the issues addressed by occupational toxicologists in the pharmaceutical and chemical industries are highlighted in Table 27.2. Among these, a major difference lies in the physical and functional nature of the substances involved. Pharmaceutical agents are generally handled as solids, while chemical industry products are generally processed as liquids or vapors. Although there is a greater focus on the consequences of occupational exposure, the occupational toxicologist in the chemical industry rarely has the available wealth of information that exists in the pharmaceutical industry. New drug dossiers include toxicological information

TABLE 27.1 Comparison of Occupational and Preclinical Toxicology

	Occupational	Preclinical
Purpose	Potential for effects from unintended exposure	Predict and evaluate clinical findings and preclude serious hazards from clinical use
Routes of administration	Inhalation, direct contact with skin or eyes	Oral and/or parenteral most likely
Dose level	Not really predictable	Relative to estimated therapeutic dose or maximum tolerated dose
Duration of exposure	Extremely variable; depends on campaign/batch, procedure, and so on; may be short daily exposure for working lifetime	Dependent on therapeutic use and test model

TABLE 27.2 Toxicological Testing Requirements under EC Seventh Amendment (Directive 92/32/EC-Notification of New Substances)

Quantity Imported to, or Manufactured in, EC	Test Results to Be Submitted
<1000 kg year ⁻¹ or <5000 kg total	None needed unless the compound is considered toxic (oral LD ₅₀ 25–200 mg kg ⁻¹) or very toxic (oral LD ₅₀ <25 mg kg ⁻¹)
>1000 kg year ⁻¹ or 5000 kg total	Acute oral/dermal LD ₅₀ , acute inhalation LC ₅₀ , skin irritation, eye irritation, skin sensitization, 28-day subacute toxicity, mutagenicity (bacteriological and nonbacteriological tests), acute toxicity to fish (LC ₅₀), acute toxicity to <i>Daphnia</i>
> 10000 kg year ⁻¹ or 50000 kg total	Additional tests may be required depending on results, including Fertility—one or two generation (males or females), Teratology—additional species, subchronic or chronic—90 days–2 years Carcinogenicity—acute and subacute on additional species

as well as data on the pharmacology, pharmacokinetics, and mechanism of action, and, most importantly, much of this information has been gathered from clinical trials on human beings. Even though the data are not developed for the purpose of evaluating the occupational environment, they can be invaluable for this purpose. Clinical studies, even if the doses and routes of administration may be different from those used in clinical trials/therapeutically, provide insight into the unique responses of the human body. Another important difference in the parameters involved in the chemical and pharmaceutical industries concerns biological activity. The chemical industry strives to minimize it, while pharmaceutical agents are specifically designed to be biologically active. Recent advances in our understanding of molecular and cellular processes have led to the development of agents with improved specificity for unique receptor or molecular targets. These potent agents may present increased hazards for employees and a great challenge to the occupational toxicologist in the pharmaceutical industry.

At the same time, several types of data necessary to ensure proper management of occupational risks associated with a drug substance are not generally useful in evaluating potential patient risks. So, the necessary tests—those to evaluate ocular and skin irritation, sensitization, and inhalation toxicity, as well as assessment of the hazards of by-products and impurities that do not get incorporated into the final therapeutic product—are not performed in the normal course of development.

27.3 REGULATORY PRESSURES IN THE UNITED STATES AND THE EUROPEAN COMMUNITY

The safety and health of workers in the United States is regulated under the Occupational Safety and Health Act of 1970, which established OSHA. Since its inception, OSHA has promulgated a variety of health standards, including compound-specific regulations, permissible exposure limits (PELs), and rules for providing access to medical records (OSHA, 1986) and for communicating to employees the hazards of the materials they handle. The last regulation, the Hazard Communication Standard (OSHA, 2012), is a standard that specifically requires manufacturers or importers to carry out an evaluation of the toxicological properties of chemicals. This standard outlines specific criteria for evaluating substances as hazardous or nonhazardous. However, there still is no US regulatory requirement for testing a compound of unknown toxicity (Gad, 2018). Rather, such a compound could be classified as nonhazardous, based on the unavailability of data. Pharmaceutical agents are generally considered hazardous under the standard since they meet the criterion of having a biological effect on humans. Any adverse reaction observed during clinical use will be construed as toxicity, however irrelevant to the occupational environment. The main result of classification as hazardous is a requirement to develop a Safety Data Sheet (SDS) as the main vehicle for providing to employees. The model SDS suggested for use in complying with the OSHA Hazard Communication Standard contains a great deal of information about the physical properties and hazards and the procedures necessary to deal with the accidental spill, fire, explosion, or accidental contact with hazardous material. The standard requires that all information regarding adverse effects in human beings and most animal toxicity data be included in the SDS, however irrelevant this information may be to the work environment. The resulting SDS can be a highly technical document that may not be the optimal vehicle for conveying this type of information to manufacturing employees handling pharmaceutical agents.

In the environmental area, the EPA's Toxic Substances Control Act (TSCA) (EPA, 1976) regulations for filing of pre-manufacture notification (PMN) (EPA, 1979) have resulted in the development of toxicological information on many new industrial chemicals. New chemical entities generated for use as pharmaceutical agents are exempted from PMN requirements. This exemption may also extend to all intermediates generated during chemical synthesis. Many pharmaceutical companies have instituted toxicological testing of these compounds even though there is no specific US regulatory impetus to develop such information. The European Community (EC) has implemented several directives that parallel and exceed the OSHA Hazard Communication Standard and TSCA regulations. The European Community Directive 80/1107

(European Economic Community (EEC), 1980) requires employee communication of hazards of chemical substances as well as biological materials. Another EC directive, which was the impetus for the development of New Substances Notification Regulations in several member nations, requires the development of toxicological data on new compounds and does not exempt pharmaceutical agents or isolated intermediates (EEC, 1979). Notification and testing must be conducted in accordance with the amount of the substance manufactured in, or imported into, Europe yearly (20.2). These regulations will support the development of toxicological data on entities manufactured or processed in Europe that can in turn be applied to occupational health hazard evaluations. Pharmaceutical companies are, as demonstrated in Table 27.3, very different from chemical companies in their handling of occupational toxicology.

27.4 ORGANIZATIONAL STRUCTURE

The occupational toxicology function is organized and structured in very different ways across the industry, particularly with so much of the sector now composed of small companies that are not. The function exists in many of the major PhrMA member companies. In most of these companies, the occupational toxicology function is located within the Employee Safety/Industrial Hygiene area, while in some, it resides within the Research and Development (R&D), Toxicology, or Employee Health/Medical Services areas. How the function fits into the organization greatly depends on its mission. Occupational toxicology will function well with the R&D environment if the evaluation of occupational health hazards is considered an integral requirement in the development and approval process. In such an organization, there would likely be a greater emphasis on developing toxicological data on novel compounds and their synthetic intermediates, rather than on

existing processes or such other activities as training. Most occupational toxicology departments are located within the Employee Safety/Industrial Hygiene areas. This organization provides great opportunity for interaction and cooperation with those disciplines that are charged with implementing the toxicologists' recommendations. Good interaction between the occupational toxicologist and the industrial hygienist can be particularly useful in developing and implementing solutions to potential health hazards. However, poor understanding of the limitations of scientific data by the more engineering-oriented safety specialists may lead to unrealistic expectations for easy solutions or answers. The last existing arrangement is for the occupational toxicologist to report into the Medical Services area. This arrangement provides perhaps the easiest interactions for the toxicologist, who shares a common language and understanding of biological systems with the occupational physician. However, in order to effect any changes in the work environment, it is necessary to enlist the aid of the Employee Safety/Industrial Hygiene group, an act that may incur the potential problems mentioned earlier. Clearly, wherever the function is located, the occupational toxicologist must be able to interact well with a variety of disciplines, including R&D, Safety/Industrial Hygiene, Medical Services, Legal Services, Regulatory Affairs, Technical Services, and, of course, Operations Management.

Staffing of industrial toxicology programs varies among the different programs, including groups with a single or a few full-time PhD's who spend all of their time on occupational issues and those with one or two PhD- or master's-level staff members who may have part-time responsibility for occupational-related issues along with R&D responsibilities. The level of staffing depends, of course, on the activities assigned to the occupational toxicology group, and these may vary from one organization to another. It is impossible to generalize or recommend an adequate staffing level, since that will be dictated by the emphasis placed on specific activities.

TABLE 27.3 Comparison of Occupational Toxicology in Pharmaceutical and Chemical Industries

	Pharmaceutical	Chemical
Compounds		
Physical state	Generally solids	Liquids, vapors, polymers, solids
Biological activity	Designed for biological activity	Strive for biological inertness
Toxicology data		
Development	Focus on preclinical evaluation	Focus on occupational and general environment
Study length	Acute to chronic for final products, acute for intermediates	Acute to chronic (depending on volume)
Human data		
"ADME" ^a	Generally available for oral/parenteral routes	Not generally available
Mechanism of action, adverse effects	Targeted during drug development Extensive clinical trial studies for final products from oral or parenteral route	Not generally studied. Generally only known as a result of overexposure, accident, and so on

^a ADME: absorption, distribution, metabolism, and excretion.

Whatever the mission of the occupational toxicology function, a high level of education or professional credentials is desirable. A doctoral degree and/or board certification in toxicology should be imperative to be able to interact effectively with many of the other disciplines mentioned earlier, particularly R&D management.

27.5 ACTIVITIES

The scope of activities of occupational toxicologists may be quite different from one organization to another, depending on its specific mission, resources available, and corporate culture. In general, their activities can be divided into four broad areas: data development, data evaluation and dissemination, hazard assessment, and employee training.

27.5.1 Data Evaluation and Dissemination

It is first important to establish who will use the toxicological information provided and how this information will be applied. Unlike the preclinical toxicologist who provides information to other toxicologists, to the regulatory agencies, or to physicians for evaluation of potential therapeutic liabilities, the occupational toxicologist is providing information to a variety of individuals and functions. First, the information will be provided to the industrial hygienist or safety specialist who must evaluate the quality of the work environment and the appropriateness of personal protective equipment. Second, the information will be given to the occupational physician who must evaluate the potential causes of any symptoms reported by employees who may have been exposed to the material. Third, R&D, plant management, and/or manufacturing services must evaluate the need to implement engineering or other controls and weigh these costs against the commercial viability of the product. Last, but not least, the information must be provided to the production employees who will be handling the compound and who need to know of its hazards. Clearly, there is a need to provide the necessary information in such a way that it can be clearly understood by nonscientists. With an audience of such a potentially wide-ranging educational level and understanding, multiple communication vehicles may be necessary.

To be effective, the toxicology evaluation must meet several criteria: it must be (i) thorough, (ii) clear and concise, (iii) in a form appropriate to its target audience, and (iv) include a conclusion or recommendation.

Thoroughness can be achieved through an exhaustive search of the published literature using the available computerized databases. There is a risk, particularly when dealing with pharmaceutical agents, that the most relevant information to occupational toxicology can be overlooked in the great number of clinical case reports, many of which are not rele-

vant to the work environment. In general, little information has been published on the occupational hazards of pharmaceutical agents. A thorough review does not mean a listing of every reported clinical adverse reaction. This type of information is more likely to confuse the reader and may lead him or her to ignore the important occupational hazards. The toxicologist must, therefore, be extremely selective in performing this evaluation. A review of the available clinical information, however, may yield data that can be used in evaluation, particularly if the product has been tested for dermal administration. An integral part of assuring the thoroughness of the evaluation must be a process of updating the information on a regular basis. In general, it is unlikely that new clinical data will significantly change a review for an established pharmaceutical agent. However, new therapeutic entities should be reviewed more frequently since new data may be published on potential adverse reactions not identified in clinical trials, and these data may impact the occupational evaluation.

When providing information to technical personnel, it is best to use language that does not require the use of a medical dictionary. It is tempting to use medical terms, particularly when quoting from the clinical literature. However, use of these terms may result in poor understanding of the information and may also evoke unnecessary anxiety in the reader. A good rule of thumb is to think of what the reader will do with the information: if the biological effect will require more than a few words to be clearly explained in plain language and it is irrelevant or unimportant to the work environment, it is best left off any communication to the field.

It is not always possible to reach a conclusion regarding the degree of hazard of exposure to a compound, particularly if the data are not directly relevant to the work environment. There is often a temptation to provide a thorough evaluation, setting out all necessary information in plain language but leaving the formulation of a conclusion to the reader. However, if it is difficult for the trained toxicologist to reach such a conclusion, it must be even more difficult for the layperson. If an estimate of the hazard cannot be reached, then the evaluation must be concluded with a recommendation of the type of exposures that may increase hazard or the type of effect that is most likely to occur should there be an overexposure. These may at least give the industrial hygienist or physician a useful reference point. At the same time, it is important to express to the reader the inherent limitations of such a conclusion. The audience may expect black-and-white answers; if this is not possible, they should be made to understand why.

Perhaps the most difficult part of the communication equation is the ability to match the information to the audience. This may be best illustrated using an example. Over the past 10 years, one company has developed several vehicles for communicating information to various audiences. One instrument is the toxicology review. In general, this is a one- to two-page

document that reviews the published literature on the compound. A reference list is prepared and maintained on file for future reference. This review is provided to safety, medical, and industrial hygiene personnel and, if appropriate, research chemists. These individuals have received training to help them understand the terms used and the effects outlined. A second method of communication involves a computerized database. This personal computer-based system, which provides only bottom-line information, is available online via a modem to safety, industrial hygiene, nursing, and research personnel (Sussman and Gáler, 1990). It includes only that information specifically relevant to the work environment and necessary for compliance with OSHA Hazard Communication Standard or EC Directive 80/1107. A third vehicle was developed jointly with an industrial hygiene department and consists of a short paragraph highlighting the specific hazards of the compound followed by safe handling recommendations. A fourth commonly used method is the SDS. The toxicology department prepares the toxicology section of the SDS. The appropriate other disciplines complete the remaining sections, and the completed SDS is then reviewed and approved by a committee. Lastly, for certain compounds, on-site training programs, such as those described in the following text, can be presented by the toxicologist on the hazards of the chemical. These various formats for the same information were developed to serve the information all needs and educational levels of various audiences. This is one approach to filling the need to communicate toxicological information to a variety of groups. The appropriate vehicle for each company will, of course, depend on the available resources and corporate culture. Even a large number of formats may not suffice. The occupational toxicologist should determine, through discussions and follow-up communications, how the information is received and if it is understood. The communication of toxicological information may represent approximately 50% of the occupational toxicologists' responsibilities, thus explaining the level of commitment to developing appropriate formats. The SDS alone is often insufficient for the successful communication of health hazard information to employees.

27.5.2 Data Development

The motivation for conducting toxicological tests for pharmaceutical, chemical intermediates, and impurities arises from the need to ensure the health of employees by preventing the occurrence of adverse reactions from occupational exposure. Employers thus secondarily minimize the associated potential for work interruption. Programs in place at many larger companies routinely test new drug candidates and/or isolated synthetic intermediates for the purpose of occupational health hazard evaluation.

The development of a toxicological testing program for occupational health hazard evaluation requires consideration of (i) the compounds to be tested, (ii) the stage of drug

development at which testing occurs, (iii) the specific tests to be conducted, and (iv) the means for funding.

These four issues are, of course, interdependent, and it is not always possible to deal with one without affecting the others. As indicated previously, drug candidates undergo extensive toxicological testing to ensure an adequate margin of safety for patients. Additional tests are usually required to obtain information specific to the work environment. By contrast, synthetic intermediates are generally not subject to testing for drug safety evaluation. These compounds, if they have the potential to present an exposure hazard to employees, may warrant evaluation. Clearly, it is neither feasible nor necessary to conduct the same level of testing required for drug marketing approval. However, a toxicological assessment can often be developed to determine whether these isolated intermediates have the potential to elicit toxicity from exposures that could occur during work.

Compounds should be selected for testing on the basis of an evaluation of potential exposure and likelihood of them causing adverse effects. The first evaluation is best achieved by including the research chemist, industrial hygienist, and/or safety specialist in the decision-making process. They are in the best possible position for judging potential sources of employee exposure. Including these disciplines in the pretesting stage ensures not only their commitment to the program but also that the studies will be designed with careful consideration of the work experience. The second evaluation, an estimate of toxic effects, may be obtained from a comparison of the compounds in question to known toxic agents, also known as a structure-activity relationship (SAR) evaluation, and the sophistication of available software programs for obtaining a quantitative estimate of toxicity using SAR models. However, it is most likely that an SAR evaluation will be achieved by simple comparison to the final product, similar pharmacological agents, or raw materials that have known toxic properties. Information on potential exposures and toxic effects can, thus, be utilized to decide which compounds to test or to assign priorities to compounds selected for testing.

The timing of these studies depends greatly on the developmental track for the test compounds and may vary for intermediates and final products. Discovery early in the development process that an isolated intermediate poses a significant health hazard may prompt a change in the chemical synthesis or process or in the implementation of engineering controls or personal protective equipment. Thus, it is generally useful to test intermediates at an early stage. This approach presents several practical problems. First, in a long development program, such as that occurs in the pharmaceutical industry, there are many opportunities for changing the synthetic route for reasons other than toxicity. Thus, a large percentage of the intermediates tested during the early development stages may be replaced in the ultimate manufacturing process. Second, only a fraction of new drug candidates actually reach the drug approval process. Therefore, the majority of intermediates

tested early in development process will likely never reach large-scale manufacture. Conducting a toxicological assessment of intermediates at a later stage in the development process presents a comparable set of advantages and disadvantages: it is more likely that the compounds tested will be manufactured on a large scale, but the ability to make fundamental changes in the chemical process will be greatly diminished. Testing of new drug candidates for occupational health hazards can be an integral part of the drug safety evaluation process. Acute oral toxicity is frequently evaluated as the first step in the drug's safety assessment. Adding acute dermal toxicity and, thus, skin irritation evaluation at the same time can often be accomplished with a minimum impact on the development schedule. This additional information can then be used not only to protect employees manufacturing supplies of the chemical but also those laboratory employees handling test doses of the substance. Eye irritation testing (*in vivo* or *in vitro*) requires minimal amounts of test compounds and could also be accomplished at the same time. Sensitization testing requires a greater commitment in terms of time and the quantity of compounds needed. Therefore, investigation of a compound's allergenic properties is often postponed until sufficient toxicological information is available to permit a decision as to whether the compounds will advance to the next stage in the development process.

Practical considerations of funding and the selection of the testing laboratory need to be addressed when developing an occupational toxicology testing program, and such are addressed in the chapter on contracting out of studies. As indicated earlier, if the activity is located within the R&D department, it may be simple to include the cost of conducting these tests within the new drug's development budget. There is a possible risk in this situation, however, that the safety and industrial hygiene communities may be inadvertently omitted from the prioritization process and the information loop. Explaining the necessity of testing programs to nonscientific management personnel may be challenging. Solutions to these barriers may be found with R&D funding of testing or designation of testing cost, thus possibly including these programs in research funds.

While there are no set regulations on what tests should be done or when these should be conducted and indeed no activity to preclude such testing on animal welfare grounds, there is general agreement as to the type of effects that need to be addressed: skin and eye irritation, sensitization, and acute oral and dermal toxicity. Testing for these effects generally involves studies of short duration. Thus, results can often be obtained relatively quickly. Additional tests for inhalation toxicity and/or sensory irritation are conducted by several companies.

Although there is general agreement on the effects to be investigated, the methods used have not necessarily been consistent. Several companies have developed protocols uniquely tailored to the needs of their workplace health hazard evaluation

and their in-house testing resources. The most common protocols utilized for occupational health hazard evaluation are briefly described on Table 27.4 (Gad and Chengelis, 1998).

These modifications included a combined protocol to assess acute dermal toxicity as well as skin irritation in rabbits and a stepwise approach to acute oral toxicity determination rather than a classic LD₅₀ (Gáler, 1989). Doses are selected based on regulatory criteria, such as those that are required for classification as a toxic under the OSHA Hazard Communication Standard and/or EC 80/1107. Testing for eye irritation involves a modification of current methods using rabbits. While in some views there is no justification for testing cosmetic products in live animals, eye irritation information pertaining to unique pharmacological chemicals is important to protect employees from accidental exposures. There should be careful consideration of whether a version of the rabbit eye irritation test or one of the currently available *in vitro* alternatives will best service the needs of the occupational toxicologist. Current protocols include refinements to the original method, including a reduction in the number of animals used, the application of topical anesthetics to decrease animals' sensation, and rinsing with distilled water following the instillation of the test compound to allow evaluation of the benefits of washing the eye as a first aid measure. Another refinement that may be utilized is a reduction in the amount of material instilled into the eye (Griffith and Yam, 1989). In general, modifications of this type have not affected the reliability of this test (Hatoum et al., 1990) and may, in fact, better simulate possible workplace accidents and provide additional information.

The battery of tests shown in Table 27.4 can provide useful information to complete a workplace hazard assessment. However, they are not the only tools that may be used to determine the toxic potential of a workplace contaminant. Additional tests may be required to provide more rigorous recommendations. Depending on the results of initial tests, a second stage of testing may be initiated to address specific needs. For example, sensory irritation tests may be conducted for compounds that are found to have irritant properties. The sensory irritation test, developed by (Alarie, 1966), is used to develop a parameter—the RD₅₀—that has been directly correlated with threshold limit values (TLVs) for a certain class of compounds (Kane et al., 1979; Alarie, 1981). However, the usefulness of this test for solid compounds, which include most pharmaceutical agents, has not been determined. Results of genotoxicity tests may present a need for testing in additional systems to assess genotoxic potential. Mechanistic studies may also be appropriate for certain compounds, such as intermediates, in the synthesis of inhibitors of specific enzymes or receptor agonists/antagonists. The information available from clinical, pharmacological, or pharmacokinetic studies on the final drug can be useful in determining possible avenues for investigation. A particularly interesting type of study, yet to be developed, might involve determination of the absorption and the bioavailability of compounds from

TABLE 27.4 Summary of Protocols Used for Current Test Methods

Test	Species	Method	Dose	Data Application	Additional Data
Acute toxicity					
Oral	Rat or mouse	$N = 5 \text{ sex}^{-1} \text{ dose}^{-1}$, 14-day observation period, necropsy with/without histopathology	Chosen as limit (0.5 or 5 g kg^{-1}) or for LD_{50}	Classify compounds as harmful/toxic/highly toxic	
Dermal	Rabbit	$N = 5 \text{ sex}^{-1} \text{ dose}^{-1}$, 24 h dermal application under occlusion, 14-day observation period, necropsy with/without histopathology, dermal irritation scores	Chosen as limit (2 g kg^{-1}) or for LD_{50}	Classify compounds as harmful/toxic/highly toxic, selection of protective equipment	Irritation potential class, target organ information
Inhalation	Rat or mouse	$N = 5 \text{ sex}^{-1} \text{ dose}^{-1}$, 4 h nose only or whole body exposure, 14-day observation period, necropsy with/without histopathology	Chosen as limit (20 g m^{-3}) or for LD_{50}	Classify compounds as harmful/toxic/highly toxic, selection of protective equipment	Respiratory irritation potential, target organ information
Skin irritation	Rabbit	$N = 3$; 4 h application under semiocclusive binder to abraded and nonabraded skin, irritation scores at ½, 1, 24, 48, and 72 h	500 mg site^{-1}	Classify irritation potential	
Eye irritation	Rabbit	$N = 3 \text{ group}^{-1}$; into right eye, compare to untreated eye; test only compounds with $\text{pH} < 12$ or > 2 ; score at 1, 24, 48, and 72 h and up to 21 days for corneal opacity, conjunctivitis, and iritis; may use a rinse with some animals	100 mg or 0.1 mL in standard protocol or 10 mg or 0.01 mL in low-volume protocol	Classify eye irritation potential, selective equipment	Evaluate first aid methods, ocular toxicity
Sensitization					
Buehler method	Guinea pigs	$N = 10\text{--}15$; topical applications one to three times per week for 3 weeks, 2-week rest then challenge at a naïve site; concurrent negative/vehicle and positive controls	Up to 500 mg or 0.5 mL dose^{-1}	Classify as sensitizer—most sensitive for moderate-to-strong sensitizers, selection of protective equipment, and evaluation of allergic reactions	Repeated dermal dosing, additional data on skin irritation, and dermal absorption
Maximization	Guinea pigs	$N = 10\text{--}15$; combines two intradermal +/- adjuvant and one topical occlusive administration for induction, 2-week rest then topical application for challenge at naïve site; concurrent positive and negative/vehicle controls	0.1 mL of compound in solution for induction, nonirritating concentration for challenge	May be sensitive to mild sensitizing agents but may also overpredict severity	
Local lymph node	Mouse (female)	$N = 5$, combines dermal exposure on ear with IV challenge by tail vein on 6th day with tritiated methyl thymidine	$25 \mu\text{L}$ of compound in solvent on each ear for 3 days	Does produce some false positives	No rechallenger possible

occupational exposures that could then be related to similar parameters developed in clinical or preclinical pharmacokinetic studies. The need to conduct additional testing will depend on the application of the information by the individual toxicologist and the resources available. The cost of additional tests should be weighed against the cost of applying the most conservative interpretation of the data to the work environment. In some cases, implementing stricter controls based on preliminary tests may be less costly than conducting more extensive confirmatory testing.

27.5.3 Occupational Exposure Limits (OELs)

In the manufacture of both active pharmaceutical ingredients (API) and final formulated drug products, before initiation of the manufacturing process for the materials, it is essential to determine what degree of protection is required for the workers during the manufacture and, from there, what steps must be taken (ranging from modest personal protective gear to having a fully contained—and separated from the operators—process).

The end result will be placing the subject material in a category. Such classification systems assign materials to categories ranging from 1 (the lowest level of concern) to either 5 or 6 (depending on the “system” used and the hazard level of concern). The most widely used system is SafeBridge (classes 1–5), but our firm and many others use a 1–6 system (see Table 27.6).

Uncertainty factors are used in response to data quality. The key point here is that production workers theoretically do not derive any health benefit from drug exposure and thus any biological effect is to be avoided.

There has recently been increasing pressure from governmental agencies and animal rights advocates to reduce the number of animals used in toxicological testing. As alternative toxicological methods become more accurate and sophisticated, they should be considered for incorporation into the occupational toxicology battery. Additional tools such as computer-aided quantitative structure–activity relationship (QSAR) evaluations may also be considered as additions or alternatives to animal tests (Jurs et al., 1985; Klopman, 1985; Frierson et al., 1986; Enslein, 1988). As indicated previously, QSAR methods may be particularly well suited to aid in the selection and/or prioritization of chemicals for testing, particularly in the case of intermediates. Alternative test methods currently under investigation, such as those being proposed for replacement of the Draize eye irritation test, do not appear to be well suited to the testing of pharmaceuticals or their synthetic intermediates (Booman et al., 1988, 1989). An intensive program of testing the available alternative models with compounds in this class is required to determine the ultimate usefulness of these alternative testing methods.

Occupational toxicologists from several companies supported a program to evaluate several experimental models as

alternatives to the rabbit eye irritation test (Gáler et al., 1993; Sina et al., 1994). As a result of this cooperative study, several of the participating companies have implemented the routine use of several of these alternative models in their test batteries (R.G. Sussman and J. Sina, personal communications, 2004), thus effectively increasing the number and classes of compounds evaluated in alternative models.

27.5.4 Hazard Assessment

Individual companies have, nonetheless, developed methodologies for establishing occupational exposure limits (OELs) based on the type of data available and other resources available to the company/public. One method involves a formula for extrapolating to an 8 h time-weighted average from the therapeutic dose of the drug using safety factors (Sargent and Kirk, 1988). A group composed of occupational toxicologists from several companies presented a monograph at the second annual Occupational Toxicology Roundtable, held in November 1989, regarding the development of OELs (Gáler et al., 1989, 1992). Several methods are available for developing OELs: analogy, correlation, safety and uncertainty factors, and low-dose extrapolation (Table 27.5). The appropriate method must be selected on the basis of the appropriateness of the available data. For example, low-dose extrapolation may be appropriate only if sufficient pharmacokinetic data are available to build a suitable physiologically based pharmacokinetic (PBPK) model. Analogy is a method by which the OEL for one compound is adopted for a second, based on the two compounds’ structural and functional similarity. This method is suitable only if the two compounds are similar in every aspect, including therapeutic or toxic dose, physical properties, and the like. Correlation is similar to analogy in that it compares similar compounds. However, the OEL is chosen based on a key property of the chemical that influences its toxicological properties. An example would be the use of the relative potency of two drugs as the key

TABLE 27.5 Methods for Setting Occupational Exposure Limits (OELs)

Method	Formula
Analogy	$OEL_i = OEL_j$
Correlation	$OEL_j = (PP_i/PP_j) \times OEL_i$
Safety factors	$OEL = \text{reference dose} / UF_1 \times UF_2 \times SF \times BR$
Low-dose extrapolation	$OEL = (\text{rodent RSD} \times (BW_H/BW_R)^{-1/3}) / BR$ or, if PBPK is available $OEL = (\text{human reference dose}) / BR$

Source: Adapted from Gáler et al. (1989).

BR, breathing rate for 8-h workday; BW, body weight; OEL, occupational exposure limit; PBPK, physiologically based pharmacokinetic model; PP, physical property; RSD, risk specific dose; SF, safety factor; UF_1 , uncertainty in extrapolation to NOEL; UF_2 , uncertainty from interspecies extrapolation.

property used to adjust the reference OEL. The most commonly used method is that of applying safety and/or uncertainty factors to a reference dose, which may be the lowest therapeutic dose. In using this method, it is important to choose the reference dose and end point with great care. In general, the most sensitive end point should be chosen. Uncertainty factors are selected to approximate levels from effective doses and to account for interspecies differences. A safety factor is selected based on the overall toxicological evaluation of the compound. Because it is necessary to look at the complete toxicological profile, it is generally inappropriate to assign specific values to each type of toxic effect.

Most commonly employed now is the approach suggested initially by Sargent and Kirk (1988), where the OEL for airborne pharmaceutical materials is calculated as

$$\text{OEL} = \frac{\text{NOAEL}(\text{mg kg}^{-1})(\text{BW in kg})}{(\text{UF})(V \text{ in } \text{m}^3)(\alpha)(s)}$$

where NOAEL is the no-effect level in the most sensitive species, BW is body weight, UF is an uncertainty factor (usually 10), V is the volume of air breathed by a worker in 8 h (usually 10 m³ is used), α is an adjustment for bioavailability between routes (if the animal data is from a route other than inhalation), and s is for already slate plasma levels if known (Binks, 2003). The FDA HED factor is commonly used in place of plasma levels if the steady state is unknown.

The OEL process has essentially become an industry standard. While US OSHA regulations do not require that manufacturers establish OELs, European governmental agencies do. The first country to require this activity is the United Kingdom, under its Control of Substances Hazardous to Health (COSHH) Regulations (Health and Safety Executive, 1988; Agius, 1989). A similar requirement is included in the EC Directive 80/1107, which was promulgated into law by other EC member nations.

In creating a program for establishing OELs, several disciplines will generally be included in the development or approval process. In those programs that are currently in place, Safety/Industrial Hygiene, Manufacturing or Technical Services, Medical Services, Legal Services, R&D, and, of course, Occupational Toxicology may take part in the process. While the ability to make the OEL level in the workplace does not drive the process, the OEL may often be issued as an interim guideline to provide manufacturing locations an opportunity to bring their operations into compliance and for the development of a suitable industrial hygiene sampling and analysis method.

27.5.5 Employee Training

The ultimate client for the services of the occupational toxicologist is the manufacturing or research employee who

must be informed of and protected from the potential hazards of chemicals present in the work environment. Providing employees with health hazard information directly through presentations or training programs accomplishes this task better than most written communications, and it provides an excellent way to build confidence in the organization within its safety and health programs. The trust gained in this manner can be an invaluable asset when a company is challenged with the manufacture of especially toxic or potent compounds. Face-to-face communication will also promote discussions with line employees and give the occupational toxicologist the opportunity to learn of those adverse health effects that might otherwise go unnoticed or uninvestigated.

There are several areas for which it may be useful to consider developing specific training programs. The Hazard Communication Standard requires that employees be trained to understand the hazards of chemicals as they are outlined in the SDS. There is an obvious need for the occupational toxicologist to be involved in the development of an internal training program or the selection of a commercial program to address this need. In addition to this required training, it may be useful to consider a more in-depth program on basic concepts involved in health hazard evaluation, particularly the dose-response relationship and the different types of chronic health hazards. It may be particularly important to promote an understanding of health hazard information obtained at work as well as through the news media. There are several commercial training programs available that may be useful for this purpose, including computer-based self-training programs and videos.

Table 27.6 presents what is currently the most commonly used classification system for pharmaceutical occupational risks. Based on the assigned categorization from this risk, appropriate worker protection methods are selected (Olsen et al., 2002).

As most pharmaceutical manufacturing is now performed on contract (in “toll” manufacturers), categorization is usually performed on contract (by a firm such as SafeBridge) or by a consultant. Specific training on compounds of interest can also be useful, particularly before the beginning of a manufacturing campaign, and is particularly effective if coupled with industrial hygiene training on appropriate safe handling techniques. If a testing program is in place, it is good policy to present an evaluation of the information gained in the compound’s testing program to the research or manufacturing chemists involved.

Specific training on compounds of interest can also be useful, particularly before the beginning of a manufacturing campaign, and is particularly effective if coupled with industrial hygiene training on appropriate safe handling techniques. If a testing program is in place, it is good policy to present an evaluation of the information gained in the compound’s testing program to the research or manufacturing chemists involved.

TABLE 27.6 Banding Decision Matrix

	Band 1	Band 2	Band 3 (Default)	Band 4	Band 5	Band 6
OEL (TWA, 8 h)	>1 mg m ⁻³	1 mg m ⁻³ to 10 µg m ⁻³	10–1 µg m ⁻³	1–0.1 µg m ⁻³	<0.1 µg m ⁻³	≪0.1 µg m ⁻³
Potency (mg day ⁻¹)	>100 mg	1–100 mg	0.1–1 mg	0.01–0.1 mg	<0.01 mg	≪0.01 mg
Severity of acute (life-threatening) effects	Low	Low/moderate	Moderate	Moderate/high	High	Extreme
Acute warning properties	Excellent	Good	Fair	Fair/poor	Poor	None
28D TDLo (mg kg ⁻¹)	>500 mg kg ⁻¹	200–500 mg kg ⁻¹	50–200 mg kg ⁻¹	5–50 mg kg ⁻¹	0.5–5 mg kg ⁻¹	<0.5 mg kg ⁻¹
90D TDLo (mg kg ⁻¹)	>200 mg kg ⁻¹	80–200 mg kg ⁻¹	20–80 mg kg ⁻¹	2–20 mg kg ⁻¹	0.2–2 mg kg ⁻¹	<0.2 mg kg ⁻¹
Onset of acute oral toxicity (rat)	>500 mg kg ⁻¹	200–500 mg kg ⁻¹	50–200 mg kg ⁻¹	5–50 mg kg ⁻¹	0.5–5 mg kg ⁻¹	<0.5 mg kg ⁻¹
Onset of warning symptoms	Immediately	Immediately/ minutes–hours	Immediately/hour	Delayed	Indeterminate	Indeterminate
Medically treatable symptoms	Yes	Yes	Yes	Borderline	No	No
Need for medical intervention	Not required	Not required	May be required	Required	Required immediately	Required immediately
Likelihood of chronic effects (e.g., cancer, reproductive, developmental)	Unlikely	Unlikely	Possible	Known	Known	Known
Severity of chronic (life-shortening) effects	None	None	Low	Moderate	High	Extreme
Cumulative effects	None	None	Low to moderate	High	Extreme	Extreme
Irritation	Not an irritant	Slight to moderate irritant	Moderate	Severe	Corrosive	Extremely corrosive
Sensitization	Not expected	Mild sensitizer	Moderate sensitizer	Strong sensitizer	Extreme sensitizer	Extreme sensitizer
Reversibility	Reversible	Reversible	Reversible	Irreversible	Irreversible	Irreversible
Alteration of quality of life (disability)	Unlikely	Unlikely	Possible	Probably	Unknown	Unknown

Issues continuing to gain in importance for pharmaceutical industry occupational toxicologists are those relating to the new, more potent drugs currently being designed. Current drugs have therapeutic dose levels ranging down to the submicrogram (and in some cases, even nanogram) levels. Hazard assessment and OEL development, already difficult, may be nearly impossible or inappropriate when dealing with drugs active at pico- or femtogram levels. Alternative methods of evaluating occupational exposures and assuring a safe work environment may need to be developed, then there are biotechnology products and their associated issues.

A third of all new drugs come from the biotechnology pipeline, most commonly peptides and proteins with significant allergenic potential in an occupational setting. The potential occupational health hazards of this class of potent but high molecular weight products have not been fully evaluated. Because of the inherent functional and structural differences, the extrapolation of testing methods from traditional pharmaceutical products to biotechnology-derived compounds may be fraught with many difficulties. Hypersensitivity and other immunologically based toxicities are particularly of concern for protein- and peptide-based therapeutics.

27.6 CONCLUSION

The field of occupational toxicology in the pharmaceutical industry presents continuing challenges to the industry, particularly as it shifts increasingly to an outsourced function in companies. The occupational toxicologist finds that he or she must become an “expert” in several fields and not be limited to the scientific area. Unlike the preclinical toxicologist, the occupational practitioner functions under less-stringent regulatory requirements and minimal precedents. Additionally, as new classes of therapeutic agents enter development and commerce, new concerns and challenges will accompany them.

STRATEGY AND PHASING FOR NONCLINICAL DRUG SAFETY EVALUATION IN THE DISCOVERY AND DEVELOPMENT OF PHARMACEUTICALS

28.1 INTRODUCTION

The preclinical assessment of the safety of potential new therapeutic entities represents a special case of the general practice of nonclinical safety assessment (Gad, 1996, 2000, 2009) possessing its own peculiarities and special considerations and differing in several ways from the practice of toxicology in other fields—for some significant reasons. It is constantly changing, but in an evolutionary (not revolutionary) manner, and while there have been enormous progress under international harmonization, “fragmentation” of regulatory details between agencies and even divisions of agencies continues. Because of the economics involved and the essential close intertwining with other activities (e.g., clinical trials, chemical process optimization, formulation development, regulatory reviews), the development and execution of a crisp, timely, and flexible, yet scientifically sound, program are a prerequisite for success. The ultimate aim of preclinical assessment also makes it different. A good pharmaceutical safety assessment program seeks to efficiently and effectively move, potential therapeutic agents with suitable safety for the use intended into, and support them through, the clinical evaluation, then to registration, and, finally, to the market. This requires the quick identification of those agents that are either fundamentally not safe or that may require a paradigm shift in their formulation or use. At the same time, the very biological activity which makes a drug efficacious also acts to complicate the design and interpretation of safety studies—especially true for biologics.

Such evaluations occur on different time scales because of different objectives. Many of the most critical steps must be designed and executed before there is a clear understanding of the details of the clinical use of the therapeutic,

including route, regiment, appropriate patient population, and duration of use. There is the traditional Big Pharma case and different versions used predominantly by the much more numerous small pharmaceutical cases. These small (or virtual) pharma cases may be either the short case (do only what is required to initiate and support initial clinical trials) or the midgame (a variety where studies to support further clinical trials are preformed but spread out). Pharmaceuticals, unlike industrial chemicals, agricultural chemicals, and environmental agents, are intended to have human exposure and biological activity, and, unlike these materials and food additives, pharmaceuticals are intended to have biological effects on the people that receive them. Frequently, the interpretation of results and the formulation of decisions about the continued development and eventual use of a drug are based on an understanding of both the potential adverse effects of the agent (its safety) and its likely benefits, as well as the dose separation between these two (the “therapeutic index”). This makes a clear understanding of dose–response relationships critical so that the actual risk/benefit ratio can be identified. It is also essential that the pharmacokinetics be understood and that “doses” (plasma tissue levels) at target organ sites are known (Scheuplein et al., 1990). Integral evaluation of pharmacokinetics is essential to any effective safety evaluation program.

The development and safety evaluation of pharmaceuticals have many aspects specified by regulatory agencies, and this has also tended to make the process more complex (until recently, as the International Conference on Harmonization (ICH) has tended to take hold) as markets have truly become global, though not totally harmonized internationally. An extensive set of safety evaluations is absolutely required before a product is ever approved for market. There are even novels on the subject (see Zbinden, 1992) and subsequently a

steady flow of “thrillers.” Regulatory agencies have increasingly come to require not only the establishment of a “clean dose” in two species with adequate safety factors to cover potential differences between species but also an elucidation of the mechanisms underlying such adverse effects as are seen at higher doses and are not well understood. These regulatory requirements are compelling for the pharmaceutical toxicologist (Traina, 1983; Smith, 1992). There is not, however, a set menu for what must be done. Rather, much (particularly in terms of the timing of testing) is open to professional judgment and is tailored for the specific agent involved and its therapeutic claim.

The discovery, development, and registration of a pharmaceutical are an immensely expensive operation and represent a rather unique challenge. PhRMA estimated that for every 9000–10000 compounds specifically synthesized or isolated as potential therapeutics, one (on average) will actually reach the market. Other estimates suggest that a more realistic figure is one in every 200 that enter clinical trials will make it to market, though these do not all necessarily end up being financially successful. This process is illustrated diagrammatically in Figure 28.1. Each successive stage in the process is more expensive, making it of great interest to identify as early as possible those agents that are likely not to go the entire distance, allowing a concentration of effort on the compounds that have the highest probability of reaching the market. Compounds “drop out” of the process primarily for four reasons:

- Toxicity (or lack of toxicity tolerance) in human.
- Lack of efficacy
- Lack of bioavailability of the active moiety in human
- Being late to gain approval and market adaptation into clinical practice.

Early identification of poor or noncompetitive candidates in each of these three categories is thus extremely important (Fishlock, 1990), forming the basis for the use of screening in pharmaceutical discovery and development. How much and which resources to invest in screening, and each successive step in support of the development of a potential drug, are matters of strategy and phasing that are detailed in Section 28.6 of this chapter. *in vitro* methods are increasingly providing new tools for use in both early screening and the understanding of mechanisms of observed toxicity in preclinical and clinical studies (Gad, 1989b, 2001, 2009), particularly with the growing capabilities and influence of genomic and proteomic technologies. This is increasingly important as the societal concern over drug prices has grown (Littlehales, 1999). Additionally, the marketplace for new drugs is exceedingly competitive. The rewards for being either early (first or second) into the marketplace or achieving a significant therapeutic advantage are enormous in terms of eventual market share. Additionally, the first drug approved sets agency expectations for those drugs which follow. In mid-2014, there were 508 pharmaceutical products awaiting approval (120 of these biotech products)—the “oldest” having been in review for 7 years—and some 22000 additional agents in the Investigation New Drug (IND) stage (Food and Drug Administration [FDA] website). Not all of these (particularly the oldest) will be economically successful.

The successful operation of a safety assessment program in the pharmaceutical industry requires that four different phases of the product-related operation be simultaneously supported. These four phases of pharmaceutical product support (discovery support, IND support, clinical and registration support, and product support) constitute the vast majority of what is done by the safety assessment groups in the pharmaceutical industry. The constant adjustment of balance of resources

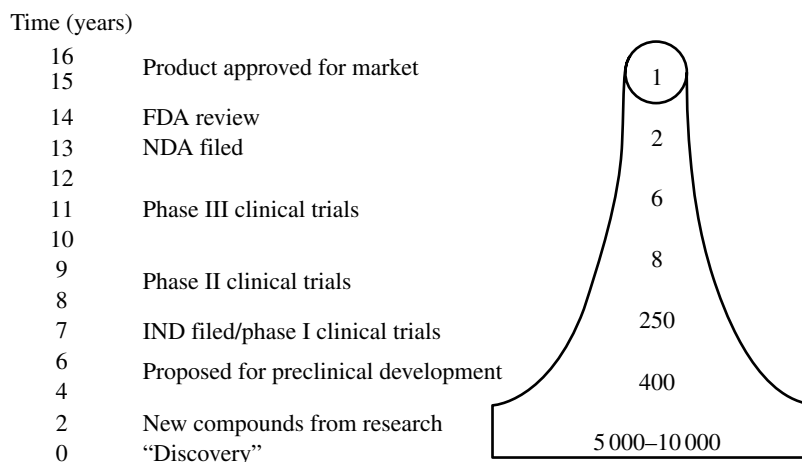

FIGURE 28.1 Attrition during development of new molecules with promise of therapeutic potential. Over the course of taking a new molecular entity through scale-up, safety and efficacy testing, and, finally, to market, typically only one out of every 9000–10000 will go to the marketplace.

between these four areas is the greatest management challenge in pharmaceutical safety assessment. An additional area, occupational toxicology, is conducted in a manner similar to that for industrial environments and is the subject of Chapter 27 of this volume. In most companies, occupational toxicology is the responsibility of a separate group.

The usual way in which transition (or “flow”) between the different phases is handled in safety assessment is to use a tiered testing approach. Each tier generates more specific data (and costs more to do so) and draws on the information generated in earlier tiers to refine the design of new studies. Different tiers are keyed to the support of successive decision points (go/no go points) in the development process, with the intent of reducing risks as early as possible.

The first real critical decisions concerning the potential use of a compound in humans are the most difficult. They require an understanding of how well particular animal models work in predicting adverse effects in man (usually very well, but there are notable lapses; e.g., giving false positives and false negatives) and an understanding of what initial clinical trials are intended to do. However, an approved IND grants one entry into limited evaluations of drug effects in human, flexibility in the execution, and analysis of these studies offers a significant opportunity to also investigate efficacy (O’Grady and Linet, 1990).

Once past the discovery and initial development stages, the safety assessment aspects of the process become extremely tightly connected with the other aspects of the development of a compound, particularly the clinical aspects. These interconnections are coordinated by project management systems. At many times during the early years of the development process, safety assessment constitutes the rate-limiting step—it is, in the language of project management, on the critical path.

Another way in which pharmaceutical safety assessment varies from toxicology as practiced in other industries is that it is a much more multidisciplinary and integrated process. This particularly stands out in the incorporation of the evaluation of absorption, distribution, metabolism, and excretion (ADME) aspects in the safety evaluation process. These pharmacokinetic/metabolism (PKM) aspects are evaluated for each of the animal model species (most commonly the rat, dog, minipig, or primate) utilized to evaluate the preclinical systemic toxicity of a potential drug prior to evaluation in man. Frequently, *in vitro* characterizations of metabolism for model (or potential model) species and man are performed to allow optimal model selection and understanding of findings. This allows for an early appreciation of both the potential bioavailability of active drug moieties and the relative predictive values of the various animal models. Such data early on are also very useful (in fact, sometimes essential) in setting dose levels for later animal studies and in projecting safe dose levels for clinical use. Unlike the case in most other areas of industrial toxicology, one is not limited to extrapolating the relationships between administered dose and systemic effects.

Rather, one has significant information on systemic levels of the therapeutic moiety; typically, total area under the curve (AUC), peak plasma levels (C_{max}), and plasma half-lives, at a minimum.

The state-of-the-art for preclinical safety assessment has now developed to the point where the resulting products of the effort (reports, IND/new drug application [NDA] summaries, and the overall professional assessment of them) are expected to reflect and integrate the best effort of all the available scientific disciplines. Actual data and discussion should thus come from toxicology, pharmacology, pathology, and metabolism, at a minimum. The success of current premarket efforts to develop and ensure that only safe drugs make it to market is generally good, but clearly not perfect. This is reflected in popular (Arnst, 1998; Raeburn, 1999) and professional (Lazaron et al., 1998; Moore et al., 1998) articles looking at both the number of recent marketed drug withdrawals for safety (summarized in Table 28.1) and at rates of drug-related adverse drug events and deaths in hospital patients. It is hoped that this system can be improved, and there are continuing efforts to improve or optimize drug candidate selection and development (Lesko et al., 2000). Indeed, the entire pharmaceutical development paradigm is clearly in need of a complete change—a synthesis, as opposed to a continual application of small corrections.

28.2 REGULATORY REQUIREMENTS

Minimum standards and requirements for safety assessment of new pharmaceuticals are established by the need to meet regulatory requirements for developing, and eventually gaining approval to market, the agent. Determining what these requirements are is complicated by (i) the need to compete in a global market, which means gaining regulatory approval in multiple countries that do not have the same standards or requirements, and (ii) the fact that the requirements are documented as guidelines, the interpretation of which is subject to change as experience alters judgments. The ICH process has much improved this situation, as detailed in Chapter 2. ICH (M3)(R2) (2009) clearly denotes what nonclinical studies are required to support clinical drug development. Unfortunately, since then additional requirements (safety pharmacology and immunotoxicology) have been promulgated by additional guidelines. Accordingly, M3 is not all current or inclusive in its guidance. Since the last edition of this book, the requirements for submission of data, reports, and active submissions to be placed in highly stylized electronic submission forms has become the standard case.

Standards for the performance of studies (which is one part of regulatory requirements) have as their most important component good laboratory practices (GLPs). GLPs largely dictate the logistics of safety assessment—training, adherence to

TABLE 28.1 Postapproval Adverse Side Effects and Related Drug Withdrawals Between 1990 and 2011 in the USA

Year	Drug	Indication/Class	Causative Side Effect
1990	Boric acid and borates	Antimicrobial/skin rash	Death from neurotoxicity
1990	Dilevalol	Antihypertensive/hypertension	Liver
1990	Loperamide	Antidiarrheal/diarrhea	Paralytic ileus
1991	Enkaid (4 years on market)	Antiarrhythmic	Cardiovascular (sudden cardiac death)
1992	Genaconazole	Antimicrobial/fungal infection	Hepatocellular cancer
1992	Sulfadimidine	Antimicrobial/bacterial infection	Hematologic: thrombocytopenia
1992	Temafloxacin	Antimicrobial/bacterial infection	Hematologic, immunologic, liver, metabolism, urinary tract
1992	Temafloxacin	Antibiotic	Blood and kidney
1993	HA-1A (Centoxin)	Monoclonal antibody/sepsis	Death
1993	Nebacumab	Monoclonal antibody/sepsis	Infection risk/accelerated death
1994	Pentosan polysulfate sodium	Anti-thrombotic/cystitis, osteoarthritis	Hematologic: thrombocytopenia
1994	Remoxipride	Antipsychotic	Hematologic
1995	Sparfloxacin	Antimicrobial/bacterial infection	QTc prolongation, phototoxicity
1996	Chlormezanone	Muscle relaxant	Skin, drug dependence, liver
1996	Cyclandelate	Vasodilator/Raynaud's disease	Not effective for use
1996	Tolrestat	Hypoglycemic/diabetes	Liver
1997	Dexfenfluramine	Psychostimulant/obesity	Cardiovascular/respiratory
1997	Selegiline	Antiparkinsonian	Drug interaction
1997	Troglitazone	Hypoglycemic/diabetes	Liver
1997	Fenfluramine*/dexafluramine (combo used since 1984) (*24 years on market)	Diet pill	Heart valve abnormalities
1998	Bromfenac	Analgesic	Liver
1998	Erythryl tetranitrate	Antihypertensive/angina pectoris	Insufficient evidence: skin
1998	Mibefradil	Antihypertensive	Drug interactions, musculoskeletal
1998	Posicor (mibefradil) (1 year on market)	Ca ²⁺ channel blocker	Lethal drug interactions (inhibited liver enzymes)
1998	Duract (bronfemic sodium) (early preapproval warnings of liver enzymes)	Pain relief	Liver damage
1999	Levamisole	Anthelmintic/worm infestation	Hematologic, nervous system
1999	Rotavirus vaccine	Vaccine/rotavirus	Gastrointestinal intussusception
1999	Trovafloxacin	Antimicrobial/bacterial infection	Liver
1999	Trovan (use severely restricted)	Antibiotic	Liver/kidney damage
1999	Raxar	Quinolone antibiotic	QT internal prolongation/ventricular arrhythmias (deaths)
1999	Hismanal	Antihistamine	Drug–drug interactions
1999	RotaShield	Rotavirus vaccine	Bowel obstruction
2000	Alosetron	Antispasmodic/IBS	Gastrointestinal
2000	Cisapride monohydrate	Prokinetic agent/gastro-esophageal reflux	Cardiovascular, drug interactions
2000	Clobenzorex	Psychostimulant/obesity	Drug abuse, psychiatric
2000	Thioridazine	Antipsychotic	Retinopathy, cardiovascular
2000	Renzulin (approved December 1996)	Type 2 diabetes	Liver damage
2000	Propulsid	Heartburn	Cardiovascular irregularities/deaths
2000	Lotronex	Irritable bowel syndrome	Ischemic colitis/death
2001	Cerivastatin	Antilipemic/hyperlipidemia	Renal, musculoskeletal
2001	Chloral hydrate	Sedative-hypnotic/hypnosedation	Tumorigenicity
2001	Levacetylmethadol	Antidote/opioid dependence	Cardiovascular
2001	Rapacuronium bromide	Anesthetic	Respiratory: bronchospasm
2001	Phenylpropanolamine (PPA)	OTC ingredient	Hemorrhagic stroke
2001	Baychlor	Cholesterol reducing (statin)	Rhabdomyolysis (muscle-weakening) (deaths)
2002	Lyme disease vaccine	Vaccine/bacterial infection (Lyme disease)	Musculoskeletal (arthralgia)

(Continued)

TABLE 28.1 (Continued)

Year	Drug	Indication/Class	Causative Side Effect
2002	Sibutramine	Psychostimulant/obesity	Cardiovascular
2003	Alphacetylmethadol	Analgesic	Cardiovascular
2004	Bepriidil	Antiarrhythmic/cardiac arrhythmia	Cardiovascular
2004	Rofecoxib	Analgesic	Cardiotoxicity
2004	Serzone	Antidepressant	Liver failure and injury
2004	Vioxx	Arthritis (COX-2 inhibitor)	Heart attack/cardiovascular (thrombosis)
2005	Natalizumab	Monoclonal antibody/multiple sclerosis (MS) and Crohn's disease	Nervous (combination)
2005	Technetium (^{99m} Tc) fanolesomab	Radiography	Cardiovascular
2005	Valdecocixib	Analgesic	Cardiovascular, skin
2005	Tysabri	Multiple sclerosis (MS)	Progressive multifocal leukoencephalopathy (PML)
2005	Bextra	Arthritis (COX-2 inhibitor)	Skin reaction (sometimes fatal)
2006	Dolophine (methadone hydrochloride)	Treatment of moderate to severe pain	Respiratory depression and cardiac arrhythmias
2007	Interferon-gamma-1b	Immunomodulatory/idiopathic pulmonary fibrosis	Accelerated death
2007	Lumiracoxib	Analgesic	Liver
2007	Pergolide mesylate	Anti-parkinsonian	Cardiovascular
2007	Tegaserod	Antispasmodic/IBS, constipation	Cardiovascular
2007	Trimethobenzamide	Antihistamine/motion sickness, GI infections, medication induced nausea	Due to new FDA regulation; lack of effectiveness, teratogenicity
2007	Zelnorm	Constipation	Cardiovascular safety
2007	Permax	Parkinson's disease	Heart-valve damage
2008	Inhaled Insulin (Exubera)	Hormones/diabetes	Lung cancer
2008	Lapdap	Antimalarial	Hemolytic anemia
2008	Laropiprant/nicotinic acid	Antilipemic/facial flushing	High frequency of nonfatal but serious side effects
2008	Sargramostim	Immunostimulator/bone marrow transplantation	Immune-mediated
2008	Trasylol	Bleeding	Increased risk of death
2008	Acomplia	Weight loss	Severe depression/suicide
2009	Efalizumab	Monoclonal antibody/autoimmune disease	Leukoencephalopathy
2009	Raptiva	Psoriasis	PML
2010	Gemtuzumab oxogamicin	Monoclonal antibody/leukemia	Accelerated death
2010	Sitaxentan sodium	Antihypertensive	Hepatotoxicity
2010	Meridia	Weight loss	Cardiovascular safety
2010	Avandia	Diabetes	Cardiovascular safety
2010	Darvon&Darvocet	Pain	Addiction
2010	Mylotarg	AML	Veno-occlusive disease
2011	Drotecogin alfa	Antithrombotic/sepsis	Insufficient evidence; bleeding risk
2011	Viva Globin	Primary immune deficiencies	Thrombolytic adverse extents (CV)

Fifty-one percent of approval drugs had serious postapproval identified side effect.

other regulations (such as those governing the requirements for animal care), and (most of all) the documentation and record-keeping that are involved in the process. There are multiple sets of GLP regulations (in the United States alone, agencies such as the FDA and Environmental Protection Agency [EPA] each have their own) that are not identical; however, adherence to US FDA GLPs (FDA, 1987a) will rarely lead one astray.

Not all studies that are done to assess the preclinical safety of a new pharmaceutical need to be done in strict adherence to GLPs. Those studies that are “meant to support the safety of a new agent” (i.e., are *required* by regulatory guidelines) must be so conducted or run a significant risk of rejection. However, there are also many other studies of an exploratory nature (such as range finders and studies done to understand the mechanisms of toxicity) that are not required by the FDA,

which may be done without strict adherence to GLPs. A common example is those studies performed early on to support research in selecting candidate agents. Such studies do not meet the requirements for having a validated analytical method to verify the identity, composition, and stability of materials being assayed, yet they are essential to the processes of discovery and development of new drugs. All such studies must eventually be reported to the FDA if an IND application is filed, but the FDA does not in practice “reject” such studies (and therefore the IND) because they are “non-GLP”

Food and Drug Administration Modernization Act (FDAMA) passed in 1997 and has subsequently been renewed every 5 years. There is a second set of “standards” of study conduct that are less well defined. These are “generally accepted practice,” and though not written down in regulation, are just as important as GLPs for studies to be accepted by the FDA and the scientific community. These standards, which are set by what is generally accepted as good science by the scientific community, include techniques, instruments utilized, and interpretation of results. Most of the chapters in this book will reflect these generally accepted practices in one form or another.

Guidelines establish which studies must be done for each step in the process of development. Though guidelines supposedly are suggestion (and not requirements), they are in fact generally treated as minimums by the promulgating agency. The exceptions to this are special cases where a drug is to meet some significant need (a life-threatening disease such as acquired immunodeficiency syndrome [AIDS] or ALS) or where there are real technological limitations as to what can be done (as with many of the new biologically derived (or biotechnology) agents, where limitations on compound availability and biological responses make traditional approaches inappropriate).

There are some significant differences in guideline requirements between the major countries (see Gad (2010) for an excellent international overview of requirements), though this source is now becoming dated. The core of what studies are generally done is those studies conducted to meet US FDA requirements. These are presented in Table 28.2. As will be discussed in Chapter 2, these guidelines are giving way to the ICH guidelines. However, while the length and details of studies have changed, the nature and order of studies remain the same.

The major variations in requirements for other countries still tend to be in the area of special studies. The United States does not formally require any genotoxicity studies, but common practice for US drug registration is to perform at least a bacterial gene mutation assay (Ames test), a mammalian cell mutation assay, and a clastogenicity assay, while Japan requires specific tests, including a gene mutation assay in *Escherichia coli*. Likewise, the European Economic Community (EEC) has a specified set of requirements, while individual countries have additional special requirements

(e.g., Italy requires a mutagenicity assay in yeast). As detailed in Chapter 6, the new ICH genotoxicity guidelines have come to meet multinational requirements. Japan maintains a special requirement for an antigenicity assay in guinea pigs. The new safety pharmacology requirements are likely to be adopted over a period of time by different adherents.

It is possible to interact with the various regulatory agencies (particularly the FDA) when peculiarities of science or technology leave one with an unclear understanding of what testing is required. It is best if such discussions directly involve the scientists who understand the problems, and it is essential that the scientists at the FDA be approached with a course of action (along with its rationale) that has been proposed to the agency in advance.

The actual submissions to a regulatory agency that request permission either to initiate (or advance) clinical trials of a drug or to market a drug are not just bundles of reports on studies. Rather, they take the form of summaries that meet mandated requirements for format, accompanied by the reports discussed in these summaries. In the United States, these summaries are the appropriate section of the IND and NDA, which have now been harmonized in the ICH Common Technical Document (CTD) format. The formats for these documents have recently been revised (FDA, 1987b). The EEC equivalent is the expert report, as presented in EEC Directive 75/319. Similar approaches are required by other countries. In each of these cases, textual summaries are accompanied by tables that also serve to summarize significant points of study design and of study findings.

What all of these approaches have in common is that they are to present integrated evaluations of the preclinical safety data that are available on a potential new drug. The individual studies and reports are to be tied together to present a single, cohesive overview of what is known about the safety of a drug.

Leber (1987) presents an excellent overview of the regulatory process involved in FDA oversight of drug development and gives the historical perspective for the evolution of the conservative process that is designed to ensure that any new pharmaceutical is both safe and efficacious.

There are other regulatory, legal, and ethical safety assessment requirements beyond those involved in the selection and marketing of a drug as a product entity. The actual drug product must be manufactured and transported in a safe manner and any waste associated with this manufacture disposed of properly. Chapter 14 of this volume specifically addresses this often-overlooked aspect of safety assessment programs.

28.3 ESSENTIAL ELEMENTS OF PROJECT MANAGEMENT

It is important to keep in mind that safety assessment is only one of many components involved in the discovery and

TABLE 28.2 Synopsis of General Guidelines for Animal Toxicity Studies (US FDA, *Total Drug Quality*) and ICH M3 (R2)

Category	Duration of Human Administration ^a	Phase ^b	Subacute or Chronic Toxicity ^c	Special Studies
Oral or parenteral	Several days (up to 3) Up to 2 weeks	I, II, III, NDA I II III, NDA	Two species: 2 weeks Two species: 4 weeks Two species: up to 4 weeks Two species: up to 3 months	For parenterally administered drugs; compatibility with blood and local tolerance at injection site where applicable
	Up to 3 months 6 months to unlimited	I, II III NDA I, II III NDA	Two species: 4 weeks Two species: 3 months Two species: up to 6 months Two species: 3 months Two species: 6 months or longer Two species: 12 months in rodents 9 months in nonrodents +2 rodent species for CA 18 months (mouse)—may be met by use of a transgenic model 24 months (rat)	
Inhalation (general anesthetics)	Single administration	I, II, III, NDA	Four species: 5 days (3 h day ⁻¹)	
Dermal	Single application	I	One species: single 24 h exposure followed by 2-week observation	Sensitization
	Single or short-term application	II	One species: 20-day repeated exposure (intact and abraded skin)	
	Short-term application Unlimited application	III NDA	As aforementioned As aforementioned, but intact skin study extended up to 6 months	
Ophthalmic	Single application	I	One species: 3 weeks, daily applications, as in clinical use	Eye irritation tests with graded doses
	Multiple application	I, II, III NDA	One species: duration commensurate with period of drug administration	
Vaginal or rectal	Single application	I	Two species: duration and no. of applications determined by the proposed use	Local and systematic toxicity after vaginal or rectal application in two species
	Multiple application	I, II, III, NDA		
Drug combinations ^d	I II, III, NDA	Two species: up to 3 months		Lethality by appropriate route, compared to components run concurrently in one species

^aPhase I dosing of females if childbearing potential requires a segment II study in at least one species; phase III dosing of this population requires a segment I study and both segment II studies.

^bPhases I, II, and III are defined in Section 130.0 of the new drug regulations.

^cAcute toxicity should be determined in three species; subacute or chronic studies should be conducted by the route to be used clinically. Suitable mutagenicity studies should also be performed.

Observations:

Body weights	Food consumption	Behavior
Metabolic studies	Ophthalmologic examination	Fasting blood sugar
Gross and microscopic examination	Hemogram	Liver and kidney function tests
Coagulation tests	Others as appropriate	

^d Where toxicity data are available on each drug individually.

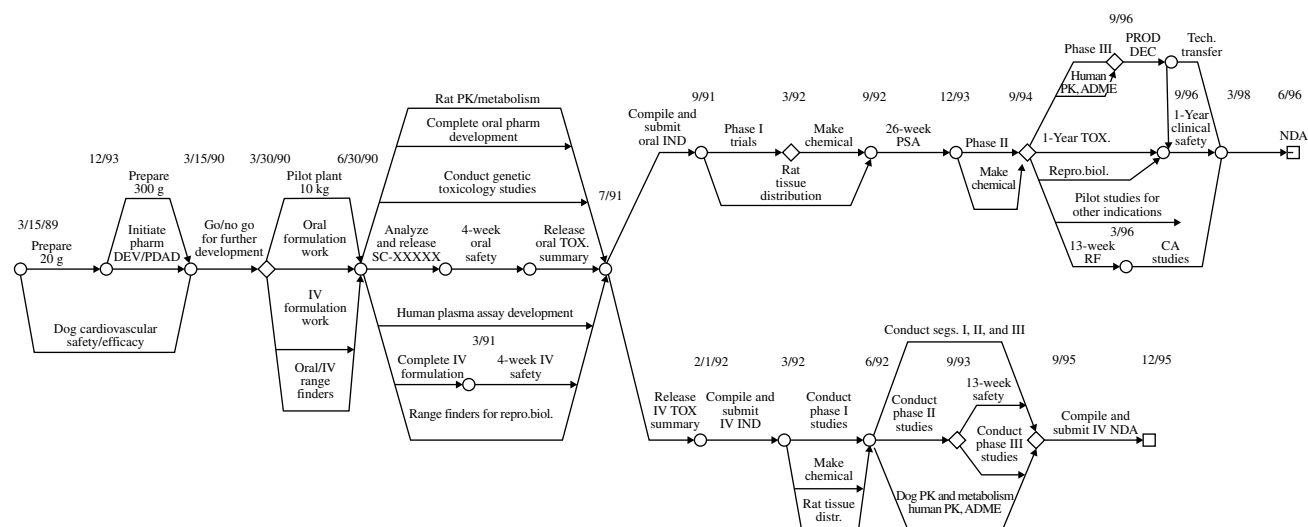

FIGURE 28.2 An example of program evaluation and review technique (PERT) chart of the development of a new pharmaceutical through to the filing of a new drug application (NDA). Circles are “nodes” indicating completion of activities. Diamonds are initiation points for tasks that have starting points independent of others. This “network” serves to illustrate the relationships between different activities and to evaluate effects of changes on project timing.

development of new pharmaceuticals. The entire process has become enormously expensive and completing the transit of a new drug from discovery to market has to be as efficient and expedition a process as possible. Even the narrow part of this process (safety assessment) is dependent on many separate efforts. Compounds must be made, analytical and bio-analytical methods developed, and dosage formulations developed, to name a few. One needs only to refer to Beyer (1978), Hamner (1990), Matoren (1984), Sneader (1986) (a good short overview), or Spilker (1994), Guarino (2009), or Blass (2015) for more details on this entire process and all of its components.

The coordination of this entire complex process is the province of project management, the objective of which is to ensure that all the necessary parts and components of a project match up. This discipline in its modern form was first developed for the Polaris missile project in the 1960s. Its major tool that is familiar to pharmaceutical scientists is the “network” or program evaluation and review technique (PERT) chart, as illustrated in Figure 28.2. This chart is a tool that allows one to see and coordinate the relationships between the different components of a project. One outcome of the development of such a network is the identification of the rate-limiting steps, which, in aggregate, comprise the critical path (see Table 28.3 for a lexicon of the terms used in project management).

A second graphic tool from project management is the Gantt chart, as illustrated in Figure 28.3. This chart allows one to visualize the efforts under way in any one area, such as safety assessment, for all projects that are currently being worked on.

Figure 28.4 shows a hybrid of the PERT and Gantt charts, designed to allow one to visualize all the resources involved in any one project.

As understanding of the key concepts of project management and their implications is critical of strategic planning and thinking for safety assessment, Kliem (1986) and Knutson (1980) offer excellent further reading in the area of project management.

28.4 SCREENS: THEIR USE AND INTERPRETATION IN SAFETY ASSESSMENT

Much (perhaps even most) of what is performed in safety assessment can be considered screening—trying to determine if some effect is or is not (to an acceptable level of confidence) present (Zbinden et al., 1984). The general concepts of such screens are familiar to toxicologists in the pharmaceutical industry because the approach is a major part of the activities of the pharmacologists involved in the discovery of new compounds. But the principles underlying screening are not generally well recognized or understood, and such an understanding is essential to the proper use, design, and analysis of screens (Gad, 1988, 1989a). Screens are the biological equivalent of exploratory data analysis (EDA) (Tukey, 1977).

Each test or assay has an associated activity criterion, that is, a level above which the activity of interest is judged to be present. If the result for a particular test compound meets this criterion, the compound may pass to the next stage. This criterion could be based on statistical significance (e.g., all compounds

TABLE 28.3 Glossary of Project Management Terms

Activity	The work or effort needed to complete a particular event. It consumes time and resources
Average daily resource requirement	The likely amount of resources required to complete an activity or several activities on any workday during a project. The average daily labor requirement is one example
CPM	Acronym for critical path method. A network diagramming technique that places emphasis on time, cost, and the completion of events
Critical path	The longest route through a network that contains activities absolutely crucial to the completion of the project
Dummy arrow	A dashed line indicating an activity that uses no time or resources
Duration	The time it takes to complete an activity
Earliest finish	The earliest time an activity can be completed
Earliest start	The earliest an activity can begin if all activities before it are finished. It is the earliest time that an activity leaves its initiation node
Event	A synonym for node. A point in time that indicates the accomplishment of a milestone. It consumes neither time nor resources and is indicated whenever two or more arrows intersect
Free float	The amount of time that an activity can be delayed without affecting succeeding activities
Gantt chart	A bar chart indicating the time interval for each of the major phases of a project
Histogram	A synonym for bar chart
Latest finish	The latest time an activity can be completed without extending the length of a project
Latest start	The latest time an activity can begin without lengthening a project
Leveling	The process of “smoothing” put labor, material, and equipment requirements to facilitate resource allocation. The project manager accomplishes this by “rescheduling” noncritical activities so that the total resource requirements for a particular day match the average daily resource requirements
Most likely time	Used in PERT diagramming. The most realistic time estimate for completing an activity or project under normal conditions
Node	A synonym for event
Optimistic time	Used in PERT diagramming. The time the firm can complete an activity or project under the most ideal conditions
PERT	Acronym for program evaluation and review technique. A network diagramming technique that places emphasis on the completion of events rather than cost or time
Pessimistic time	Used in PERT diagramming. The time the firm can complete an activity or project under the worst conditions
Project	The overall work or effort being planned. It has only one beginning node and ending node. Between those nodes are countless activities and their respective nodes
Project phase	A major component, or segment, of a project. It is determined by the process known as project breakdown structuring
Total float	The total amount of flexibility in scheduling activities on a noncritical path. Hence, it provides the time an activity could be prolonged without extending a project’s final completion date

with observed activities significantly greater than the control at the 5% level could be tagged). However, for early screens, such a formal criterion may be too strict, resulting in few compounds being identified as “active.”

A useful indicator of the efficacy of an assay series is the frequency of discovery of truly active compounds. The frequency is related to the probability of discovery and to the degree of risk (hazard to health) associated with an active compound passing a screen undetected. These two factors in turn depend on the distribution of activities in the series of compounds being tested and the chances of rejecting or accepting compounds with given activities at each stage.

Statistical modeling of the assay system may lead to the improvement of the design of the system by reducing the interval between discoveries of active compounds. The objectives behind a screen and considerations of (i) costs for pro-

ducing compounds and testing and (ii) the degree of uncertainty about test performance will determine desired performance characteristics of specific cases. In the most common case of early toxicity screens performed to remove possible problem compounds, preliminary results suggest that it may be beneficial to increase the number of compounds tested, decrease the numbers of animals per group, and increase the range and number of doses. The result will be less information on more structure, but there will be an overall increase in the frequency of discovery of active compounds (assuming that truly active compounds are entering the system at a steady rate).

The methods described here are well suited to analyzing screening data when the interest is truly in detecting the absence of an effect with little chance of false negatives. There are many forms of graphical analysis methods available, including some newer forms that are particularly well suited

FIGURE 28.3 Gantt, or bar, chart showing scheduling of major safety assessment activities (studies) involved in pharmaceutical development project.

to multivariate data (the type that is common in more complicated screening test designs). It is intended that these aspects of analysis will be focused on in a later publication.

The design of each assay and the choice of the activity criterion should, therefore, be adjusted, bearing in mind the relative costs of retaining false positives and rejecting false negatives. Decreasing the group sizes in the early assays reduces the chance of obtaining significance at any particular level (such as 5%), so that the activity criterion must be relaxed, in a statistical sense, to allow more compounds through. At some stage, however, it becomes too expensive to continue screening many false positives, and the criteria must be tightened accordingly. Where the criteria are set depends on what acceptable noise levels in a screening system.

28.4.1 Characteristics of Screens

An excellent introduction to the characteristics of screens is Redman's (1981) interesting approach, which identifies four characteristics of an assay. Redman assumes that a compound is either active or inactive and that the proportion of activities in a compound can be estimated from past experience. After testing, a compound will be classified as positive or

negative (i.e., possessing or lacking activity). It is then possible to design the assay so as to optimize the following characteristics:

1. *Sensitivity*: The ratio of true positives to total actives
2. *Specificity*: The ratio of true negatives to total inactives
3. *Positive accuracy*: The ratio of true to observed positives
4. *Negative accuracy*: The ratio of true to observed negatives
5. *Capacity*: The number of compounds that can be evaluated
6. *Reproducibility*: The probability that a screen will produce the same result at another time (and, perhaps, in some other lab)

An advantage of testing many compounds is that it gives the opportunity to average activity evidence over structural classes or to study quantitative structure–activity relationships (QSARs). QSARs can be used to predict the activity of new compounds and thus reduce the chance of *in vivo* testing on negative compounds. The use of QSARs can increase the proportion of truly active compounds passing through the system.

FIGURE 28.4 Hybrid project Gantt chart which identifies work of each development function (“line operation”) in development of new compound and how it matches phase of development.

To simplify this presentation, data sets drawn only from neuromuscular screening activity were used. However, the evaluation and approaches should be valid for all similar screening data sets, regardless of source. The methods are not sensitive to the biases introduced by the degree of interdependence found in many screening batteries that use multiple measures (such as the neurobehavioral screen):

1. Screens almost always focus on detecting a single end point of effect (such as mutagenicity, lethality, neurotoxicity, or development toxicity) and have a particular set of operating characteristics in common.
2. A large number of compounds are evaluated, so ease and speed of performance (which may also be considered efficiency) are very desirable characteristics.
3. The screen must be very sensitive in its detection of potential effective agents. An absolute minimum of active agents should escape detection; that is, there

should be very few false negatives (in other words, the type II error rate or beta level should be low). Stated yet another way, the signal gain should be way up.

4. It is desirable that the number of false positives be small (i.e., there should be a low type I error rate or alpha level).
5. Items 2–4, which are all to some degree contradictory, require the involved researchers to agree on a set of compromises, starting with the acceptance of a relatively high-alpha level (0.10 or more), that is, an increased noise level.
6. In an effort to better serve Item 2, safety assessment screens are frequently performed in batteries so that multiple end points are measured in the same operation. Additionally, such measurements may be repeated over a period of time in each model as a means of supporting Item 3.

7. This screen should use small amounts of compound to make Item 1 possible and should allow evaluation of materials that have limited availability (such as novel compounds) early on in development.
8. Any screening system should be validated initially using a set of blind (positive and negative) controls. These blind controls should also be evaluated in the screening system on a regular basis to ensure continuing proper operation of the screen. As such, the analysis techniques used here can then be used to ensure the quality or modify performance of a screening system.
9. The more that is known about the activity of interest, the more specific the form of screen that can be employed. As specificity increases, so should sensitivity.
10. Sample (group) sizes are generally small.
11. The data tend to be imprecisely gathered (often because researchers are unsure of what they are looking for) and therefore possess extreme within-group variability. Control and historical data are not used to adjust for variability or modify test performance.
12. Proper dose selection is essential for effective and efficient screen design and conduct. If insufficient data are available, a suitably broad range of doses must be evaluated (however, this technique is undesirable on multiple grounds, as has already been pointed out).

The design, use, and analysis of screens are covered in detail in Chapter 4 of this volume.

28.5 STRATEGY AND PHASING

Regulatory requirements and our understanding of the pharmacology, marketing, and clinical objectives for a potential product provide a framework of requirements for the safety assessment of potential new pharmaceuticals. How one meets these requirements is not fixed, however. Rather, exactly what is done and when are reflections of the philosophy and managerial climate of the organization that is doing the discovery and development. It should be kept in mind that establishing and maintaining an excellent information based on the biological basis for a compound's expected therapeutic activity and safety is essential but often left undone. This subject is addressed in Chapter 2 of this volume.

There are multiple phases involved in the safety assessment portion of the discovery, development, and marketing process. The actual conduct of the studies in each phase forms the basis of the bulk of the chapters in this book. However, unless the pieces are coordinated well and utilized effectively (and completed at the right times), success of the safety assessment program is unlikely or very expensive.

First, support needs to be given to basic research (also called discovery, biology, or pharmacology in different organizations) so that it can efficiently produce a stream of potential new product compounds with as few overt toxicity concerns as possible. This means that there must be early and regular interaction between the individuals involved and that safety assessment must provide screening services to rank the specific safety concerns of the compounds. These screens may be *in vitro* (both for genetic and nongenetic end points) or *in vivo* (designed on purpose for a single end point, such as effects on reproductive performance, promotion activity, etc.). There must also be an ongoing work to elucidate the mechanisms and structure–activity relationships behind those toxicities that are identified (Gad, 1989b).

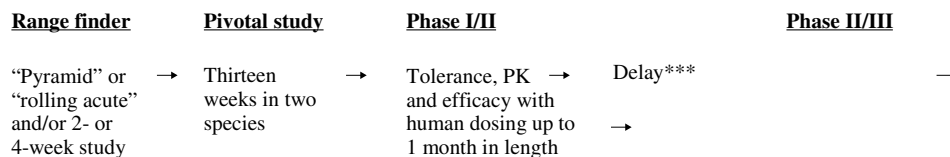

Second, it is the traditional core of safety assessment that is viewed as development. Development includes providing the studies to support compounds getting into the clinic (an IND application being filed and accepted); evaluating a compound to the point at which it is considered safe, able to be absorbed, and effective (clinical phase II); and, finally, registration (filing an NDA and having it approved). Various organizations break this process up differently. Judgments are generally made on the likelihood of compounds failing (“dying”) at different stages in the clinical development process, and the phasing of preclinical support is selected and/or adjusted accordingly. If an organization has a history of many compounds failing early in the clinic (such as in the initial phase I tolerance trials, where there may be only 3–10 days of human dosing), then initial “pivotal” preclinical studies are likely to be only 4-week-long studies. If compounds tend to fail only in longer efficacy trials, then it is more efficient to run longer initial preclinical trials. Figure 28.5 shows several variations on these approaches. Additionally, the degree of risk involved in study design (particularly in dose selection) is also an organizational characteristic. Pivotal studies can fail on two counts associated with dose selection. Either they cannot identify a “safe” (no-effect) dose, or they can neglect to find a dose that demonstrates a toxic effect (and therefore allows identification of potential target organs). Therefore, picking the doses for such studies is an art that has been risky because, traditionally, only three different dose groups have been used, and before clinical trials are conducted, there is at best a guess as to what clinical dose will need to be cleared. The use of four (or five) dose groups only marginally increases study cost and, in those cases where the uncertainty around dose selection is great, provides a low-cost alternative to repeating the study.

Pivotal studies can also be called *shotgun tests*, because it is unknown in advance what end points are being aimed at. Rather, the purpose of the study is to identify and quantitate all potential systemic effects resulting from a single exposure to a compound. Once known, specific target organ effects can then be studied in detail if so desired. Accordingly, the generalized design of these studies is to expose groups of animals to

Plan 1: Clinical decision point** is short-term tolerance or human pharmacokinetics

Plan 2: Clinical decision point is an indication of efficacy in man

Plan 3: Plan for success or resources are not a constraint

FIGURE 28.5 Three different approaches to matching preclinical safety efforts to support clinical development of new drug. Which is the best one for any specific case depends on the considerations of resource availability and organizational tolerance of “risk.” In plan 1, little effort will be “wasted” on projects that fail during early (phase I) clinical trials, but if phase I trials are successful, there will be major delays. In plan 3, clinical development will never be held up waiting for more safety work, but a lot of effort will go into projects that never get past phase I. Plan 2 is a compromise. Delays are to allow additional preclinical (animal safety) studies to support longer clinical trials in accordance with FDA or other applicable guidelines.

controlled amounts or concentrations of the material of interest and then to observe for a measure as many parameters as practical over a period past or during the exposure. Further classification of tests within this category would be the route by which test animals are exposed/dosed or by the length of dosing. “Acute,” for example, implies a single exposure interval (of 24h or less) or dose of test material. Using the second scheme (length of dosing), the objectives of the successive sets of pivotal studies could be defined as follows:

Acute or dose range-finding (DRF) studies:

1. Set maximum doses for next studies.
2. Identify very or unusually toxic agents.
3. Estimate upper limit of tolerability.
4. Identify organ system affected.

Either 2-week studies:

1. Set doses for next studies.
2. Identify organ toxicity.
3. Identify very or unusually toxic agents.
4. Estimate lethality potential.

5. Evaluate potential for accumulation of effects.
6. Get estimate of kinetic properties (blood sampling/urine sampling).

Or 4-week studies:

1. Set doses for next studies.
2. Identify organ toxicity.
3. Identify very or unusually toxic agents.
4. Estimate lethality potential.
5. Evaluate potential for accumulation of effects.
6. Get estimate of kinetic properties (blood sampling/urine sampling).
7. Elucidate nature of specific types of target organ toxicities induced by repeated exposure.

13-week studies (now commonly included as an interim necropsy and report in chronic studies):

1. Set doses for next studies.
2. Identify organ toxicity.
3. Identify very or unusually toxic agents.

4. Evaluate potential for accumulation of effects.
5. Evaluate pharmacokinetic properties.
6. Elucidate nature of specific types of target organ toxicities induced by repeated exposure.
7. Evaluate reversibility of toxic effects.

Chronic studies:

1. Elucidate nature of specific types of target organ toxicities induced by prolonged repeated exposure.
2. Identify potential carcinogens.

The problems of scheduling and sequencing toxicology studies and entire testing programs have been minimally addressed in print. Though there are several books and many articles available that address the question of scheduling multiple tasks in a service organization (French, 1982) and an extremely large literature on project management (as briefly overviewed earlier in this chapter), no literature specific to a research testing organization exists.

For all the literature on project management, however, a review will quickly establish that it does not address the rather numerous details that affect study/program scheduling and management. There is, in fact, to my knowledge, only a single article (Levy et al., 1977) in the literature that addresses scheduling, and it describes a computerized scheduling system for single studies.

There are commercial computer packages available for handling the network construction, interactions, and calculations involved in what, as will be shown later, is a complicated process. These packages are available for use on both mainframe and microcomputer systems.

Scheduling for the single study case is relatively simple. One should begin with the length of the actual study and then factor in the time needed before the study is started to secure the following resources:

- Animals must be on hand and properly acclimated (usually for at least 2 weeks prior to the start of the study).
- Vivarium space, caging, and animal care support must be available.
- Technical support for any special measurements such as necropsy, hematology, urinalysis, and clinical chemistry must be available on the dates specified in the protocol.
- Necessary and sufficient test material must be on hand.
- A formal written protocol suitable to fill regulatory requirements must be on hand and signed.

The actual study (from first dosing or exposure of animals to the last observation and termination of the animals) is called

the in-life phase, and many people assume the length of the in-life phase defines the length of a study. Rather, a study is not truly completed until any samples (blood, urine, and tissue) are analyzed, slides are prepared and microscopically evaluated, data are statistically analyzed, and a report is written, proofed, and signed off. Roll all of this together, and if you are conducting a single study under contract in an outside laboratory, an estimate of the least time involved in its completion should be equal to (other than in the case of an acute or single and point study) no more than

$$L + 6 \text{ weeks} + \Delta L$$

where L is the length of the study. If the study is a single end-point study and does not involve pathology, then the least time can be shortened to $L + 6$ weeks. In general, the best that can be done is $L + 10$ weeks.

When one is scheduling out an entire testing program on contract, it should be noted that if multiple tiers of tests are to be performed (such as an acute, 2-week, 13-week, and life-time studies), then these must be conducted sequentially, as the answer from each study in the series defines the design and sets the doses for the subsequent study.

If, instead of contracting out, one is concerned with managing a testing laboratory, then the situation is considerably more complex. The factors and activities involved are outlined later. Within these steps are rate-limiting factors that are invariably due to some critical point or pathway. Identification of such critical factors is one of the first steps for a manager to take to establish effective control over either a facility or a program.

Before any study is actually initiated, a number of pre-study activities must occur (and, therefore, these activities are currently under way—to one extent or another—for the studies not yet under way but already authorized or planned for this year for any laboratory):

- Test material procurement and characterization
- Development of formulation and dosage forms for study
- If inhalation study, development of generation and analysis methodology, chamber trials, and verification of proper chamber distribution
- Development and implementation of necessary safety steps to protect involved laboratory personnel arrangement for waste disposal
- Scheduling to assure availability of animal rooms, manpower, equipment, and support services (pathology and clinical)
- Preparation of protocols
- Animal procurement, health surveillance, and quarantine
- Preparation of data forms and books

- Conduct of prestudy measurements on study animals to set baseline rates of body weight gain and clinical chemistry values

After completion of the in-life phase (i.e., the period during which live animals are used) of any study, significant additional effort is still required to complete the research. This effort includes the following:

- Preparation of data forms and books, preparation of tissue slides, and microscopic evaluation of these slides
- Preparation of data tables
- Statistical analysis of data
- Preparation of reports

There are a number of devices available to a manager to help improve the performance of a laboratory involved in these activities. One such device (cross-training) is generally applicable enough to be particularly attractive.

Identification of rate-limiting steps in a toxicology laboratory over a period of time usually reveals that at least some of these are variable (almost with the season). At times, there is too much work of one kind (say, inhalation studies) and too little of another (say, dietary studies). The available staff for inhalation studies cannot handle this peak load, and since the skills of these two groups are somewhat different, the dietary staff (which is now not fully occupied) cannot simply relocate down the hall and help out. However, if, early on, one identifies low- and medium-skill aspects of the work involved in inhalation studies, one could cross-train the dietary staff at a convenient time so that it could be redeployed to meet peak loads.

It should be kept in mind that there are a number of common mistakes (in both the design and conduct of studies and in how information from studies is used) that have led to unfortunate results, ranging from losses in time and money and the discarding of perfectly good potential products to serious threats to people's health. Such outcomes are indeed the great disasters in product safety assessment—especially since many of them are avoidable if attention is paid to a few basic principles.

It is quite possible to design a study for failure. Common shortfalls include the following:

1. Using the wrong animal model.
2. Using the wrong route or dosing regimen.
3. Using the wrong vehicle or formulation of test material.
4. Using the wrong dose level. In studies where several dose levels are studied, the worst outcome is to have an effect at the lowest dose level tested (i.e., the safe dosage in animals remains unknown). The next worst outcome is to have no effect at the highest dose tested (generally meaning that the signs of toxicity remain

unknown, invalidating the study in the eyes of many regulatory agencies).

5. Making leaps of faith. An example is to set dosage levels based on others' data and to then dose all test animals. At the end of the day, all animals in all dose levels are dead. The study is over; the problem remains.
6. Using the wrong concentration of test materials in a study. Many effects (e.g., both dermal and gastrointestinal irritation) are very concentration-dependent.
7. Failing to include a recovery (or rebound) group. If one finds an effect in a 90-day study (say, gastric hyperplasia), how does one interpret it? How does one respond to the regulatory question, "Will it progress to cancer?" If an additional group of animals were included in dosing and then were maintained for a month after dosing had been completed, recovery (reversibility) could be both evaluated and (if present) demonstrated.

Additionally, there are specialized studies designed to address end points of concern for almost all drugs (carcinogenicity, reproductive, or developmental toxicity) or concerns specific to a compound or family of compounds (e.g., local irritation, neurotoxicity, or immunotoxicity). When these are done, timing also requires careful consideration. It must always be kept in mind that the intention is to ensure the safety of people in whom the drug is to be evaluated (clinical trials) or used therapeutically. An understanding of special concerns for both populations should be considered essential.

Safety evaluation does not cease being an essential element in the success of the pharmaceutical industry once a product is on the market. It is also essential to support marketed products and ensure that their use is not only effective but also safe and unclouded by unfounded perceptions of safety problems. This requires not only that clinical trials be monitored during development (Spector et al., 1988) but also that experience in the marketplace be monitored.

The design and conduct of safety assessment studies and programs also require an understanding of some basic concepts:

1. The studies are performed to establish or deny the safety of a compound rather than to characterize the toxicity of a compound.
2. As pharmaceuticals are intended to affect the functioning of biological systems, and safety assessment characterizes the effects of higher-than-therapeutic doses of compounds, it is essential that one be able to differentiate between hyperpharmacology and true (undesirable) adverse effects.
3. Focus of the development process on a new pharmaceutical not only is an essential aspect of success but is also difficult to maintain. Clinical research units generally desire to pursue as many or as broad claims

as possible for a new agent and frequently also apply pressure for the development of multiple forms for administration by different routes. These forces must be resisted because they vastly increase the work involved in safety assessment and they may also produce results (in one route) that cloud evaluation (and impede Institutional Review Board [IRB] and regulatory approval) of the route of main interest.

28.6 CRITICAL CONSIDERATIONS

In general, what the management of a pharmaceutical development enterprise wants to know at the beginning of a project are three things: what are the risks (and how big are they), how long will it take, and how much (money and test compound) will it take?

The risks question is beyond the scope of this volume. The time question was addressed earlier in this chapter. How much money is also beyond the scope of this volume. But calculating projected compound needs for studies is a fine challenge in the design and conduct of a safety evaluation program. The basic calculation is simple. The amount needed for a study is equal to

$$NWILD$$

where

N = the number of animals per group

W = the mean weight per animal during the course of the study (in kg)

I = the total number of doses to be delivered (such as in a 28-day study, 28 consecutive doses)

L = a loss or efficiency factor (to allow for losses in formulation and dose delivery, a 10% factor is commonly employed, meaning a value of 1.1 is utilized)

D = the total dose factor (This is the sum of all the dose levels. For example, if the groups are to receive 1000, 300, 100, and 30 mg kg⁻¹, then the total dose factor is 1000 + 300 + 100 + 30 or 1430 mg kg⁻¹.)

As an example, let us take a 28-day study in rats where there are 10 males and 10 females per group and the dose levels employed at 1000, 3000, 100, and 30 mg kg⁻¹. Over the course of the 28 days, the average weight of the rats is likely to be 300 g (or 0.3 kg). This means our values are the following:

$$N = 20$$

$$W = 0.3 \text{ kg}$$

$$I = 28$$

$$L = 1.1$$

$$D = 1430 \text{ mg kg}^{-1}$$

and, therefore, our total compound needs will be (20)(0.3)(28)(1.1)(1430 mg) = 2642.64 mg or 2.642 g.

This is the simplest case but shows the principles.

A governing principle of pharmaceutical safety assessment is the determination of safety factors—the ratio between the therapeutic dose (that which achieves the desired therapeutic effect) and the highest dose which evokes no toxicity. This grows yet more complex (but has less uncertainty) if one bases these ratios on plasma levels rather than administered doses. Traditionally based on beliefs as to differences of species sensitivity, it has been held that a minimum of a fivefold (5×) safety factor should be observed based on toxicity findings in nonrodents and a 10-fold (10×) based on rodents.

The desire to achieve at least such minimal therapeutic indices and to also identify levels associated with toxicity (and the associated toxic effects) forms the basis of dose selection for systemic (and most other *in vivo*) toxicity studies.

28.7 SPECIAL CASES IN SAFETY ASSESSMENT

It may seem that the course of preclinical safety assessment (and of other aspects of development) of a pharmaceutical is a relatively linear and well-marked route, within some limits. This is generally the case—but not always. There are a number of special cases where the pattern and phasing of development (and of what is required for safety assessment) do not fit the usual pattern. Four of these cases are the following:

1. When the drug is intended to treat a life-threatening disease, such as AIDS
2. When the drug is actually a combination of two previously existing drug entities
3. When the drug actually consists of two or more isomers
4. When the drug is a peptide produced by a biotechnology process

Drugs intended to treat a life-threatening disease for which there is no effective treatment are generally evaluated against less rigorous standards of safety when making decisions about advancing them into and through clinical testing. This acceptance of increased risk (moderated by the fact that the individuals involved will die if not treated at all) is balanced against the potential benefit. These changes in standards usually mean that the phasing of testing is shifted: animal safety studies may be done in parallel or (in the case of chronic and carcinogenicity studies) after clinical trials and commercialization. But the same work must still eventually be performed.

Combination drugs, at least in terms of safety studies up to carcinogenicity studies, are considered by regulatory agencies

as new drug entities and must be so evaluated. The accordingly required safety tests must be performed on a mixture with the same ratio of components as is to be a product. Any significant change in ratios of active components means one is again evaluating, in regulatory eyes, a new drug entity.

Now that it is possible to produce drugs that have multiple isomers in the form of single isomers (as opposed to racemic mixtures), for good historical reasons, regulatory agencies are requiring at least some data to support any decision to develop the mixture as opposed to a single isomer. One must, at a minimum, establish that the isomers are of generally equivalent therapeutic activity and, if there is therapeutic equivalence, that any undesirable biological activity is not present to a greater degree in one isomer or another.

28.8 POTENTIAL MARKET WITHDRAWAL ISSUES

Section 505(e) of the FD&L act covers eight bases for potential withdrawal of an approved drug from the market. Five of these are mandatory (the drug shall be withdrawn), and three are discretionary (may be withdrawn). The five causes for mandatory removal are as follows:

-
1. Safety—clinical or other evidence shows the drug to be unsafe
 2. Safety—based on clinical evidence not in NDA or known to FDA that drug is “not shown to be safe”
 - For example, VIOXX Cox-2 NSAID (2004)
 - For example, Seldane (following Allegra approval)
 - For example, Avastin for breast cancer (2011)
 3. Effectiveness—new evidence shows lack of substantial evidence of effectiveness
 4. Failure to file required patent information
 5. Application includes untrue statement of material fact
 - For example, KV Pharmaceutical (1998)
-

The three discretionary causes are the following:

-
1. Failure to have a system for maintaining required records, to permit access to records, or to file required reports
 2. New information: serious manufacturing deficiencies and not corrected within reasonable time after written notice
 3. New information: labeling is false or misleading and not corrected within reasonable time after written notice
 - Generic MiraLax (Rx/OTC marketing) (October 2008)
-

There are other screening discretionary causes for which there is no clear legal authority to also be invoked and are rarely challenged. These include the following:

-
- Legal Authority uncertain (but not challenged)
 - Failure to submit bioavailability or bioequivalence data
 - Failure to explain omission of investigation or other information pertinent to evaluation of drug (omission itself not basis for withdrawal)
 - Good laboratory practice violations
 - Informed consent/IRB violations
 - Refusal to permit inspection (applicant or clinical research organization [CRO])
 - Voluntary—applicant request for withdrawal
 - Product no longer marketed (e.g., Redux)
 - Failure to meet postmarketing endpoints (e.g., Iressa, Oforta, one indication for Celebrex)
 - Voluntary—FDA request
 - Safety issues with postmarket trial (e.g., Mylotarg, Meridia)
 - Citizen petition
 - Raising alleged safety concerns
 - Confusion over product names
 - Imminent hazard to public health
 - Summary suspension with opportunity for expedited hearing
 - HHS secretary’s decision—only used once in the late 1970s
 - Agency “mistake” (American Therapeutics case)
 - Advisory Committee recommendation
 - Darvon/Darvocet (propoxyphene) (1/2009)
 - AdCom voted to withdraw approval based on safety issues
 - FDA (November 2010) based on new data, requested withdrawal; manufacturer agreed
 - Vicodin, Percocet (narcotics + acetaminophen) (6/2009)
 - AdCom voted to withdraw approval; no FDA action yet
-

All of these are from either safety, lack of efficacy, or defects in data supplied to support the drugs initial approval or subsequent maintenance on the market.

28.9 SUMMARY

It is the belief of this author that the entire safety assessment process that supports pharmaceutical research and development is a multistage process of which no single element is overwhelmingly complex. These elements must be coordinated and their timing and employment carefully considered on a repeated basis. Focus on the objective of the process, including a clear definition of the questions being addressed by each study, is essential, as is the full integration of the technical talents of each of the many disciplines involved. A firm understanding of the planned clinical

development of the drug is essential. To stay competitive requires that new technologies be identified and incorporated effectively into safety assessment programs as they become available. It is hoped that this volume will provide the essential knowledge of the key elements to allow these goals to be realized.

29

THE APPLICATION OF *IN VITRO* TECHNIQUES IN DRUG SAFETY ASSESSMENT

29.1 INTRODUCTION

The key assumptions underlying modern toxicology are (Zbinden, 1987) (i) that other organisms can serve as accurate predictive models of toxicity in man (Gad, 1996, 2015); (ii) that selection of an appropriate model to use is the key to accurate prediction of potential hazard in man, and (Lijinsky, 1988); (iii) that understanding the strengths and weaknesses of any particular model is essential to translating potential hazards identified in these models to assess relevant hazard in man and in the subsequent management of actual risks. Recently, it has become clear that it is also possible to understand the causality of differences between species and pharmacokinetic (toxicokinetic) responses, and from these understandings to be able to integrate findings across species and have a better understanding (and thus ability to predict) of human responses. Historically higher animals (mammals) have been used in studies with significant focus on collecting descriptive data (reinforced by being able to translate methods such as clinical chemistry and pathology from human medicine). This approach to model selection and data collection in toxicological research became the subject of critical scientific review starting in the early 1980s. Usually in toxicology, when we refer to “models,” we really have meant test organisms or systems, although, in fact, the manners in which parameters are measured (and which parameters are measured to characterize an end point of interest) are also critical parts of the model (or, indeed, may actually constitute the “model”).

Although there are well-accepted principles for test organism selection, these have not generally been the actual final basis for such selection. It is a fundamental hypothesis of both historical and modern toxicology that adverse effects caused by chemical entities in higher animals are generally

the same as those induced by those entities in man. There are many who point to individual exceptions to this and conclude that the general principle is false. Yet, as our understanding of molecular biology advances and we learn more about the similarities of the structure and function of higher organisms at the molecular level, the more it becomes clear that the mechanisms of chemical toxicity are largely identical in all higher life forms, including humans. The target sites are molecular, and differences in responses are all about similarities in receptor populations, in receptor population distribution in organ systems, and in the manner and means of getting toxicophores to these sites or preventing them from reaching these sites. In this sense, it is now the age of translational toxicology. This increased understanding has caused some of the same people who question the general principle of predictive value in turn suggest that our state of knowledge is such that mathematical models or simple cell culture systems could be used just as well as intact higher animals to predict toxicities in man. This last suggestion has unfortunately missed the point that the final expressions of toxicity in man or in animals are frequently the summations of extensive and complex interactions on cellular, biochemical, and molecular (even gene) levels. Zbinden (1987) and Gad (1996, 2015) published extensively in this area, including a very advanced defense of the value of animal models. Lijinsky (1988) has reviewed the specific issues about the predictive value and importance of animals in carcinogenicity testing and research. Although it was once widely believed, and may still be believed by many animal rights activists, that *in vitro* mutagenicity tests would entirely replace animal bioassays for carcinogenicity, this is clearly not the case on scientific, public health, or regulatory grounds (despite the limitations of the current bioassay models). Although there are differences in the responses of various species (including man) to carcinogens, the overall

predictive value of such results, when tempered by judgment, is clear. At the same time, a well-reasoned use of *in vitro* or other alternative test model systems is essential to the continued development of a product safety assessment program that is effective, efficient, and relevant to human safety (Gad, 1990a, 2000, 2009, 2015).

The subject of intact animal models and their proper selection and use have been addressed elsewhere (Gad, 2015) and will not be further addressed here. However, alternative models which use other than intact higher organisms are seeing increasing use in toxicology for a number of reasons. The acceptance of these alternatives in regulatory toxicology continues to progress much more slowly.

The first and most significant factor behind the interest in the so-called *in vitro* systems has clearly been philosophical and political—an unremitting campaign by a wide spectrum of individuals concerned with the welfare and humane treatment of laboratory animals (Gad, 2009)—though some are also clearly simply antiscience and antitechnology. In 1959, Russell and Burch first proposed what have come to be called the three Rs of humane animal use in research—replacement, reduction, and refinement. These have served as the conceptual basis for reconsideration of animal use in research. Efforts continue along these lines (Singer, 1975; May et al., 2009; Birnbaum and Stokes, 2010).

Replacement means utilizing methods that do not use intact animals in place of those that do. For example, veterinary students may use a canine cardiopulmonary resuscitation simulator, Resusci-Dog, instead of living dogs; cell cultures may replace mice and rats that are fed new products to discover substances poisonous to humans. In addition, using the preceding definition of animal, an invertebrate (e.g., a horseshoe crab) could replace a vertebrate (e.g., a rabbit) in a testing protocol.

Reduction refers to the use of fewer animals. These are wide variations in estimates of animals in research, ranging as high as 127 million in a year (Boo and Knight, 2009). For instance, changing practices allows toxicologists to estimate the lethal dose of a chemical with as few as one-tenth the number of animals used in traditional tests. In biomedical research, long-lived animals, such as primates, may be used in multiple sequential protocols, assuming that they are not deemed inhumane or scientifically conflicting. Designing experimental protocols with appropriate attention to statistical inference can lead to decreases or to increases in the number of animals used. Through coordination of efforts among investigators, several tissues may be simultaneously taken from a single animal. Reduction can also refer to the minimization of any unintentionally duplicative experiments, perhaps through improvements in information resources.

Refinement entails the modification of existing procedures so that animals are subjected to less pain and distress. Refinements may include administration of anesthetics to animals undergoing otherwise painful procedures, administration of tranquilizers for distress, humane destruction prior to

recovery from surgical anesthesia, and careful scrutiny of behavioral indices of pain or distress, followed by cessation of the procedure or the use of appropriate analgesics. Refinements also include the enhanced use of noninvasive imaging technologies that allow earlier detection of tumors, organ deterioration, or metabolic changes and the subsequent early euthanasia of test animals.

Progress toward these first three Rs has been previously reviewed (Gad, 1990b; Salem, 1995; Salem and Katz, 1998; Indans, 2002; Gribaldo, 2007; Gad, 2015). However, there is a fourth R—responsibility—which was not in Russell and Burch's initial proposal (Russell and Burch, 1959). To toxicologists this is the cardinal R. They may be personally committed to minimizing animal use and suffering and to doing the best possible science of which they are capable, but at the end of it all, toxicologists must stand by their responsibility to be conservative in ensuring the safety of the people using or exposed to the drugs and chemicals produced by our society.

Since 1980, issues of animal use and care in toxicological research and testing have become one of the fundamental concerns of both science and the public. Are our results predictive of what may or may not be seen in man? Are we using too many animals, and are we using them in a manner that gets the answer we need with as little discomfort to the animals as possible? How do we balance the needs of man against the welfare of animals?

During the same time frame, interest and progress in the development of *in vitro* test systems for toxicity evaluations have also progressed. Early reviews by Hooisma (1982), Neubert (1982), and Williams et al. (1983) record the proceedings of conferences on the subject, but Rofe's (1971) review was the first found by this author. Although it is hoped that in the long term, some of these (or other) *in vitro* methods will serve as definitive tests in place of those that use intact animals, at present it appears more likely that their use in most cases will be as screens. Frazier (1992) and Gad and Chengelis (1997) give recent overviews of the general concepts and status of *in vitro* alternatives.

The entire product (drugs, devices, agricultural, and consumer products) safety assessment process, in the broadest sense, is a multistage process in which none of the individual steps are overwhelmingly complex, but the integration of the whole process involved fitting together a large complex pattern of pieces. The single most important part of this product safety evaluation program is, in fact, the initial overall process of defining and developing an adequate data package on the potential hazards associated with the product life cycle (the manufacture, sale, use, and disposal of a product and associated process materials). To do this, one must ask a series of questions in a highly interactive process, with many of the questions designed to identify and/or modify their successors. The first is—what information is needed?

Required here is an understanding of the way in which a product is to be made and used and the potential health and

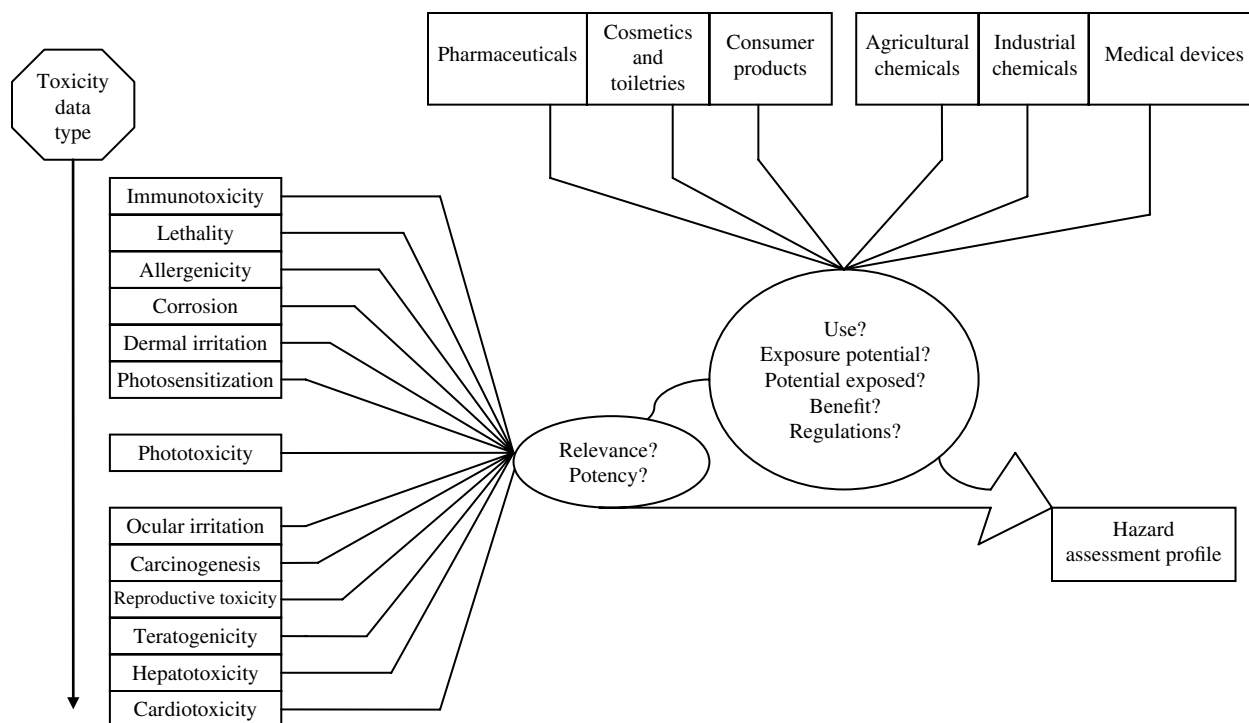

FIGURE 29.1 Development of a hazard assessment profile.

safety risks associated with exposure of humans who will be associated with these processes. Such an understanding is the basis of a hazard and toxicity profile. Once such a profile has been established (as illustrated in Figure 29.1), the available literature is searched to determine what is already known.

Taking into consideration this literature information and the previously defined exposure profile, a tier approach (Table 29.1) has traditionally been used to generate a list of tests or studies to be performed. What goes into a tier system is determined by regulatory requirements imposed by government agencies as well as the philosophy of the parent organization, economics, and available technology. How such tests are actually performed is determined on one of two bases. The first (and most common) is the menu approach: selecting a series of standard design tests as “modules” of data. The second is an interactive/iterative approach, where strategies are developed and studies are designed, based on both needs and what has been learned to date about the product. This process has been previously examined in some detail. Our interest here, however, is in the specific portion of the process involved in generating data—the test systems.

29.2 *IN VITRO* TESTING IN PHARMACEUTICAL SAFETY ASSESSMENT

The preclinical assessment of the safety of potential new pharmaceuticals and new devices represents a special case of

the general practice of toxicology (Meyer, 1989; Gad, 1999, 2015), possessing its own peculiarities and special considerations and differing in several ways from the practice of toxicology in other fields—for some significant reasons. Because of the economics involved and the essential close interactions with other activities (e.g., clinical trials, chemical process optimization, formulation development, regulatory reviews), the development and execution of a crisp and flexible, yet scientifically sound, program are a prerequisite for success. The ultimate aim of preclinical safety and biocompatibility assessment also makes them different. A good safety assessment program seeks to efficiently and effectively move safe potential therapeutic agents or devices into the clinical evaluation, then to registration, and finally to market and to support them through this process. This requires the quick identification of those agents that are not safe so that efforts (and limited resources) are not wasted on them.

Pharmaceuticals are intended to have human exposure. Furthermore, pharmaceuticals are intended to have biological effects on the people that receive them. Frequently, the interpretation of results and the formulation of decisions about the continued development and eventual use of a drug are based on an understanding of both the potential adverse effects of the agent and its likely benefits, as well as the dose separation between these two. This makes a clear understanding of dose–response relationship critical, so that the actual risk/benefit ratio can be identified. It is also essential that the pharmacokinetics

TABLE 29.1 The Usual Way of Characterizing the Toxicity of a Compound or Product Is to Develop Information in a Hierarchical (Tier) Approach Manner

Testing Tier	Mammalian Toxicology	Genetic Toxicology	Remarks
0	Literature review	Literature review	Upon initial identification of a problem, database of existing information, and particulars of use of materials are established
1	Cytotoxicity screens GPMT or LLNA Acute systemic toxicity	Ames test <i>In vitro</i> SCE <i>In vitro</i> cytogenetics	R&D material and low-volume chemicals with severely limited exposure
2	Receptor binding, that is, hERG Subacute studies ADME Local tissue tolerance Safety pharmacology Ocular Dermal Vascular Hematologic Irritation	Comet assay <i>In vivo</i> SCE <i>In vivo</i> cytogenetics	Medium-volume materials and/or those with a significant chance of human exposure
3	Subchronic studies Reproduction Developmental toxicity Chronic studies Mechanistic studies	—	Any materials with a high volume or a potential for widespread or long-term human exposure or one that gives indications of specific long-term effects

More information is required (a higher tier level is attained) as the volume of production and potential for exposure increase. A common scheme is shown.

be understood and that “doses” (plasma tissue levels) at target organ sites (both therapeutic and toxicological) be known (Scheuplein et al., 1990). Integral pharmacokinetics are essential to such a safety program, especially now that there is wider recognition of the existence and importance of subpopulations with different metabolic competencies. As we have come to understand that pharmacogenetics underlie many of the subpopulation effects we see in both the safety and efficacy of drugs, we have also come to recognize that *in vitro* methods also offer some of the best and most efficient means of understanding the basis for these differences and for identifying members of specific subpopulations.

The development and safety evaluation of pharmaceuticals and medical devices have many aspects broadly or tightly specified by regulatory agencies (Gad, 2001, 2009). An extensive set of defined safety evaluations is required before a product is ever approved for market. For pharmaceuticals, regulatory agencies have increasingly come to require not only the establishment of a “clean dose” in two species with adequate safety factors to cover potential differences between species but also an elucidation of the mechanisms underlying those adverse effects that are seen at higher doses and are not well understood. These regulatory requirements are compelling to the pharmaceutical toxicologist (Traina, 1983). There is not, however, a set menu of what must be done. Rather, much (particularly in terms of the timing of testing) is open to professional judgment. Devices have tended to be more set

pieces in their testing approach but are beginning to likewise require more mechanistic understanding to allow for competitive positioning in the marketplace. The discovery, development, and registration of a pharmaceutical or biologic are an immensely expensive operation and represent a rather unique challenge. For every 9000–10000 compounds specifically synthesized or isolated as potential therapeutics, one (on average) will actually reach the market (though of every 250 actually entering development, two will likely reach the marketplace). The overall cost for each successful compound is currently estimated to be between 1 and 1.3 billion dollars (though those figures are, of course, burdened with the cost of all the unsuccessful compounds), with each successive stage in the development process being more expensive. This dynamic makes it of great interest to identify as early as possible those agents that are likely not to go the entire distance, allowing a concentration of effort on the compounds that have the highest probability of reaching the market (and of possessing therapeutic utility) to do so.

Compounds “drop out” of the process primarily for three reasons: (i) toxicity or (lack of) tolerance, (ii) (lack of) efficacy, and (iii) (lack of) bioavailability of the therapeutic active moiety in humans. Early identification of “losers” in each of these three categories is thus extremely important (Fishlock, 1990), forming the basis for the use of screening in pharmaceutical discovery and development. How much and which resources to invest in screening and each successive

TABLE 29.2 Levels of Models for Safety Assessment and Toxicological Research

Level/Model	Advantages	Disadvantages
<i>In vivo</i> (intact higher organism)	Full range of organismic responses similar to target species	Cost Ethical/animal welfare concerns Species-to-species variability
Lower organisms (earthworms and fish)	Range of integrated organismic responses	Frequently lack responses typical of higher organisms, animal welfare concerns
Isolated organisms	Intact yet isolated tissue and vascular system	Donor organism still required
	Controlled environment and exposure conditions	Time-consuming and expensive, no intact organismic responses, limited duration of viability
Cultured cells	No intact animals directly involved	Instability of system
	Ability to carefully manipulate system	Limited enzymatic capabilities and viability of system
	Low cost, ability to study a wide range of variables	No (or limited) integrated multicell and/or organismic responses
Chemical/biochemical systems	No donor organism problems, low cost, long-term stability of preparation; Ability to study a wide range of variables; Specificity of response.	No <i>de facto</i> correlation to <i>in vivo</i> systems; limited to investigation of a single defined mechanism
Genomics and proteomics	Speed and broad scope	Much effort is still required to correlate to intact organism effects
Computer simulations	No animal welfare concerns, speed and low per-evaluation cost	May not have predictive value beyond a narrow range of structures Expensive to establish

step in support of the development of a potential drug are matters of strategy and phasing that are detailed elsewhere (Gad, 2000). A range of test systems is available to be used in screening and in the definitive testing that follows for selected promising compounds. Table 29.2 presents a summary of the levels of available model systems. Those test systems that involve *in vitro* methods are now providing new tools for use in both early screening and in understanding the mechanisms of observed toxicity in preclinical and clinical studies (Gad, 1988b). Devices are generally less complicated in design and in their testing procedures and have a much lower rate of failure in the qualification and approval stages that precede going to market. The trend in devices, however, is for regulatory authorities to require more testing, to be more critical of results, and to take longer in the review and approval process.

The entire safety assessment process that supports new product research and development is a multistage effort in which none of the individual steps are overwhelmingly complex, but for which the integration of the whole process involves fitting together a large and complex pattern of pieces. This chapter proposes an approach in which integration of *in vitro* test systems calls for a modification of the approach to the general safety assessment problem. This modification can be addressed by starting with the current general case and progressing to a means of changing the process in an iterative fashion as new tools become available. Particularly with an understanding of mechanisms of toxicity becoming increasingly important in both candidate drug selection and the design and evaluation of the relevance of findings, the

integration of *in vitro* methodologies particularly into the pharmaceutical safety assessment process has become essential. Determining what information is needed calls for an understanding of the way in which the device or pharmaceutical is to be made and used, as well as an understanding of the potential health and safety risks associated with exposure of humans who will be either using the drug/device or associated with the processes involved in making it. This is on the basis of a hazard and toxicity profile. Once such a profile is established, the available literature is searched to determine what is already known. Much of the necessary information for support of safety claims in registration of a new drug/device is regulatorily mandated. This is not the case at all, however, for those safety studies done (i) to select candidate products or materials for development, or (ii) to design pivotal safety studies to support registration, or (iii) to pursue mechanistic questions about materials and products in development.

Taking into consideration this literature information and the previously defined exposure profile, investigators have traditionally used a tier approach to generate a list of tests or studies to be performed based on regulatory requirements. What goes into a tier system is determined by (i) regulatory requirements imposed by government agencies, (ii) the philosophy of the parent organization, (iii) economics, and (iv) available technology. How such tests are actually performed is determined on one of the two bases. The first (and most common) is the menu approach, which involves selecting a series of standard design tests as “modules” of data. This assumes that all drugs or devices are alike except for route and duration of administration. The second is an interactive/

iterative approach, where strategies are developed and studies are designed based both on needs and on what has been learned to date about the product.

29.3 DEFINING TESTING OBJECTIVE

The initial and most important aspect of a product safety evaluation program is the series of steps that leads to an actual statement of the problem or of the objectives of testing and research programs. This definition of objectives is essential and, as proposed here, consists of five steps: (i) defining product or material use, (ii) estimating or quantitating exposure potential, (iii) identifying potential hazards, (iv) gathering baseline data, and (v) designing and defining the actual research program to answer outstanding questions.

29.3.1 Objectives Behind Data Generation and Utilization

To understand how product safety and toxicity data are used and how the data generation process might be changed to better meet the product safety assessment needs of society, it is essential to understand that different regulatory organizations have different answers to these questions. The ultimate solution is in the form of a multidimensional matrix, with the three major dimensions of the matrix being (i) the toxicity/biocompatibility data type (lethality, sensitization, corrosion, irritation, photosensitization, phototoxicity, etc.), (ii) exposure characteristics (extent, population size, population characteristics, etc.), and (iii) the stage in the research and development process we are dealing with.

What is called for is a careful zero-based consideration of what the optimum product safety assessment strategy for a particular development problem should be. Before formulating such a strategy and deciding what mix of tests should be used, it is first necessary to decide criteria for what would constitute an ideal (or at least acceptable) test system.

The ideal test should have an end-point measurement that provides data such that dose–response relationships can be obtained where possible or necessary (and such are almost always necessary). Furthermore, any criterion of effect must be sufficiently accurate in the sense that it can be used to reliably resolve the relative toxicity of two compounds that produce distinct (in terms of hazard to humans) yet similar responses. In general, it may not be sufficient to classify compounds into generic toxicity categories, such as “intermediate” toxicity, since a candidate chemical that falls in a given category yet is borderline to the next more severe toxicity category should be treated with more concern than a second candidate that falls at the less-toxic extreme of the same category. Therefore, it is useful for a test system to be able to rank compounds with potentially similar uses accurately within any common toxicity category.

The end-point measurement of the “ideal” test system must be objective, so that a given compound will give similar results when tested using the standard test protocol in different laboratories. If it is not possible to obtain reproducible results in a given laboratory over time or between various laboratories, then the historical database against which new compounds are evaluated will be time- and laboratory-dependent. Along these lines, it is important for the test protocol to incorporate internal standards to serve as quality controls (QCs). Thus, test data could be represented utilizing a reference scale based on the test system response to the internal controls. Such normalization, if properly documented, could reduce between-test variability.

The test results from any given compound should be reproducible both intrinsically (within the same laboratory over time) and extrinsically (between laboratories). If these conditions are not satisfied, then there will be significant limitations on the application of the test system because it could potentially produce conflicting results at different times and places. Such a possibility would significantly reduce confidence in the outcome of any single assay or assay set. From a regulatory point of view, this possibility would be highly undesirable (and perhaps indefensible). Alternatives to current *in vivo* test systems basically should be designed to evaluate the subject toxic response in a manner as closely predictive of that occurring in humans as possible while also reducing animal use and avoiding inhumane treatments where possible.

From a practical point of view, several additional features of the “ideal” test should be satisfied. The test should be rapid so that the turnaround time for a given compound is reasonable. Obviously, the speed of the test and the ability to conduct tests on several candidate drugs or materials simultaneously will determine the overall productivity. The test should be inexpensive, so that it is economically competitive with current testing practices (in the pharmaceutical industry, any reduction in critical path time for decisions has great economic value, so speed is generally preferable to lower cost—within limits). And finally, the technology should be easily transferred from one laboratory to another without excessive capital investment specific to test implementation. Although some of these practical considerations may appear to present formidable limitations for a given test system at the present time, the possibility of future developments in testing technology could overcome these obstacles.

29.4 TEST SYSTEMS: CHARACTERISTICS, DEVELOPMENT, AND SELECTION

Any useful test system must be sufficiently sensitive to ensure that the incidence of false negatives is low. Clearly, a high incidence of false negatives is intolerable. In such a

situation, a large number of dangerous chemical agents would be carried through extensive additional testing only for it to be found that they possess undesirable toxicological properties after the expenditure of significant time and money. On the other hand, a test system that is overly sensitive will give rise to a high incidence of false positives, which will have the deleterious consequence of rejecting potentially beneficial chemicals. The “ideal” test will fall somewhere between these two extremes and thus provide adequate protection without unnecessarily stifling development.

The “ideal” test should have an end-point measurement that provides data such that dose–response relationships can be obtained. Furthermore, any criterion of effect must be sufficiently accurate in the sense that it can be used reliably to resolve the relative toxicity of two test chemicals that produce distinct (in terms of hazard to humans) yet similar responses. In general, it may not be sufficient to classify test chemicals into generic toxicity categories. For instance, if a test chemical falls into an “intermediate” toxicity category, yet is borderline to the next more severe toxicity category, it should be treated with more concern than a second test chemical that falls at the less-toxic extreme of the same category. Therefore, it is essential for a test system to be able to both place test chemicals in an established toxicity category and rank materials relative to others in the category.

The end-point measurement of the “ideal” test system must be objective. This is important to ensure that a given test chemical will give similar results when tested using the standard test protocol in different laboratories. If it is not possible to obtain reproducible results in a given laboratory over time or between various laboratories, then the historical database against which new test chemicals are evaluated will be time-/laboratory-dependent. If this condition is the case, then there will be significant limitations on the application of the test system since it could potentially produce conflicting results. From a regulatory point of view, this possibility would be highly undesirable. Along these lines, it is important for the test protocol to incorporate internal standards to serve as QCs. Thus, test data could be represented utilizing a reference scale based on the test system response to the internal controls. Such normalization, if properly documented, could reduce interest variability.

From a practical point of view, there are several additional features of the “ideal” test which should be satisfied. Alternatives to current *in vivo* test systems basically should be designed to evaluate the observed toxic response in a manner as closely predictive of the outcome of interest in man as possible. In addition, the test should be fast enough to ensure that the turnaround time for a given test chemical is reasonable for the intended purpose, very rapid for a screen, and timely for a definitive test. Obviously, the speed of the test and the ability to conduct tests on several chemicals simultaneously will determine the overall productivity. The test should be inex-

pensive, so that it is economically competitive with current testing practices, and finally, the technology should be easily transferred from one laboratory to another without excessive capital investment (relative to the value of the test performed) for test implementation.

It should be kept in mind that although some of these practical considerations may appear to present formidable limitations for any given test system at the present time, the possibility of future developments in testing technology could overcome these obstacles. In reality, these practical considerations are grounds for consideration of multiple new candidate tests on the basis of competitive performance. The most predictive test system in the universe of possibilities will never gain wide acceptance if it takes years to produce an answer or costs substantially more than other test systems that are only marginally less predictive.

The point is that these characteristics of the “ideal” test system provide a general framework for evaluation of alternative test systems in general. No test system is likely to be “ideal.” Therefore, it will be necessary to weigh the strengths and weaknesses of each proposed test system in order to reach a conclusion on how “good” a particular test is.

In both theory and practice, *in vivo* and *in vitro* tests have potential advantages. Tables 29.3 and 29.4 summarize their advantages. How, then, might the proper tests be selected, especially in the case of the choice of staying with an existing test system or adopting a new one? The next section will present the basis for selection of specific tests.

29.5 *IN VITRO* MODELS

In vitro models, at least as screening tests, have been in use in toxicology since the early 1980s. The last 20+ years have brought a great upsurge in interest in such models. This increased interest is due to economic and animal welfare pressures and technological improvements.

Criteria against which an *in vitro* model should be evaluated for its suitability in replacing (partially or entirely) an accepted *in vivo* model are incorporated in the process detailed in Table 29.5, which presents the proposed steps for taking a new *in vitro* testing technology from being a research construct to a validated and accepted test system.

There are substantial potential advantages in using an *in vitro* system in toxicological testing which include isolation of test cells or organ fragments from homeostatic and hormonal control and accurate dosing and quantification of results. It should be noted that, in addition to the potential advantages, *in vitro* systems per se also have a number of limitations which can contribute to them not being acceptable models. Findings from an *in vitro* system that either limit their use in predicting *in vivo* events or make them totally unsuitable for the task include wide differences in the doses needed

TABLE 29.3 Rationale for Using *In Vivo* Test Systems

1. Provides evaluation of actions/effects on intact animal organ–tissue interactions.
2. Either neat chemicals or complete formulated products (complex mixtures) can be evaluated.
3. Either concentrated or diluted products can be tested.
4. Yields data on the recovery and healing processes.
5. Required statutory tests for agencies under such laws as the Federal Hazardous Substances Act (unless data are already available); Toxic Substances Control Act; Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA); and Organisation for Economic Co-operation and Development (OECD) and Food and Drug Administration laws.
6. Quantitative and qualitative tests with scoring system generally capable of ranking materials as to relative hazards.
7. Amenable to modifications to meet the requirements of special situations (such as multiple dosing or exposure schedules).
8. Extensive available database and cross-reference capability for evaluation of relevance to human situation.
9. The ease of performance and relative low capital costs in many cases.
10. Tests are generally both conservative and broad in scope, providing for maximum protection by erring on the side of overprediction of hazard to man.
11. Tests can be either single end point (such as lethality and corrosion) or shotgun (also called multiple end point, including such test systems as a 13-week oral toxicity study).

TABLE 29.4 Limitations of *In Vivo* Testing Systems Which Serve as a Basis for Seeking *In Vivo* Alternatives for Toxicity Tests

1. Complications and potential confounding or masking findings of *in vivo* systems.
2. *In vivo* systems may only assess short-term site of application or immediate structural alterations produced by agents. Specific *In vivo* tests may only be intended to evaluate acute local effects (i.e., this may be a purposeful test system limitation).
3. Technician training and monitoring are critical (particularly in view of the subjective nature of evaluation).
4. *In vivo* tests in animals do not perfectly predict results in humans if the objective is to exclude or identify severe-acting agents.
5. Structural and biochemical differences between test animals and humans make extrapolation from one to the other difficult.
6. Lack of standardization of *in vivo* systems.
7. Variable correlation with human results.
8. Large biological variability between experimental units (i.e., individual animals).
9. Large, diverse, and fragmented databases which are not readily comparable.

to produce effects or differences in the effects elicited. Some reasons for such findings are detailed in Table 29.6.

Tissue culture has the immediate potential to be used in two very different ways by industry. First, it has been used to

examine a particular aspect of the toxicity of a compound in relation to its toxicity *in vivo* (i.e., mechanistic or explanatory studies). Second, it has been used as a form of rapid screening to compare the toxicity of a group of compounds for a particular form of response. Indeed, the pharmaceutical industry has used *in vitro* test systems in these two ways for years in the search for new potential drug entities.

The theory and use of screens in toxicology have previously been reviewed (Gad, 1988a, 1989a, b). Mechanistic and explanatory studies are generally called for when a traditional test system gives a result that is either unclear or is one for which the relevance to the real-life human exposure is doubted. *In vitro* systems are particularly attractive for such cases because they can focus on very defined single aspects of a problem or pathogenic response, free of the confounding influence of the multiple responses of an intact higher-level organism. Note, however, that the first one must know the nature (indeed the existence) of the questions to be addressed. It is then important to devise a suitable model system, which is related to the mode of toxicity of the compound.

There is currently much controversy over the use of *in vitro* test systems—will they find acceptance as “definitive tests systems” or only be used as preliminary screens for such final tests? Or, in the end, not be used at all? Almost certainly, all three of these cases will be true to some extent. Depending on how the data generated are to be used, the division between the first two is ill defined at best.

Before trying to definitely answer these questions in a global sense, each of the end points for which *in vitro* systems are being considered should be overviewed and considered against the factors outlined to this point.

29.6 LETHALITY

Many of the end points of interest in toxicology present a fundamental limitation to the development and use of an *in vitro* or nonmammalian system in place of established *in vivo* methods. While cytotoxicity is a component mechanism in many of these toxic responses, disruption or diminution of the integrated function of multiple cells and systems is just as important.

The evaluation of lethality (symbolized in the public mind by the LD₅₀ test) would seem to offer a unique opportunity for the development and use of alternatives. Approaches to alternatives for lethality testing include no living materials at all (the structure–activity relationship [SAR] or computer model approaches), those that use no intact higher organisms (but rather cultured cells or bacteria) and those that use lower forms of animal life (e.g., invertebrates and fish). Each of these approaches presents a different approach to the objective of predicting acute lethality in humans or, rarely, economic animals and will be examined in turn.

TABLE 29.5 Multistage Scheme for the Development, Validation, and Transfer of *In Vitro* Test System Technology in Toxicology

Stage I: Statement of Test Objective

- A. Identify existing test system and its strengths and weaknesses
- B. Clearly state objectives for alternative test system
- C. Identify potential alternative test system

Stage II: Define Developmental Test Design

- A. Identify relevant variables
- B. Evaluate effects of variables on test system
- C. Optimize test performance
- D. Understand what the test does in a functional sense
 1. Is it a simulation of an *in vivo* event?
 2. Is this simply a response to the presence of the agent?
 3. Is the measured response a functional step or link in the *in vivo* event of interest?
 4. Is the measured response a functional step or link in the *in vivo* event of interest or some intermediate stage?
 5. Is this an effect on some structure or function analogous to the *in vivo* structure or function?

Stage III: Evaluate Performance of Optimum Test

- A. Develop library of known positive- and negative-response materials of diverse structure and a range of response potencies (i.e., if the end point is irritation, then materials should range from nonirritating to severely irritating)
- B. Use optimum test design to evaluate the library of “knowns” under “blind” conditions
- C. Compare correlation of test results with those of other test systems and with real case of interest—results in humans

Stage IV: Technology Transfer

- A. Present and publish results through professional media (at society meetings and in peer-reviewed journals)
- B. Provide hands-on training to personnel from other facilities and facilitate internal evaluations of test methods

Stage V: Validation

- A. Arrange for test of coded samples in multiple laboratories (i.e., interlaboratory validation)
- B. Compare, present, and publish results
- C. Gain regulatory acceptance

Stage VI: Continue to Refine and Evaluate Test System Performance and Utilization

- A. Continually strive for an understanding of why the test “works” and its relevance to effects in man
- B. Remain skeptical. Why should any one of us be the one to make the big breakthrough? Clearly, there is some basic flaw in the design or conduct of the study which has given rise to these promising results. Doubt, check, and question; let your most severe critic review the data; go to a national meeting and give a presentation; then go back home and doubt, check, and question some more!

Stage VII: Regulatory Acceptance and Adaptation

- A. Accepted use will first be side by side with existing system, which it will come to supplant
- B. It will be modified in use as practical factors reveal means of optimization

TABLE 29.6 Possible Interpretations When *In Vitro* Data Do Not Predict Results of *In Vivo* Studies

1. Chemical is not absorbed at all or is poorly absorbed in *in vivo* studies
2. Chemical is well absorbed but is subject to “first-pass effect” in the liver
3. Chemical is distributed so that less (or more) reaches the receptors than would be predicted on the basis of its absorption
4. Chemical is rapidly metabolized to an active or inactive metabolite that has a different profile of activity and/or different duration of action from that of the parent drug
5. Chemical is rapidly eliminated (e.g., through secretory mechanisms)
6. Species of the two test systems used are different
7. Experimental conditions of the *in vitro* and *in vivo* experiments differed and may have led to different effects from those expected. These conditions include factors such as temperature or age, sex, and strain of animal
8. Effects elicited *in vitro* and *in vivo* by the particular test substance in question differ in their characteristics
9. Tests used to measure responses may differ greatly for *in vitro* and *in vivo* studies, and the types of data obtained may not be comparable
10. The *in vitro* study did not use adequate controls (e.g., pH, vehicle used, volume of test agent given, and samples taken from sham-operated animals), resulting in “artifacts” of method rather than results
11. *In vitro* data cannot predict the volume of distribution in central or in peripheral compartments
12. *In vitro* data cannot predict the rate constants for chemical movement between compartments
13. *In vitro* data cannot predict the rate constants of chemical elimination
14. *In vitro* data cannot predict whether linear or nonlinear kinetics will occur with specific dose of a chemical *in vivo*
15. Pharmacokinetic parameters (e.g., bioavailability, peak plasma concentration, and half-life) cannot be predicted solely on the basis of *In vitro* studies
16. *In vivo* effects of chemical are due to an alteration in the higher-order integration of an intact animal system, which cannot be reflected in a less complex system

There are systems that do not directly use any living organisms but, rather, seek to predict the lethality (in particular, the LD₅₀) of a chemical on the basis of what is known about structurally related chemicals. Such SAR systems have improved markedly over the last 10 years (Enslein et al., 1983b; Lander et al., 1984) but are still limited. Accurate predictions are usually possible only for those classes of structures where data have previously been generated on several members of the classes. For new structural classes, the value of such predictions is minimal. Accordingly, this approach is valuable when working with analogs in a series but not for novel structures. It is also a strong argument for getting as many data as possible into the published literature.

A more extensive and once promising approach has been the use of various cultured cell systems. Kurack et al. (1986), for example, have developed and suggested a system based on cultured mammalian hepatocytes. The system does metabolize materials in a manner like mammalian target species and has shown promise in a limited battery of chemicals. Such mammalian cell culture and bacterial screening systems have significant weaknesses for assessing the lethality of many classes of chemicals, since they lack any of the integrative functions of a larger organism. Thus, they would miss all agents that act by disrupting functions such as the organophosphate pesticides, most other neurologically mediated lethal agents, and agents that act by modifying hormonal or immune systems.

Clive et al. (1979) have reported on the correlation of the LC₅₀ of a variety of chemicals in mouse lymphoma cell cultures with their oral LD₅₀ in mice, as shown in Figure 29.2. No linear correlation is present, but highly cytotoxic substances (in this group) are significantly more toxic orally. Given the impression of some LD₅₀ values, due to such factors as steep-

FIGURE 29.2 Graph showing a comparison of the lethality of a group of 18 drugs of diverse structure in *in vivo* (mouse) and *in vitro* (cultured mouse lymphoma cells) test systems. Correlation of these LD₅₀/LC₅₀ values is very poor, though extreme high- and low-scale values seem to be more closely associated in the two systems.

ness of slope of the lethality curve, the lack of linear correlation should be no surprise. Most recently, Ekwall et al. (1989) have reported on the MEIC program system, which utilizes a battery of five cellular systems. For a group of ten chemicals, the system provided good correlation with, or predictive power of, rat LD₅₀.

Recently, Parce et al. (1989) reported on a biosensor technique in which cultured cells are confined to a flow chamber through which a sensor measures the rate of production of acidic metabolites. It is proposed to use this as a functional measure of cytotoxicity and as a screening technique for a number of uses, including *in vivo* lethality.

Three lower species of intact animals have been proposed for use in screening or testing of the lethal effects of chemicals. First, some researchers have shown a good correlation between the LD₅₀ of the same chemicals in rats. This correlation is nonlinear but still suggests that more toxic materials could be at least initially identified and classified in some form of screening system based on *Daphnia*. A broader range of chemical structures will need to be evaluated, however, and some additional laboratories will need to confirm the finding. It must also be kept in mind that the metabolic systems and many of the other factors involved in species differences (as presented in Gad and Chengelis (1997), Gad (2015)) contribute to a nonlinear correlation and may also make the confidence in prediction of human effects in cases somewhat limited.

Earthworms have been one of the more common species used to test chemicals for potential hazardous impact on the environment. The 48-h contrast test has proved to be a fast and resource-effective way of assessing acute toxicity of chemicals in earthworms and is outlined in Table 29.7.

The standardized method, approved by the EEC, is discussed by Neuhauser et al. (1986). This test is for environmental

TABLE 29.7 Earthworm 48 h Contact Test: Acute Lethality

1. Place filter paper of known size (9 cm or 12 × 6.7 cm) in a petri dish or standard scintillation vial
2. Dilute test article in acetone or some other volatile solvent
3. Slowly and evenly deposit known amounts of test-article solution onto filter paper
4. Dry thoroughly with air or nitrogen gentle stream
5. Add 1.0 mL of distilled water to filter paper
6. Add worm (*Lumbricus rubellus*). Use 400–500 mg body weight range
7. Then replicate vials per concentration
8. Store/incubate in the absence of light at 15–20°C for 48 h
9. Examine for lethality (swollen, lack of movement upon warming up to room temperature, and lack of response to tactile stimulation)
10. Express dose as $\mu\text{g cm}^{-2}$ and mortality as usual. Calculate LD₅₀ using standard techniques
11. Always include negative and positive (benchmark) controls

impact assessment where cross-laboratory comparisons are important. If, however, one wishes to adopt this technology for the purpose of screening new chemicals or releasing batches of antibiotics, then variants of this method may be acceptable, as internal consistency is more important than interlaboratory comparisons. There are two important considerations. First, because of seasonal variation in the quality of earthworms obtained from suppliers, positive controls or comparator chemicals should be included on every assay run. Second, distilled water must be used, as worms are quite sensitive to contaminants that may occur in chlorinated water. The filter paper should completely cover the sides of the vessel; otherwise, the worms will simply crawl up the sides to escape the adverse stimulus the chemical contact may provide.

Using these techniques, Roberts and Dorough (1985) and Neuhauser et al. (1986) have compared acute toxicity in a variety of organic chemicals in several earthworm species. While there are some obvious differences between worm species, in general, the rank order of toxicity is about the same. *Lumbricus rubellus* tends to be the most sensitive species. All earthworms are very sensitive to carbofuran under the conditions of this test. Neuhauser et al. (1985a, b) have proposed a toxicity-rating scheme based on acute lethality in the earthworms which are similar to the more familiar scheme based on acute lethality in rodents (Table 29.8). Roberts and Dorough (1985) and Neuhauser et al. (1986) have published extensive compilations of acute lethality in worms and compared these with acute lethality in rats and mice. A selection of these are shown in Table 29.9. Applying the rating scheme of Neuhauser, most chemicals receive about the same toxicity rating based on results in *Eisenia fetida* and mice. This may suggest that replacing the LD₅₀ with the LC₅₀ for rating toxicity (e.g., for transportation permits) deserves serious consideration.

The main advantages of the 40h contact test are the savings of time and money. The cost savings fall into three categories. First, earthworms are cheap. One hundred *L. rubellus* will cost about US \$2.00. The one hundred mice they could replace in screens and QC testing, for example, would cost \$300–\$400 (£150–£200) at an exchange rate of \$2.00 = £1.00. Second, earthworms require no vivarium space, and their use could reduce the number of rodents used, resulting in a net decrease in vivarium use. Third, adapting the 48h contact test would require little capital investment other than a dedicated under-the-counter refrigerator set at 15–20°C. Otherwise, the assay can be easily performed in a standard biochemistry laboratory. With regard to time savings, the standard lethality test with rodents requires 7–14 days of postdosing observations. The 48h contact test is completed in 48h. Not only is the turn-around time faster but also the amount of time that technical personnel will have to spend observing animals and recording observations will be reduced. An incidental advantage of earthworms is that they are cold-blooded vertebrates and thus are exempt from current animal welfare laws.

TABLE 29.8 Earthworm Toxicity—Toxicity Rating

Rating	Designation	Rat LD ₅₀ (mg kg ⁻¹)	<i>Eisenia fetida</i> LC ₅₀ (µg cm ⁻²)
1	Super toxic	<5	<1.0
2	Extremely toxic	5–50	1.0–10
3	Very toxic	50–500	10–100
4	Moderately toxic	500–5000	100–1000
5	Relatively nontoxic	>5000	>1000

Source: Adapted From Neuhauser et al. (1985a, b).

TABLE 29.9 Earthworm Acute Lethality: Comparative Values

Chemical	<i>Eisenia fetida</i> (LC ₅₀)	Mouse (LD ₅₀)
2,4-Dinitrophenol	0.6 (1)	45 (2)
Carbaryl	14 (3)	438 (3)
Benzene	75 (3)	4700 (4)
1,1,1-Trichloroethane	83 (3)	11 240 (5)
Dimethyl phthalate	550 (4)	7 200 (5)

There are two main disadvantages to the use of earthworms in acute toxicity testing. First, there are a limited number of end points. Other than death and a few behavioral abnormalities (Stenersen 1979; Drewes et al., 1984), the test does not yield much qualitative information. Second, there probably is some institutional bias. Because the test is basically low technology (no tissue culture) and uses a nonmammalian model, it may be easy to dismiss the utility of the test.

Finally, the use of smaller species of fish as a surrogate for man has gained some supporters. Currently, the zebra fish has shown significance as a surrogate model for mammalian species toxicity (Hill et al., 2005; Chiu et al., 2008; Tanguay and Reimers, 2008) and as a screen for carcinogens (Stern and Zon, 2003; Berghmans et al., 2005). There is certainly no reason why they could not be used for screening water-soluble compounds for extreme acute toxicity.

Although the intact organisms would seem to be the most utilitarian on the face of it, they still will not totally replace mammalian systems, owing to the need to be concerned about those systems that are significantly different in the higher organisms. Still, it would appear that for those compounds for which human exposure is not intentional, testing in an intact lower organism system (or perhaps even in a cell culture system) should be sufficient to identify agents of significant concern. In these cases, lethality testing in intact mammals is probably unwarranted.

29.6.1 Ocular Irritation

Testing for potential to cause irritation or damage to the eyes remains the most active area for the development (and validation) of alternatives and the most sensitive area of animal

TABLE 29.10 Rationales for Seeking *In Vitro* Alternatives for Eye Irritancy Tests

1. Avoid whole-animal and organ *in vivo* evaluation.
2. Strict Draize scale testing in the rabbit assesses only three eye structures (conjunctiva, cornea, and iris), and traditional rabbit eye irritancy tests do not assess cataracts, pain, discomfort, or clouding of the lens.
3. *In vivo* tests assess only inflammation and immediate structural alterations produced by irritants (not sensitizers, photoirritants, or photoallergens). Note, however, that the test was (and generally is) intended to evaluate any pain or discomfort.
4. Technician training and monitoring are critical (particularly in view of the subjective nature of evaluation).
5. Rabbit eye tests do not perfectly predict results in humans, if the objective is either the total exclusion of irritants or the identification of truly severe irritants on an absolute basis (i.e., without false positives or negatives). Some (such as Reinhardt et al., 1985) have claimed that these tests are too sensitive for such uses.
6. There are structural and biochemical differences between rabbit and human eyes which make extrapolation from one to the other difficult. For example, Bowman's membrane is present and well developed in man (8–12 μm thick) but not in the rabbit, possibly giving the cornea greater protection.
7. Lack of standardization.
8. Variable correlation with human results.
9. Large biological variability between experimental units.
10. Large, diverse, and fragmented databases which are not readily comparable.

testing in biomedical research. This has been true since the beginning of the 1980s. Table 29.10 presents an overview of the reasons for pursuing such alternatives. The major reason, of course, has been the pressure from public opinion.

Indeed, many of the *in vitro* tests now being evaluated for other end points (such as skin irritation and lethality) are adaptations of test systems first developed for eye irritation uses. A detailed review of the underlying theory of each test system is beyond the scope of this chapter. Frazier et al. (1987) and Gad (1993) performed such reviews, and Table 29.11 presents an updated version of the list of test systems overviewed in those volumes.

There are six major categories of approach to *in vitro* eye irritation tests. Because of the complex nature of the eye, the different cell types involved, and interactions between them, it is likely that a successful replacement for existing *in vivo* systems (such as the rabbit) would require some form of battery of such test systems. Many individual systems, however, might constitute effective screens in defined situations. The first five of these aim at assessing portions of the irritation response, including alterations in tissue morphology, toxicity to individual component cells or tissue physiology, inflammation or immune modulation, and alterations in repair and/or recovery processes. These methods have the limitation that they assume that one of the component parts can or will predict effects in the complete organ system. While each component may serve well to predict the effects of a set of chemical structures which determine part of the ocular irritation response, a valid assessment across a broad range of structures will require the use of a collection or battery of such tests.

The sixth category contains tests that have little or no empirical basis, such as computer-assisted SAR models. These approaches can only be assessed in terms of how well or poorly they perform. Table 29.12 presents an overview of all six categories and some of the component tests within

them, updated from the assessment by Frazier et al. (1987), along with references for each test.

Given that there are now some 80 or more potential *in vitro* alternatives, the key points along the route to the eventual objective of replacing the *in vivo* test systems are thus: (i) How do we select the best candidates from this pool? (ii) How do we want to use the resulting system (as a screen or test)? (iii) How do we gain regulatory and user acceptance of the appropriate test systems?

There have been some large-scale validations of some of these tests (IRAG, 1993). Most of the individual investigators have performed smaller “validations” as part of their development of the test system, and in a number of cases, trade associations have sponsored comparative and/or multi-laboratory validations. At least for screening, several systems should be appropriate for use and, in fact, are used now by several commercial organizations. But the Interagency Regulatory Alternatives Group (1993) and the Interagency Coordinating Committee on the Validation of Alternative Methods (1997) have coordinated and reported on large-scale evaluations. In terms of use within defined chemical structural classes, use of *in vitro* systems for testing of chemicals for nonhuman exposure should supplant traditional *in vivo* systems once validated on a broad scale by multiple laboratories. Broad use of single tests based on single end points (such as cytotoxicity) is not likely to be successful, as demonstrated by such efforts as those of Kennah et al. (1989). In 2015, the FDA announced that it would no longer require a rabbit eye test but rather wanted the alternative bovine corneal opacity and permeability (BCOP) test except in cases where the therapeutic in question is intended for direct administration to the eye (typically by injection).

29.6.2 Dermal Irritation

Extensive progress has been made in devising alternative (*in vitro*) systems for evaluating the dermal irritation potential

TABLE 29.11 *In Vitro* Alternatives for Eye Irritation Tests

Morphology
 Enucleated superfused rabbit eye system (Burton et al., 1981)
 Balb/c 3T3 cells/morphological assays (HTD) (Borenfreund and Puerner, 1984)

Cell Toxicity
 Adhesion/cell proliferation
 BHK cells/growth inhibition (Reinhardt et al., 1985)
 BHK cells/colony formation efficiency (Reinhardt et al., 1985)
 BHK cells/cell detachment (Reinhardt et al., 1987)
 SIRC cells/colony-forming assay (North-Root et al., 1982)
 Balb/c 3T3 cells/total protein (Shopsis and Eng, 1985)
 BCL/D1 cells/total protein (Balls and Horner, 1985)
 Primary rabbit corneal cells/colony-forming assay (Watanabe et al., 1988)

Membrane integrity
 LS cells/dual dye staining (Scaife, 1982)
 Thymocytes/dual fluorescent dye staining (Aeschbacher et al., 1986)
 LS cells/dual dye staining (Kemp et al., 1983)
 RCE-SIRC-P815-YAC-1/Cr release (Shaddock et al., 1985)
 L929 cells/cell viability (Simons, 1981)
 Bovine red blood cell/hemolysis (Shaddock et al., 1985)
 Mouse L929 fibroblasts/erythrocin C staining (Frazier, 1988)
 Rabbit corneal epithelial and endothelial cells/membrane leakage (Meyer and McCulley, 1988)
 Agarose diffusion (Barnard, 1989)
 Corneal protein profiles (Eurell and Meachum, 1994)

Cell metabolism
 Rabbit corneal cell cultures/plasminogen activator (Chan, 1985)
 LS cells/ATP assay (Kemp et al., 1985)
 Balb/c 3T3 cells/neutral red uptake (Borenfreund and Puerner, 1984)
 Balb/c 3T3 cells/uridine uptake inhibition assay (Shopsis and Sathe, 1984)
 HeLa cells/metabolic inhibition test (MIT-24) (Selling and Ekwall, 1985)
 MDCK cells/dye diffusion (Tchao, 1988)

Cell and Tissue Physiology
 Epidermal slice/electrical conductivity (Oliver and Pemberton, 1985)
 Rabbit ileum/contraction inhibition (Muir et al., 1983)
 Bovine cornea/corneal opacity (Muir, 1984)
 Proposed mouse eye/permeability test (Maurice and Singh, 1986)

Inflammation/Immunity
 Chlorioallantonic membrane (CAM)
 CAM (Leighton et al., 1983)
 HET-CAM (Luepke, 1985)
 Bovine corneal cup model/leukocyte chemotactic factors (Elgebaly et al., 1985)
 Rat peritoneal cells/histamine release (Jacaruso et al., 1985)
 Rat peritoneal mast cells/serotonin release (Dubin et al., 1984)
 Rat vaginal explant/prostaglandin release (Dubin et al., 1984)
 Bovine eye cup/histamine (Hm) and leukotriene C4 (Lt/C4) release (Benassi et al., 1986)

(Continued)

TABLE 29.11 (Continued)

Recovery/Repair
 Rabbit corneal epithelial cells/wound healing (Jumblatt and Neufeld, 1985)

Other
 EYTEX assay (Gordon et al., 1986; Soto et al., 1988)
 Computer-based structure–activity relationship (SAR) (Enslin, 1984)
Tetrahymena/motility (Silverman, 1983)

of chemicals since this author first reviewed the field (Gad and Chengelis, 1997). Table 29.12 overviews 20 proposed systems which now constitute five very different approaches.

The first approach (I) uses patches of excised human or animal skin maintained in some modification of a glass diffusion cell which maintains the moisture, temperature, oxygenation, and electrolyte balance of the skin section. In this approach, after the skin section has been allowed to equilibrate for some time, the material of concern is placed on the exterior surface and wetted (if not a liquid). Irritation is evaluated either by swelling of the skin (a crude and relatively insensitive method for mild and moderate irritants), by evaluation of inhibition of uptake of radiolabeled nutrients, or by measurement of leakage of enzymes through damaged membranes.

The second set of approaches (II) utilizes a form of surrogate skin culture comprising a mix of skin cells which closely mirror key aspects of the architecture and function of the intact organ. These systems seemingly offer a real potential advantage, but, to date, the “damage markers” employed (or proposed) as predictors of dermal irritation have been limited to cytotoxicity.

The third set of approaches (III) is to use some form of cultured cell (either primary or transformed), with primary human epidermal keratinocytes (HEKs) preferred. The cell cultures are exposed to the material of interest, and then either cytotoxicity, release of inflammation markers, or decrease of some indicator of functionality (lipid metabolism, membrane permeability, or cell detachment) is measured.

The fourth group (IV) contains two miscellaneous approaches—the use of a membrane from the hen’s egg with a morphological evaluation of damage being the predictor end point (Lei et al., 1986) and the SKINTEX system, which utilizes the coagulation of a mixture of soluble proteins to predict dermal response.

Finally, in group V, there are two SAR models which use mathematical extensions of past animal results correlated with structure to predict the effects of new structures.

Many of these test systems are in the process of evaluation of their performance against various small groups of compounds for which the dermal irritation potential is known. Evaluation by multiple laboratories of a wider range of structures will be essential before any of these systems can be generally utilized.

TABLE 29.12 *In Vitro* Dermal Irritation Test Systems

System	End Point	Validation Data? ^a	References

^aEvaluated by comparison of predictive accuracy for a range of compounds compared with animal test results. Not validated in the sense used in this chapter.

29.6.3 Irritation of Parenterally Administered Pharmaceuticals

Intramuscular (IM) and intravenous (IV) injection of parenteral formulations of pharmaceuticals can produce a range of discomfort resulting in pain, irritation, and/or damage to the muscular or vascular tissue. These are normally evaluated for prospective formulations before use in humans by evaluation in intact animal models—usually the rabbit (Gad and Chengelis, 1997).

Currently, a protocol utilizing a cultured rat skeletal muscle cell line (the L6) as a model is in an interlaboratory validation program among more than ten pharmaceutical company laboratories. This methodology (Young et al., 1986) measures creatine kinase levels in media after exposure of the cells to the formulation of interest and predicts *in vivo* intramuscular damage based on this end point. It is reported to give excellent

rank-correlated results across a range of antibiotics (Williams et al., 1987) and in a recent multilaboratory evaluation, a broader structural range of compounds (PMA/Drusafe *In Vitro* Task Force, 1994).

Another proposed *in vitro* assay for muscle irritancy for injectable formulations is the red blood cell hemolysis assay (Brown et al., 1989). Water-soluble formulations are gently mixed at a 1:2 ratio with freshly collected human blood for 5 s and then mixed with a 5% w/v dextrose solution and centrifuged for 5 min. The percentage of red blood cell survival is then determined by measuring differential absorbance at 540 nm, and this is compared with values for known irritants and nonirritants. Against a very small group of compounds (four), this is reported to be an accurate predictor of muscle irritation.

There is no current candidate alternative for the venous irritation test, but the *in vitro* alternative for pyrogenicity

TABLE 29.13 Requested Reference Compounds for Skin Sensitization Studies (US Consumer Product Safety Commission)

Hydroxylamine sulfate	Penicillin G
Ethyl amino benzoate	<i>p</i> -Phenylenediamine
Iodochlorohydroxyquinoline (clioquinol, chioform)	Epoxy systems (ethylenediamine, diethylenetriamine, and diglycidyl ethers)
Nickel sulfate	Toluene-2,4-diisocyanate
Monomethyl methacrylate	Oil of Bergamot
Mercaptobenzothiazole	

testing—the *Limulus* test—is one of the success stories for the alternatives movement. It has totally replaced the classical intact rabbit test in both research and product release testing. The test is based on the jelling or color development of a pyrogenic preparation in the presence of the lysate of the amoebocytes of the horseshoe crab (*Limulus polyphemus*). It is simpler, more rapid, and of greater sensitivity than the rabbit test it replaced (Cooper, 1975).

29.6.4 Sensitization and Photosensitization

There are actually several approaches available for the *in vitro* evaluation of materials for sensitizing potential. These use cultured cells from various sources and, as end points, look at either biochemical factors (such as production of MIF—migration inhibition factor) or cellular events (such as cell migration or cell “transformation”).

While on the surface, the local lymph node assay (LLNA), previously discussed in Chapter 11, was a significant step toward replacing traditional guinea pig-based sensitization assays, it has both limitations on performance and does not eliminate the use of animals. Arancioglu et al. (2015) have proposed an *ex vivo* alternative that measures three additional end points (lymphocyte proliferation, ear swelling, and cytokine profiles) to improve test performance.

Milner (1970) reported that lymphocytes from guinea pigs sensitized to dinitrofluorobenzene (DNFB) would transform in culture, as measured by the incorporation of tritiated thymidine, when exposed to epidermal proteins conjugated with DNFB. This work was later extended to guinea pigs sensitized to *p*-phenylenediamine. He also reported (Milner, 1971) that his method was capable of detecting allergic contact hypersensitivity to DNFB in humans, using human lymphocytes from sensitized donors and human epidermal extracts conjugated with DNFB.

Miller and Levis (1973) reported the *in vitro* detection of allergic contact hypersensitivity to Dinitrochlorobenzene (DNCB) conjugated to leukocyte and erythrocyte cellular membranes. This indicated that the reaction was not specifically directed toward epidermal cell conjugates. Thulin and Zacharian (1972) extended others' earlier work on MIF-induced migration of human peripheral blood lymphocytes to a test for delayed contact hypersensitivity. Burka et al. reported in 1981 (Burka et al., 1981) on an assay system based on isolated guinea pig trachea. No further mention of this has been

found in the literature. None of these approaches have yet been developed as an *in vitro* predictive test, but work is progressing. Milner published a review of the history and state of this field in 1983 which still provides an accurate and timely overview (Milner, 1983).

Any alternative (*in vitro* or *in vivo*) test for sensitization will need to be evaluated against a battery of “known” sensitizing compounds. The Consumer Product Safety Commission in 1977 proposed such a battery, which is shown in Table 29.13. This has not yet been done for any of the proposed systems. Owing to the complexity of the system involved, it is unlikely that a suitable *in vitro* replacement system will be available soon.

Gad (1988b) published comparative data on multiple animal and human test system data for some 72 materials. Such a database should be considered for the development and evaluation of new test systems.

Troese et al. (2012), Natsch et al. (2013), Nukada et al. (2013), and Bauch et al. (2012) have proposed a scheme to combine multiple *in vitro* methods to serve as an effective means of evaluating for skin sensitization, and these are being utilized as screening tools by pharmaceutical companies.

29.6.5 Phototoxicity and Photosensitization

The Daniel test for phototoxicity (also called photoirritant contact dermatitis) utilizes the yeast *Candida albicans* as a test species and has been in use for more than 20 years (Daniel, 1965). The measured end point is simply cell death. The test is simple to perform and cheap but does not reliably predict the phototoxicity of all classes of compounds (e.g., sulfanilamide). Test systems utilizing bacteria have been suggested as alternatives over the last 10 years (Harter et al., 1976; Ashwood-Smith et al., 1980) for use in predicting the same end point.

Most recently, ICI has conducted studies on an *in vitro* phototoxicity assay which involves using three cultured cell lines: the A431 human epidermal cell line (a derived epidermal carcinoma), normal HEKs (a primary cell line derived from cosmetic surgery), and the 3T3 Swiss mouse fibroblast cell line. The protocol for this assay involves subculturing the particular cell type into microtiter tissue culture grade plates and incubating them over a period of 24 h. Following incubation, the cultures are exposed to the test compound at a concentration predetermined as nontoxic.

After a 4h exposure to the compound, the cell cultures are exposed to either UV A (320–400nm) or UV A/B (280–400nm) radiation for varying lengths of time. The degree of enhanced toxicity effected by either UV A or UV A/B radiation in the presence of the test compound relative to the control is assessed, using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. MTT undergoes a reduction reaction which is specific to mitochondrial dehydrogenases in viable cells. Work on validation of this test using 30 compounds of known phototoxic potential has shown a high degree of correlation between *in vitro* and *in vivo* results. Jackson and Goldner (1989) have described several other *in vitro* assay systems for this end point.

The area of development of *in vitro* photosensitization assays has been a very active one, as the review of McAuliffe et al. (1986) illustrates. Such tests have focused on being able to predict the photosensitizing potential of a compound and variously employed cultured mammalian cell lines, red blood cells, microorganisms, and biochemical reactions. McAuliffe's group has developed and proposed a test that measures the incorporation of tritiated thymidine into human peripheral blood mononuclear cells as a predictive test (Morison et al., 1982). They claim to have internally validated the test using a battery of known photosensitizers.

Bockstahler et al. (1982) have developed and proposed another *in vitro* test system which uses the responses of two *in vitro* mammalian virus–host cell systems to the photosensitizing chemicals proflavine sulfate and 8-methoxypsoralen (8-MOP) in the presence of light as a predictive system. They found that infectious simian virus 40 (SV40) could be induced from SV40-transformed hamster cells by treatment with proflavine plus visible light or 8-MOP plus near-UV radiation. The same photosensitizing treatments inactivated the capacity of monkey cells to support the growth of herpes simplex virus. SV40 induction and inactivation of host cell capacity for herpesvirus growth might be useful as screening systems for testing the photosensitizing potential of chemicals. Advantages (ease and speed of conduct) and disadvantages (use of potentially infective agent and the limited range of compounds evaluated to date) were found to be associated with both of these test systems.

29.6.6 Pyrogenicity

A regulatory success for adaptation of an *in vitro* model has been the use of the limulus amoebocyte lysate (LAL), the extract from blood cells (amoebocytes) from the Atlantic horseshoe crab. LAL reacts with a lipopolysaccharide bacterial endotoxin which is a component of the membrane of gram-negative bacteria. The blood is nonterminally extracted from the crabs which are raised on “farms.” This test largely (and currently still, for biologics and drug preparations) replaced the traditional USP rabbit pyrogenicity study which was terminal for the test animals. The last 7 years, however,

has seen the requirement to also perform the rabbit pyrogenicity studies for detecting material mediated (not endotoxin based) pyrogenicity.

29.6.7 Developmental Toxicity

The area of developmental toxicity actually is one of the earliest to have alternative models suggested for it and has one of the most extensive and oldest literatures. This is, of course, partly owing to such models originally being used to elucidate the essential mechanisms and process of embryogenesis.

Because of the complicated and multiphasic nature of the developmental process, it has not been proposed that any of these systems be definitive tests but rather that they serve as one form or another of a screen. As such, these test systems would either preclude or facilitate more effective full-scale evaluation in one or more of the traditional whole-animal test protocols.

The literature and field are much too extensive to review comprehensively here. There are a number of extensive review articles and books on the subject (Saxen and Saksela, 1971; Wilson, 1978; Clayton, 1979; Kochhar, 1981; Homburger and Goldberg, 1985; Faustman, 1988; Daston and D'Amato, 1989), which should be consulted by those with an in-depth interest.

The existing alternative test systems fall into six broad classes: (i) lower organisms, (ii) cell culture systems, (iii) organ culture systems, (iv) submammalian embryos, (v) mammalian embryos, and (vi) others.

Table 29.14 provides an overview of the major representatives of these six groups, along with at least one basic reference to the actual techniques involved and the system components for each.

The comparative characteristics of these different classes of test systems are presented in Table 29.15. The key point is that these systems can be used for a wide range of purposes, only one of which is to screen compounds to determine the degree of concern for developmental toxicity.

The utility of these systems for screening is limited by the degree of dependability in predicting effects primarily in people and secondarily in the traditional whole-animal test systems. Determining the predictive performance of alternative test systems requires the evaluation of a number of compounds for which the “true” (human) effect is known. In 1983, a consensus workshop generated a so-called “gold standard” set of compounds of known activity (Smith et al., 1983). The composition of this list has been open to a fair degree of controversy over the years (Flint, 1989; Johnson, 1989; Johnson et al., 1989). However, an agreed-upon “gold standard” set of compounds of known activity is an essential starting point for the validation of any single test system or battery of test systems because of the multitude of mechanisms for developmental toxicity. It is unlikely that any one system will be able

TABLE 29.14 Alternative Developmental Toxicity Test Systems

Category	Test System	Model	References
I: Lower organisms	Sea urchins	Organism	Kotzin and Baker (1972)

Screening	Expensive	Yes	Yes	Yes	Yes	Yes	Yes

NA, not available.

to stand in place of Segment II studies in two species, much less to accurately predict activity in humans. Their use as general screens or as test systems for compounds with little potential for extensive or intended human exposure will, however, probably be appropriate.

29.6.8 Target Organ Toxicity Models

This final model review section addresses perhaps the most exciting potential area for the use of *in vitro* models—specific tools to evaluate and understand discrete target organ

toxicities. Here the presumption is that there is reason to believe (or at least suspect) that some specific target organ (nervous system, lungs, kidney, liver, heart, etc.) is or may be the most sensitive site of adverse action of a systemically absorbed agent. From this starting point, a system that is representative of the target organ's *in vivo* response would be useful in at least two contexts. New developments range from specific cell-based systems to "organ-on-a-chip" technologies.

First, as with all the other end points addressed in this chapter, a target organ-predictive system could serve as a predictive system (in general, a screen) for effects in intact organisms, particularly man. As such, the ability to identify those agents with a high potential to cause damage in a specific target organ at physiological concentrations would be extremely valuable.

The second use is largely specific to this set of *in vitro* models. This is to serve as tools to investigate, identify, and/or verify the mechanisms of action for selective target organ toxicities. Such mechanistic understandings then allow for one to know whether such toxicities are relevant to man (or to condition of exposure to man), to develop means either to predict such responses while they are still reversible or to develop the means to intervene in such toxicosis (i.e., first aid or therapy), and finally to potentially modify molecules of interest to avoid unwanted effects while maintaining desired properties (particularly important in drug design).

In the context of these two uses, the concept of a library of *in vitro* models (Gad, 1989c, 1996) becomes particularly attractive. If one could accumulate a collection of "validated," operative methodologies that could be brought into use as needed (and put away, as it were, while not being used), this would represent an extremely valuable competitive tool. The question becomes one of selecting which systems/tools to put into the library and how to develop them to the point of common utility.

Additionally, one must consider what forms of markers are to be used to evaluate the effect of interest. Initially, such markers have been exclusively either morphological (in that there is a change in microscopic structure), observational (is the cell/preparation dead or alive or has some gross characteristic changed?), or functional (does the model still operate as it did before?). Recently, it has become clear that more sensitive models do not just generate a single end point type of data but rather a multiple set of measures which in aggregate provide a much more powerful set of answers.

There are multiple approaches to *in vitro* target organ models.

The first and oldest is that of the isolated organ preparation. Perfused and superfused tissues and organs have been used in physiology and pharmacology since the late nineteenth century. There is a vast range of these available, and a number of them have been widely used in toxicology (Mehendale (1989) presents an excellent overview). Almost any end point can be evaluated in most target organs (the CNS being a notable exception), and these are closest to the *in vivo* situation and therefore generally the easiest to extrapolate or conceptualize from. Those things that can be measured or evaluated in the intact organism can largely also be evaluated in an isolated

tissue or organ preparation. However, the drawbacks or limitations of this approach are also compelling.

An intact animal generally produces one tissue preparation. Such a preparation is viable generally for a day or less before it degrades to the point of losing utility. As a result, such preparations are useful as screens only for agents that have rapidly reversible (generally pharmacological or biomechanical) mechanisms of action. They are superb for evaluating mechanisms of action at the organ level for agents that act rapidly—but not generally for cellular effects or for agents that act over a course of more than a day.

The second approach is to use tissue or organ culture. Such cultures are attractive, owing to maintaining the ability for multiple cell types to interact in at least a near-physiological manner. They are generally not as complex as perfused organs, but are stable over a longer period of time, increasing their utility as screens somewhat. They are truly a middle ground between perfused organs and cultured cells. Only for relatively simple organs (such as the skin and bone marrow) are good models which perform in a manner representative of the *in vitro* organ available.

The third and most common approach remains that of cultured cell models. These can be either primary or transformed (immortalized) cells, but the former have significant advantages in use as predictive target organ models. Such cell culture systems can be utilized to identify and evaluate interactions at the cellular, subcellular, and molecular level on an organ- and species-specific basis (Acosta et al., 1985). The advantages of cell culture are that single organisms can generate multiple cultures for use, that these cultures are stable and useful for protracted periods of time, and that effects can be studied very precisely at the cellular and molecular levels. The disadvantages are that isolated cells cannot mimic the interactive architecture of the intact organ and will respond over time in a manner that becomes decreasingly representative of what happens *in vivo*. An additional concern is that, with the exception of hepatocyte cultures, the influence of systemic metabolism is not factored in unless extra steps are taken. Stamatii et al. (1981) and Tyson and Stacey (1989) present some excellent reviews of the use of cell culture in toxicology. Any such cellular systems would be more likely to be accurate and sensitive predictors of adverse effects if their function and integrity were evaluated while they were operational. For example, cultured nerve cells should be excited while being exposed and evaluated.

Finally, we now have "organ-on-a-chip" systems, which combine multiple cell systems (from one or more organs) to provide a more relevant to actual physiological function test system (Kim et al., 2015).

A wide range of target organ-specific models have already been developed and used. Their incorporation into a library-type approach requires that they be evaluated for reproducibility of response, ease of use, and predictive characteristics under the intended conditions of use. These evaluations are probably at least somewhat specific to any individual situation. Tables 29.16–29.21 present overviews of representative systems for a range of target organs: respiratory, nervous,

TABLE 29.16 Representative *In Vitro* Test Systems for Respiratory System Toxicity

System	End Point	Evaluation	References
Isolated perfused rat and rabbit lungs (S)	Damage markers: exudate of hormones	Correlation with results <i>in vivo</i>	Anderson and Eling (1976), Roth (1980), Mehendale (1989)
Alveolar macrophages (S)	Cytotoxicity: as a predictor of fibrogenicity	Correlation with <i>in vivo</i> fibrogenicity across a broad range of compounds	Reiser and Last (1979)
Lung organ culture (M, S)	Morphological: structure and macromolecular composition	Proposed from prior experience in pharmacology	Placke and Fisher (1987)
Hamster lung culture (M)	Morphological: structure and cell death	Correlation of <i>in vivo</i> effects of cigarette smoke	Stammati et al. (1981)

Letters in parentheses indicate primary employment of system: S = screening system; M = mechanistic tool.

TABLE 29.17 Representative *In Vitro* Test Systems for Neurotoxicity

System	End Point	Evaluation	References
Perfused rat phrenic nerve—hemidiaphragm (M)	Functional: release of ACh, conduction velocities, and muscle response	Correlates with <i>in vivo</i> effects of trialkyltins	Bierkamper (1982)
Primary rat cerebral cells (S)	Observational: cell growth and differentiation	Cell diameter and outgrowth	Hooisma (1982)
Primary rat tissue culture (S)	Functional: receptor–ligand binding	Binding rates	Bondy (1982), Volpe et al. (1985)
Organotypic neural cultures (S)	Functional: electrophysiological and pharmacological properties	Correlation with <i>in vivo</i> results for a range of known active agents	Spencer et al. (1986), Kontur et al. (1987)
Isolated perfused brain (M)	Functional: biochemical and electrophysiological	Unknown	Mehendale (1989)
Cultured mouse otocyst (M)	Morphological	Unknown—a tool for potentially evaluating ototoxins	Harpur (1988)

Letters in parentheses indicate primary employment of system: S = screening system; M = mechanistic tool.

TABLE 29.18 Representative *In Vitro* Test Systems for Renal Toxicity

System	End Point	Evaluation	References
Rat proximal tubular cells (S)	Functional: 3- <i>O</i> -methylglucose uptake or organic ion transport	Correlation with effects of known nephrotoxins	Boogaard et al. (1989)
Rat cortical epithelial cells (S)	Functional: biochemical	Good correlation with <i>in vivo</i> findings for nephrotoxic metals and acetaminophen	Smith et al. (1986, 1987), Rylander et al. (1987)
Isolated perfused kidney (M)	Functional: biochemical and metabolic Morphological	Correlation with <i>in vivo</i> findings for some nephrotoxins	Mehendale (1989)
Renal slices (S, M)	Full range of functional (biochemical and metabolic)	Correlation with <i>in vivo</i> findings for a range of nephrotoxins. Still allows evaluation of a degree of cell-to-cell and nephron-to-nephron interactions	Smith et al. (1988)

Letters in parentheses indicate primary employment of system: S = screening system; M = mechanistic tool.

TABLE 29.19 Representative *In Vitro* Test Systems for Cardiovascular Toxicity

System	End Point	Evaluation	References
Coronary artery smooth muscle cells (S)	Morphological evaluation—vacuole formation	Correlates with <i>in vivo</i> results	Ruben et al. (1984)
Isolated perfused rabbit or rat heart (M, S)	Functional: operational, electrophysiological, biochemical, and metabolic	Long history of use in physiology and pharmacology	Mehendale (1989)
Isolated superfused atrial and heart preparations (S, M)	Functional: operational and biochemical	Correlation with <i>in vivo</i> findings for antioxidants	Gad et al. (1977, 1979)

Letters in parentheses indicate primary employment of system: S = screening system; M = mechanistic tool.

TABLE 29.20 Representative *In Vitro* Test Systems for Hepatic Toxicity

System	End Point	Evaluation	References
Primary hepatocytes (S, M)	Multiple: <ul style="list-style-type: none"> • Biotransformation • Genotoxicity • Peroxisome proliferation • Biliary dysfunction • Membrane damage • Ion regulation • Energy regulation • Protein synthesis 	NA	Tyson and Stacey (1989), ^a Stammati et al. (1981)
Hamster hepatocytes (S)	Functional: biochemical	Correlates with <i>in vivo</i> effects of acetaminophen	Harman and Fisher (1983)
Rat liver slices (S)	Functional: alterations in ion content, leakage of damage markers, and changes in biosynthetic capability Morphological: histopathological evaluation	Rank correlation with <i>in vivo</i> findings for a wide range of chemicals	Gandolfi et al. (1989), Adams (1995), Fisher et al. (1995)
Isolated perfused liver (M)	Functional: biochemical and metabolic	Correlation with <i>in vivo</i> findings for a wide range of chemicals	Mehendale (1989), Wyman et al. (1995)

Letters in parentheses indicate primary employment of system: S = screening system; M = mechanistic tool. NA = not available.

^aTyson and Stacey estimated in 1989 that there were 800 unpublished studies of a toxicological nature on cultured hepatocytes.

TABLE 29.21 Representative *In Vitro* Test Systems for Other Target Organ Studies

Organ	System	End Point	Evaluation	References
Pancreas	Isolated perfused intestines (M)	Functional: biochemical and metabolic	Correlation with <i>in vivo</i> findings for methylprednisolone	Mehendale (1989)
GI Tract	Isolated perfused intestines (M)	Functional: biochemical and metabolic	Limited	Mehendale (1989)
Reticuloendothelial	Erythrocytes (S)	Observational: cytotoxicity Functional: inhibition of colony formation	Correlation with hemolytic effects	Stammati et al. (1981)
Testicular	Sertoli and germ cell cultures (S)	Observational: cytotoxicity Functional: steroid and hormone production	Correlation with <i>in vivo</i> effects for phytholate esters and glycol ethers	Garside (1988)
Adrenal gland	Primary adrenocortical ADC cell cultures (S, M)	Functional: cortisol production	Correlation with <i>in vivo</i> effects for three known ADC toxicants	Wolfgang et al. (1994)
Thyroid	Cultured thyroid cells (S, M)	Functional: biochemical and metabolic	Correlation with <i>in vivo</i> findings for a wide range of agents with thyroid-specific toxicity; evaluation against “negative” compounds not significant	Brown and Fabro (1981)

Letters in parentheses indicate primary employment of system: S = screening system; M = mechanistic tool.

renal, cardiovascular, hepatic, pancreatic, gastrointestinal, and reticuloendothelial. These tables do not mention any of the new coculture systems in which hepatocytes are “joined up” in culture with a target cell type to produce a metabolically competent cellular system.

For more complex organ systems, great progress has been made in deriving an integrated approach to utilizing

several types of *in vitro* model data. McKim (2012) has provided a leading edge example in preproposing such an approach for the leading cause of drug failure due to safety issues—liver-specific toxicity (particularly DLT—delayed liver toxicity) which starts with understanding the structure of the liver and the types (and functions) of different cell types in the organ.

Additionally, there are ongoing efforts to use human tissue as models to evaluate the safety and efficacy of new drugs (Coleman, 2011).

29.7 *IN SILICO* METHODS

The concept that the biological activity of a compound is a direct function of its chemical structure is now at least a century old (Crum-Brown and Fraser, 1869). During most of this century, the development and use of SARs were the domain of pharmacology and medicinal chemistry. These two fields are responsible for the beginnings of all the basic approaches in SAR work, usually with the effort being called drug design. An introductory medicinal chemistry text (such as Foye et al. (1995)) is strongly recommended as a starting place for SAR. Additionally, Burger's Medicinal Chemistry (Abraham and Rotella, 2010), with its excellent overview of drug structures and activities, should enhance at least the initial stages of identifying the potential biological actions of *de novo* compounds (drug or otherwise) using pattern recognition approach.

SAR methods have become a legitimate and useful part of toxicology since the mid-1970s and an extremely important part in the twenty-first century as Cramer et al. (1978) published the first modern approach (intended primarily to prioritize structures for toxicological evaluation). These methods are various forms of mathematical or statistical models which seek to predict the adverse biological effects of chemicals based on their structure. The prediction may be either of a qualitative (carcinogen/noncarcinogen) or quantitative (LD_{50}) nature, with the second group usually being denoted as quantitative structure–activity relationship (QSAR) models. It should be obvious at the onset that the basic techniques utilized to construct such models are those which are termed modeling and extrapolation (now called “expert systems” based on of structures and substructures) or reduction of dimensionality methods (now called “statistical SAR systems”), using a set of structures with known activity and based on proximity of overall structure descriptors in a multidimensional space. Models may also be characterized as global (covering a wide range of structural features) or local (which cover only a narrow domain of structures but tend to provide much higher accuracy of prediction within that range).

For toxicology, SARs have to be a significant and important range of uses. These can all be generalized as identifying potentially toxic effects or restated as three main uses:

1. For the selection and design of toxicity tests to address end points of possible concern.
2. If a comprehensive or large testing program is to be conducted, SAR predictions can be used to prioritize the tests, so that outlined questions (the answers to

which might preclude the need to do further testing) may be addressed first.

3. As an alternative to testing at all. Though in general, it is not believed that the state-of-the-art for SAR methods allows such usage in certain special cases (such as selecting which of the several alternative candidate compounds to develop further and then set).

Having already classified SAR methods into qualitative and quantitative, it should also be pointed out that both of these can be approached on two different levels. The first is on a local level, where prediction of activity (or lack of activity) is limited to other members of a congeneric series or structural near neighbors. The accuracy of predictions via this approach is generally greater but is of value only if one has sufficient information on some of the structures within a series of interest. The ICH (ICH M7) and FDA now accept QSAR models in place of actual mutagenicity testing for assessing mutagenicity of impurities and of drug and device extractables and leachables. Chapter 11 addresses the uses and issues of QSAR models as they are now used in safety assessment.

29.8 THE FINAL FRONTIER AND BARRIER: REGULATORY ACCEPTANCE

While in Europe there are numerous validated (by ECVAM standards) *in vitro* alternatives for personal care products and industrial and agricultural chemicals (though only two—the LAL assay for pyrogenicity and the 3T3 cell assay for phototoxicity—have acceptance for use with pharmaceutical regulators) with regulatory acceptance (as summarized in Table 29.22), this is not the case in the United States. Indeed, only four alternatives have been approved by the ICVAM process to date (Gaul, 2008). Likewise, while most primary biocompatibility testing performed in accordance with ICH (for drugs) or ISO 10993 standards (for medical devices) is performed using *in vitro* models, no new ones have been added or served to replace existing *in vivo* methods. Indeed, such new tests that have been added are *in vivo*. Though there is considerable research continuing on the development (and putatively on the validation) of many more methods (Kuehn, 2008), progress in obtaining regulatory acceptance of such methods to take the place of animal test methods is very slow, and those methods that are accepted are limited in scope screens for eye and skin irritation pyrogenicity, phototoxicity, and genotoxicity.

Thus, regulatory acceptance is, indeed, largely as it has been since 1990 with the only advance being adoption of the BCOP assay to assess ocular irritation when there is unintended potential contact with the eye, the final frontier, and true obstacle to any further significant reduction in animal use. The newest test sets are “chips,” which have specific cells

TABLE 29.22 Status of Nonanimal Methods That Have Regulatory Standing (Acceptance)

Test Method	Test System	End Point	OECD/TG or Other Regulatory Comments
<i>In vitro test methods for which there are OECD health effects test guidelines (including draft guidelines under review for acceptance) can be found at http://www.oecd.org/home/</i>			
Transcutaneous electrical resistance (TER) test	Monitors changes in the electrical resistance as a measure of loss of corneum integrity and barrier function; involves skin disks from euthanized rats	Skin corrosion (topical agents)	TG 430
Human skin models (EpiDerm™ and EPISKIN™)	Reconstructed human epidermal equivalent (commercial system) used to assess cell viability, involving the MTT reduction test	Skin corrosion (topical agents)	TG 431
3T3 NRU phototoxicity test	BALB/c 3T3 (murine) cell line cytotoxicity based on neutral red uptake to measure cell viability; not direct replacement alternative, as there is no <i>in vivo</i> equivalent test	Phototoxicity	TG 432/FDA guidance
Corrositex™ membrane barrier test	An artificial barrier system coupled to a pH-based chemical detection system	Skin corrosion (topical agents)	Draft TG 435
Bacterial reverse mutation test (Ames)	Revertant bacteria detected by their ability to grow in the absence of the amino acid	Genotoxicity	TG471/ICH, ISO, FDA guidance
<i>In vitro</i> mammalian chromosomal aberration test	Microscopic detection of chromosomal damage to cells in culture	Genotoxicity	TG473/ICH, ISO, FDA guidance
<i>In vitro</i> mammalian cell gene mutation test	Functional bioassays to monitor mutations in enzyme-encoding genes	Genotoxicity	TG476
Sister chromatid exchange assay	Cells in culture are examined after two rounds of division by metaphase arrest and chromosomal preparation; chromatid exchange is monitored by microscopy	Genotoxicity	TG479/ICH, ISO, FDA guidance
Gene mutation assay in yeast	<i>Saccharomyces cerevisiae</i> exposed to the test substance are grown under different culture conditions used to monitor mutagenic potential (cf. Ames test)	Genotoxicity	TG 480
Mitotic recombination assay in yeast	Crossover or gene conversion following exposure of yeast to the test substance; relies on different growth requirements of mutated and wild-type yeast strains	Genotoxicity	TG 481
Unscheduled DNA synthesis in mammalian cells	Measures the DNA repair synthesis after deletions caused by the test substance based on the incorporation of radioactive nucleotides into the newly synthesized DNA	Genotoxicity	TG 482/ICH, ISO, and FDA guidance
Bovine corneal opacity and permeability (BCOP)	See eye irritation table	Ocular irritation	FDA guidance
QSAR mutagenicity models	One expert-/rule-based and one statistical-based system	Mutagenicity	ICH M7(R2) FDA, ICH countries
<i>In vitro</i> micronucleus test	Cell-based assay; supplement to TG 474 (<i>in vivo</i> micronucleus test); detection of chromosomal damage and formation of micronuclei in interphase	Genotoxicity	Draft TG 487/ ICH guidance
Sex-linked recessive lethal test	<i>Drosophila</i> are exposed to the test substance. Germline transmission of mutations is monitored through two successive generations	Reproductive toxicity	TG 477
<i>Validated methods that are yet to be introduced into regulatory use</i>			
EpiOcular™	Human keratinocyte-derived model of the corneal epithelium barrier function	Eye irritation (topical application)	Retrospective (weight-of-evidence) validation (ECVAM)
<i>In vitro</i> micronucleus test	CHL/IU, CHO, SHE, or V79 cell lines are commonly used, with or without metabolic activation, to monitor damage and formation of micronuclei in interphase	Mutagenicity	Retrospective (weight-of-evidence) validation (ECVAM)
Embryonic stem cell test	3T3 cell cytotoxicity and differentiation of embryonic stem murine cell lines used to examine teratogenic potential	Developmental toxicity	Endorsed as screening test (EU)
Postimplantation rat whole-embryo test	Morphological assessment of rat embryos	Developmental toxicity	Endorsed as screening test (EU)
Micromass test	Micromass cultures of rat limb are bud monitored for inhibition of cell proliferation and differentiation	Developmental toxicity	Endorsed as screening test (EU)

(Continued)

TABLE 29.22 (Continued)

Test Method	Test System	End Point	OECD/TG or Other Regulatory Comments
<i>Methods undergoing validation</i>			
EPISKIN	Reconstructed human skin system used with MTT assay to monitor barrier function	Skin irritation	Report stage in EU
EpiDerm	Similar to EPISKIN	Skin irritation	Report stage in EU
<i>Prevalidated methods</i>			
SkinEthic eye model	Epithelial corneal cell line used for cytotoxicity testing based on the MTT reduction assay	Eye irritation	Appraisal stage in EU
<i>Methods Undergoing Development, Prevalidation, or Evaluation</i>			
Tissue culture models	Neutral red release and silicon microphysiometry or fluorescein leakage bioassays with human keratinocytes and MDCK cells, respectively; red blood cell (RBC) hemolysis test	Eye irritation	Being reviewed by ICCVAM for possible retrospective (weight-of-evidence) validation
Organotypic models	Bovine corneal opacity and permeability (BCOP) assay, with postmortem corneas; hen's egg test on the chorioallantoic membrane (HET-CAM assay); isolated rabbit and chicken eye tests (IRE and ICE)	Eye irritation	Being reviewed by ICCVAM for possible retrospective (weight-of-evidence) validation
Modified Leydig cell line	Analysis of progesterone production as a measure of the test substance effects on steroid hormone production	One-/two-generation study	For use as part of test battery
Testis slices	Assessment of steroid production capacity of the Leydig cells upon exposure of <i>ex vivo</i> rat tissue to toxicants	One-/two-generation study	For use as part of test battery
Human adrenocortical carcinoma cell line	Assay to allow entire steroid pathway effects to be mapped	One-/two-generation study	For use as part of test battery
Placental microsomal aromatase assay	Monitors the ability of substances to affect steroid production; a subcellular microsomal assay is used industrially	One-/two-generation study	For use as part of test battery

capable of detecting damage to specific organ targets. These models are used to support discovery and investigative (of toxicity) functions, but currently have no regulatory status.

29.9 SUMMARY

The tools are currently at hand (or soon will be) to provide the practicing toxicologist with unique opportunities both for identifying potentially toxic compounds in a much more rapid and efficient manner than before and for teasing apart the mechanisms underlying such toxicities on an integrated basis (from the level of the molecule to that of the intact organism). The *in vitro* systems overviewed here, once understood (by investigators and regulators) in how they function and fail (just as *in vivo* systems have come to be understood), will allow this to happen while reducing the need to have recourse to intact mammalian test systems. However, the intact animal models—and, indeed, man for pharmaceuticals—will still be an essential element in the safety assessment armamentarium for the foreseeable future, though increasingly supplemented by alternatives that have had time and utilization enough to establish their dependability.

This is a comprehensive list of methods that have been validated or that are at various stages of development for toxicity testing (OECD, 2005; Kandorona and Letasiova, 2011).

30

EVALUATION OF HUMAN TOLERANCE AND SAFETY IN CLINICAL TRIALS: PHASE I AND BEYOND

30.1 THE PHARMACEUTICAL CLINICAL DEVELOPMENT PROCESS AND SAFETY

As introduced at the beginning of this volume, the process for developing a new therapeutic is a long (6–16 years from drug inception to market approval) and costly (in reality, from US\$ 100 million to US\$ 1.6 billion, depending on how one allocates costs) process, when successful. And most therapeutics fail, with an actual decline in success rates over the last two decades. It is instructive to consider that most failures are due to a lack of demonstration of efficacy in trials and all the ways that can happen. Downing et al. (2014) have provided an excellent review of what types of clinical evidence has supported recent (2005–2012) Food and Drug Administration (FDA) approvals. It is shaped by medical needs, regulatory requirements, economics, our understanding of sciences and diseases, limitations of available technology, and sometimes politics. All of these interact to shape a process which serves to iteratively reduce risks (both economic and human safety), with the probability of failure being reduced in a stepwise fashion (Matoren, 1984; PhRMA, 2016; Gad, 2009). Figure 30.1 briefly summarizes this process.

Much has changed in the clinical trials world since the last edition of this book:

- COVID-19 has changed our society priorities and approaches to developing new therapies. Part of this has been profound change in regulatory requirements for the conduct of clinical trials and the logistics of clinical trial conduct.
- As the pharmaceutical industry and market have become more global and the need for suitable clinical trial subjects has increased, many more trials are multinational. While providing the opportunity to increase

the number and diversity of patients, this has also led to significant difficulties in controlling variability in study conduct and results between sites. Table 30.1 summarizes factors contributing to this variability.

- Nations have acted to increase both access to clinical trial participation (in the United States, all treatment trials must be regulated with clinicaltrials.gov and described on this site—see Table 30.2 for the yearly, resulting number of registered trials through 2019) and outcomes (see Mello et al., 2013 for an excellent review of progress and the issues).
- Regulations now require much more formal and rigorous approaches to collecting evaluating and reporting post market clinical safety data. Such pharmacovigilance requirements and approaches to meeting them are described in a subsequent Chapter 31.
- The successful integration of genomic data to identify at-risk populations in clinical trials and develop specific comparison biomarkers to sensitively identify desired therapeutic effects of biological therapeutic agents has vastly improved some specificity and safety (see Wilke et al., 2007 for approaches to identifying genetic risk factors for serious adverse drug reactions [ADRs]) for new drugs, and in the utilization of pharmacogenomics, challenges remain (Table 30.3).
- As of the time of this writing, revision of “The Common Rule” regulating all biomedical and behavioral research involving human subjects in the United States (covering not just FDA and other parts of the Department of Health and Human Services [HHS], but also 15 other US federal departments and agencies) is under revision (Hudson and Collins, 2015). Table 30.4 summarizes aspects of the current Common Rule and proposed changes.

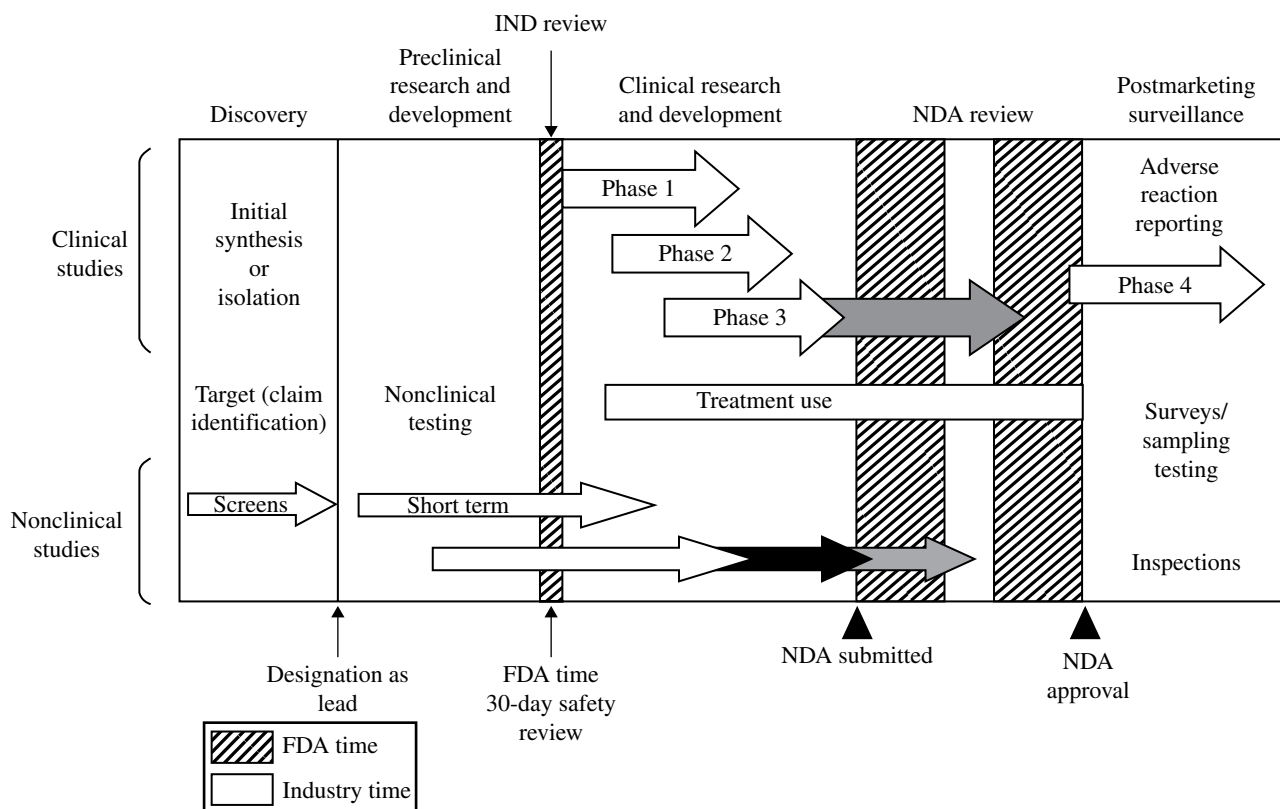

FIGURE 30.1 Pharmaceutical development process viewed as four stages (discovery, preclinical development, clinical development, and NDA review) as well as important postmarket surveillance phase.

TABLE 30.1 Sources of Variability in Drug Response That May Cause Toxicity or Lack of Efficacy

Source of Variability	Mechanism	Drug Therapy	Description of Problem
<i>Biology</i>			
Genomics	Individual patients' genomic makeup influences PK and PD, affecting drug concentration profile at the target site and the likelihood and magnitude of desired and adverse effects	Trastuzumab	PD: only effective in patients overexpressing HER2 receptor on tumor cells
		Abacavir	PD: high risk of severe hypersensitivity reaction in patients with <i>HLA-B*5701</i> allele
		Codeine	PK: lack of analgesia in carriers of nonfunctional <i>CYP2D6</i> alleles, toxicity with multiple <i>CYP2D6</i> gene copies
Other intrinsic and extrinsic factors	Comorbidity, baseline severity of disease, other altered physiological states, or external factors influencing PK and/or PD	Insulin	PD: glucose control and risk of hypoglycemia affected by stress or physical activity
		Several drugs	PK: increased toxicity due to increased absorption with concomitant consumption of grapefruit juice
<i>Behavior</i>			
Prescribing and drug handling	Inappropriate or off-label prescribing, coprescribing with an interacting drug, continued prescribing to nonresponders or medication errors	Cerivastatin Gemfibrozil Mibefradil	Rhabdomyolysis due to too high starting doses Interactions in drug label ignored Toxicity due to drug–drug interactions, label often ignored
Patient adherence	Poor adherence to prescribed drug regime, discontinuation (nonpersistence), “drug holidays,” or inadvertent overdosing	Antihypertensive drugs	Nonadherence or nonpersistence perceived as treatment-resistant hypertension
		Anti-infective therapies	Drug holidays leading to the development of resistance

Note: The overall variability and the extent of the efficacy–effectiveness gap are driven by the interplay between biological and behavioral factors. CYP2D6, cytochrome P450 2D6; HLA, human leukocyte antigen; PD, pharmacodynamics; PK, pharmacokinetics.

TABLE 30.2 Number of New Phase 2, 2/3, and 3 Clinical Trials within ClinicalTrials.gov by Year, n (%)

Receipt Year	Total	Phase 2	Phase 2/3	Phase 3
1999	202	110 (54.5)	3 (1.5)	89 (44.1)
2000	77	43 (55.8)	1 (1.3)	33 (42.9)
2001	76	41 (53.9)	1 (1.3)	34 (44.7)
2002	439	210 (47.8)	18 (4.1)	211 (48.1)
2003	348	197 (56.6)	12 (3.4)	139 (39.9)
2004	551	213 (38.7)	10 (1.8)	328 (59.5)
2005	2873	1014 (35.3)	92 (3.2)	1767 (61.5)

TABLE 30.3 Challenges in Pharmacogenomic Profiling in Drug Discovery

<i>Clinical trial design</i>
<ul style="list-style-type: none"> • There remains no clear universal consensus within the scientific community as to the best design of pharmacogenomic trials • More research is needed on the consequences of variable degrees of penetrance for drug response and adverse events
<i>Stratification of research subjects</i>
<ul style="list-style-type: none"> • Possible loss of benefits from trial participation • Possible unfair representation of certain groups or populations in trials • Possible confounding of statistical analysis and clinically relevant interpretation of results • Possible sampling biases
<i>Pharmacoeconomics</i>
<ul style="list-style-type: none"> • Narrowing of drug markets • Possible “orphan drug” syndrome • Possible “orphan population” syndrome • Questionable whether it is a good investment for venture capitalists
<i>New social risks</i>
<ul style="list-style-type: none"> • New “hidden” disease categories and new labels • Possible “shifting of blame” • Possible overemphasis on “pharmacogenomic cures”

TABLE 30.4 Major Proposed Changes in the Common Rule Notice of Proposed Rulemaking (NPRM)^a

Objective	Current Common Rule	NPRM
Enhancing respect, strengthening informed consent	Does not apply to research with de-identified specimens	Requires consent for all biospecimens, with a few exceptions
	Generally does not allow broad consent	Allows broad consent for future research use of biospecimens and data
	Provides basic elements of informed consent	Adds new elements of informed consent; streamlines consent forms to required elements
Enhancing safeguards	Requires IRBs to ensure confidentiality but provides no specific measures	Specifies privacy and security safeguards for research involving biospecimens and identifiable information
Streamlining review	Allows use of single or local IRBs for multisite studies	Requires use of single IRB for multisite studies in the United States, unless otherwise required by law
	Allows expedited review of minimal-risk research	Requires justification for continuing review of studies eligible for expedited review
	Defines minimal risk	Guidance will be published on determining minimal-risk research
Calibrating oversight	Requires IRB review of grant or contract proposals	Does not require IRB review of grant or contract proposals
	Does not apply to research not funded by Common Rule agencies	Extends rule to unregulated, privately funded clinical trials conducted at institutions funded for human subjects research
	Exempts certain types of low-risk research but does not list examples of exemptions for nonresearch activities	Sets out excluded activities; clarifies entirely exempt activities and creates new category of partially exempt categories

Source: Adapted from Hudson and Collins (2015).

^aThis table provides an overview of the major changes; it is not comprehensive. IRB denotes institutional review board. The following agencies have signed on the NPRM for the Common Rule: Department of Homeland Security, Department of Agriculture, Department of Energy, National Aeronautics and Space Administration, Department of Commerce, Social Security Administration, Agency for International Development, Department of Justice, Department of Labor, Department of Defense, Department of Education, Department of Veterans Affairs, Environmental Protection Agency, Department of Health and Human Services, National Science Foundation, Department of Transportation, and Department of Housing and Urban Development.

From our perspective (i.e., a safety assessment perspective), the purpose of all nonclinical (animal and *in vitro*) testing is to reduce the risks and probability of adverse events (AEs) in human populations. But between initial nonclinical testing (and concurrent with additional animal testing) and a drug reaching the marketplace, the potential for having adverse effects in the general patient population it is intended for is further guarded against by a scheme of increasingly more powerful human (or “clinical”) trials (Piantadosi, 1997). The final purpose of the clinical trial process (see Table 30.5) is to show a therapeutic effective and sufficiently safe (compared to the benefit to the intended patient population) and to optimize these two factors. How safety is evaluated in trials is the subject of this chapter. As has been discussed previously, “safety” is not a fixed thing but rather a relative term in balance with the needs of the patients and the benefit derived. For rapidly life-threatening diseases (cancers and ALS are more common cases, but fatal orphan and rare diseases also enter here), short (out to 2–5-year) maintenance of life and of a reasonable quality of life is an acceptable level of safety if life span and degradation of quality of life by the drug can be maintained. This is demonstrated in the conduct of cancer trials and made sharply clear comparing the conduct of standard nonorphan drugs versus drugs for orphan (rare disease) cancer drugs (Kesselheim et al., 2011).

Cancer trials themselves have evolved markedly in recent years, with adaptive trial methods (Harning, 2007; Meille et al., 2008) largely displacing the older rigid (and slower)

TABLE 30.5 Key Features of Clinical Trial Design

Phase I

- Designed to provide information about pharmacokinetics and pharmacodynamics
- The first time that human participants are involved; focused on safety
- Not always randomized
- Useful in identifying minimal and maximal dosages

Phase II

- Focus on drug efficacy, safety, and determining appropriate range of drug doses in patients with a disease or condition of interest
- Can be randomized

Phase III

- Large population sample
- Usually a comparison of new therapeutic intervention with standard treatment or placebo
- Generally a randomized and blinded study
- Often the final stage of testing before new drug approval can be granted

Phase IV

- Large-scale, long-term postmarketing studies
- Focused on identifying morbidity, mortality, and adverse events
- Might identify new indications

designs. Still, most cancer trials (especially if performed only in a single country) take years because of both the duration of a course of treatment and slow rates of patient recruitment.

Also seeking to allow more rapid and efficient (less costly) first clinical evolution (though more pharmacokinetics (PKs) and “proof of concept” than safety) are exploratory Investigational New Drug (IND)/clinical trials application (CTA) and microdosing approaches (Robinson, 2008) (see Table 30.6).

At the same time, as discussed in the earlier chapter on biotechnology products (Chapter 19), understanding of potential safety concerns with immunomodulatory monoclonal antibodies has led to changes in thinking as to dose selection in initial clinical trials of such agents and in the duration and end points of interest to provide improved characterization of the potential clinical safety of such agents (Muller and Brennan, 2009), basing consideration on target (and off-target) receptor occupancy (Ehlert, 2015) and not just plasma levels (Figure 30.2).

The most common “unexpected” (from nonclinical trial results) safety findings in first-in-human trials continue to be those involving the skin (dermatitis of one form or another) and liver (Kaplowlitz, 2001). But safety reasons for drug withdrawal have a different order of incidence:

- Hepatotoxicity (or delayed liver toxicity [DLT])
- Nephrotoxicity
- Immunotoxicity (primarily for monoclonal antibodies)
- Cardiotoxicity

Genomics and biomarkers seek to optimize the process and at least for oncology have demonstrated significant benefits, especially as we come to identify genetic associations with leading safety issues (e.g., liver toxicity; see Table 30.7).

Except for those cases where there is substantial potential to save or extend lives (such as anticancer ALS and anti-AIDS drugs) or where the intended target diseases are chronic and severe (Parkinson’s or multiple sclerosis [MS]) or the routes of administration are invasive (intrathecal), the initial evaluations in humans are performed in “normal” healthy volunteers with the primary objective being limited to defining the limits of tolerance (safety) of the potential drug and its PK characteristics. These trials may also seek to detect limited (usually surrogate—i.e., indirect) indicators of efficacy but are severely limited in doing so (Biomarkers Definitions Working Group, 2001). Later trials look at the drug’s actions on carefully defined groups of patients.

Some should be said about the special classes of studies (for cancer, HIV, ALS, and other life-threatening diseases) for which first-in-humans are not performed in normal healthy volunteer, but rather in patient. Most frequently, these are patients that have failed other available forms of therapy. Even the design of such trials is different, through the monitored

TABLE 30.6 Exploratory Clinical Study Approaches

Clinical Dosing Regimen	Recommendations for Nonclinical Safety Studies
<p><i>Microdose approach 1</i> Single or multiple doses with total dose $\leq 100 \mu\text{g}$ And total dose $\leq 1/100\text{th}$ of both NOAEL and PAD</p>	<p>Single-dose toxicity study (intended route or IV) One species, usually rodent Maximum dose of 1000-fold the clinical dose on a mg kg^{-1} or mg m^{-2} basis for IV and oral administration, respectively No safety pharmacology or genotoxicity studies</p>
<p><i>Microdose approach 2</i> Multiple doses (maximum of 5) with total dose $\leq 500 \mu\text{g}$ And each dose $\leq 100 \mu\text{g}$ And each dose $\leq 1/100\text{th}$ of both NOAEL and PAD</p>	<p>Seven-day toxicity study (intended route or IV) One species, usually rodent Maximum dose of 1000-fold the clinical dose on a mg kg^{-1} or mg m^{-2} basis for IV and oral administration, respectively No safety pharmacology or genotoxicity studies</p>
<p><i>Single-dose studies</i> Dose up to therapeutic range Maximum dose yields up to 1/2 exposure at NOAEL in most sensitive species</p> <p><i>Dosing for 3–14 days</i> Dose up to therapeutic range Not to exceed nonrodent duration Maximum dose yields up to exposure at nonrodent NOAEL or 1/2 exposure at rodent NOAEL</p>	<p>Single-dose toxicity studies Both rodent and nonrodent Maximum dose of MTD, MFD, or limited dose Safety pharmacology and Ames assay Two-week toxicity study in rodent Maximum dose of MTD, MFD, or limited dose Confirmatory study in nonrodent ($n = 3$) of minimum 3 days Dose providing exposure at rodent NOAEL Safety pharmacology and genotoxicity studies</p>
<p><i>Dosing up to 14 days</i> Dose up to therapeutic range Maximum dose yields up to exposure at NOAEL in most sensitive species, or, if no toxicity is seen in either species, 1/10th the high-dose exposure (using the lower between species)</p>	<p>Two-week toxicity studies in both rodent and nonrodent Maximum dose based on exposure multiples Safety pharmacology and genotoxicity studies</p>

Note: The five examples of exploratory clinical study approaches provided in ICH M3(R2) and the corresponding recommendations for nonclinical studies are summarized. IV, intravenous; MFD, maximum feasible dose; MTD, maximum tolerated dose; NOAEL, no-observed-adverse-effect level; PAD, pharmacologically active dose.

FIGURE 30.2 Traditional view based on administered dose or plasma concentration metric (area under the curve [AUC] or C_{max}).

safety factors and PKs are the same. As the current design for oncology is proving to have exceptional failure rates, new “adaptive” study designs are actively being pursued (Meille et al., 2008; Green and Beneditti, 2012).

With the number of drugs withdrawn from the marketplace since 1990 (or, perhaps, the degree of media coverage of such

withdrawals), public concern with the workings of the drug safety evaluation aspects of the development process has risen sharply (Ganter, 1999; Wechsler, 2001). It is currently estimated that in the United States, ADRs rank between the fourth and sixth leading cause of death (Eikelboom et al., 2001), though the majority of these remain misdosing or misuse.

TABLE 30.7 Selected Reports of Genetic Associations with Drug-Induced Liver Injury

Drug	Gene(s)	Drug Class	Form of Toxicity	Cases/Controls	References
Ximelagatran	DRB1*07 DQA1*02	Oral thrombin inhibitor	Elevation in transaminase	74/130	Kindmark et al. (2008)
Tolcapone	UGT1A16	Catechol- <i>O</i> -methyltransferase inhibitor	Asymptomatic liver transaminase elevation	135/274	Acuña et al. (2002)
Diclofenac	UGT2B7 CYP2C8 ABCC2	NSAID	Range from acute liver failure to nonspecific symptoms with transaminase elevation	24/48	Daly et al. (2007)
Tranilast ^a	UGT1A1	TGT- α antagonist	Unconjugated hyperbilirubinemia	127/99	Danoff et al. (2004)
Isoniazid	CYP2E1 NAT2	Antibiotic	Elevation in serum transaminases	49/269	Huang et al. (2003)
Isoniazid	GSTM1 NAT2	Antibiotic	Icteric hepatitis (serum bilirubin >3.0 mg dL ⁻¹)	37/33	Roy et al. (2001)
Isoniazid	DRB1*03	Antibiotic	Elevation in serum bilirubin or transaminases	22/134	Sharma et al. (2002)
Rifampin Ethambutol Pyrazinamide Streptomycin	DQA1*0102 DQB1*0201				
Amoxicillin/ clavulanic acid	DRB1*1501DRB5*0101DQA1*0102D QB1*0602	Antibiotic/penicillin analog	Jaundice and elevation in serum bilirubin	22/134	O'Donohue et al. (2000)
Tacrine	GST T1 GST M1	Parasympathomimetic	Elevation in serum transaminases	52/89	Simon et al. (2000)
Troglitazone	GSTT1 GSTM1	Thiazolidinedione	Elevation in serum transaminases	25/85	Watanabe et al. (2003)

NSAID, nonsteroidal anti-inflammatory drug; TGF- α , transforming growth factor α .

^aThis study examined the effect of tranilast on evoked Gilbert's syndrome, not hepatotoxicity.

While improvements in the nonclinical of drug safety assessment (as covered in the first 19 chapters of this book) are possible and even likely, clearly the clinical aspects (the subject of this chapter) are likely to be where most improvement is likely. This will come from both better selection of subjects for inclusion in trials and a better understanding of individual or subpopulation differences in human responses to drugs.

While there is much press about the concern that the “increased pace of drug approval” has caused the release onto the market of less safe drugs (Willman, 2000), the causes are more mundane and of much longer standing. Additionally, the actual flow of new drugs entering the market is reduced. An important reason for the high incidence of serious and fatal ADRs is that the existing drug development paradigms do not generate adequate information on the mechanistic sources of marked variability in PKs and pharmacodynamics (PDs) of new therapeutic candidates, precluding treatments from being tailored for individual patients (Ozdemir et al., 2001).

Pharmacogenetics is the study of the hereditary basis of person-to-person variations in drug response. The focus of pharmacogenetic investigations has traditionally been unusual and extreme drug responses resulting from a single gene effect. The Human Genome Project and advancements in molecular genetics have provided an unprecedented opportunity to study all genes in the human genome, including genes for drug metabolism, drug targets, and postreceptor second messenger mechanisms, in relation to variability in drug safety and efficacy. In addition to sequence variations in the genome, high-throughput and genome-wide transcript profiling

for differentially regulated mRNA species before and during drug treatment will serve as important tools to uncover novel mechanisms of drug action. Pharmacogenetic-guided drug discovery and development represent a departure for the conventional approach which markets drugs for broad patient populations, rather than smaller groups of patients in whom drugs may work more optimally.

Pharmacogenetics provides a rational framework to minimize the uncertainty in outcome of drug therapy and clinical trials and thereby should significantly reduce the risk of drug toxicity. The reader is referred to the Internet sources in Table 30.8 for more details on pharmacogenetics and drug development. Potential improvements in patient inclusion criteria will be addressed later in this chapter.

30.1.1 Pharmacokinetics

Current costs and time pressures for developing a new therapeutic motivate companies to make the best possible decision as to whether to continue or abandon the development of a new drug based on a likelihood matrix for three factors: does it work (efficacy), is it acceptably tolerated at therapeutic doses (safety), and is it possible to deliver those therapeutic doses to the target sites/organs economically via the desired route (bioavailability)? These likelihoods change most rapidly in early phase development, and most compounds abandoned during clinical development are abandoned in this phase, with the most common reason being unsuitable PKs (is it absorbed, and does it stay at therapeutic levels for an optimal or near optimal period?)

SNPs, single nucleotide polymorphisms.

(Rolan, 1997). Hence the assessment of PKs in early phase drug development is strategically important, but as discussed poorly targeted, it is receptor selectivity and occupancy at therapeutic targets that is critical but rarely addressed—not plasma levels, but their surrogate. Some of the drug development issues which are likely to be answered at least in part by a thoughtful interpretation of PK data include the following:

1. Is the compound adequately absorbed to be likely to have a therapeutic effect?
2. Is the compound absorbed with a speed consistent with the desired clinical response?
3. Does the compound stay in the body long enough to be consistent with the desired duration of action?
4. Is the within- or between-subject variability acceptable given the likely therapeutic index of the compound?
5. Is there evidence of a formulation problem?
6. Is there a dose range which produces plasma (or tissue) concentrations which are likely to be associated with a desired clinical response, or which gives rise to safety concerns?
7. Is there a relationship between plasma concentrations and a relevant measure of drug effect?
8. Are metabolites produced which may confound the therapeutic response or safety profile?
9. From the absorption, metabolisms, and excretion profile, are there subsets of the target population which may behave differently from expected?
10. Considering the above issues, what is a suitable dosing regimen for clinical efficacy trials?

As most drugs are preferably given orally, absorption which is complete, consistent, and predictable is desirable. Although it may be possible from solubility, lipophilicity, pK_a , molecular size, and animal data to make some prediction about likely absorption, only a study in humans will give quantitative data as the mechanisms of drug absorption are complex and still incompletely understood (Washington et al., 2001). It may be helpful here to distinguish between the terms “absorption” and “bioavailability.”

“Absorption” refers to the fraction of the administered dose which is taken into the body. If a drug is taken up into intestinal cells but then extensively metabolized, it is still regarded as having been absorbed. However, for drug to be “bioavailable,” unchanged drug must reach the systemic circulation. Hence a drug with a very high first-pass metabolism might be well absorbed but poorly bioavailable. Although in therapeutic terms poor absorption and poor bioavailability pose similar problems, it is important to distinguish between them, because there are likely to be different possible solutions. Poor

absorption might be approached by reformulation, change in the route of administration, or the development of a prodrug; extensive presystemic metabolism might only be avoided by change in the route of administration or chemical modification. Poor absorption is still frequently encountered in modern drug development, because the rational drug discovery process often puts more emphasis on potency and selectivity (because these programs are run by biochemists and pharmacologists) than factors likely to be associated with good absorption. This can result in lead compounds which perform very well *in vitro* but which may present major bioavailability and/or formulation problems (see discussion of this by Rolan et al., 1994) *in vivo* and in the clinic.

Quantitative assessment of the extent of absorption (absolute bioavailability) is most rigorously obtained by comparison of the areas under the plasma concentration–time curves (after adjusting for dose) following intravenous (IV) and oral administration. However, even after oral administration alone, some idea of absorption or bioavailability can be obtained in the following ways:

1. If a drug is not substantially metabolized, urinary excretion of unchanged drug may be a useful measure of absorption and bioavailability.
2. If a drug is substantially metabolized but it is reasonable to assume that metabolites are not produced in the gut lumen, urinary recovery of drug and metabolites might be a useful measure of absorption.
3. If the “apparent” plasma clearance (dose/area under the plasma concentration–time curve; equivalent to true clearance/fraction of dose absorbed) gives an implausibly high value of clearance (e.g., greater than hepatic and renal plasma flow), it is likely the bioavailability is low. However, this could be due to presystemic metabolism in addition to low absorption.
4. If there is a very large within- or between-subject variability in “apparent” clearance, this might indicate variable absorption or bioavailability, which in turn is often seen when absorption or bioavailability is low.

Determining whether absorption is related to the formulation or to an intrinsic property of the molecule can be obtained by comparing absorption from a solid formulation and an oral solution, ideally with an IV solution as a reference.

Some idea of the rate of absorption can be obtained from examination of the plasma concentration–time profile. It should be remembered, however, that the time to maximum plasma concentration (t_{max}) is not when absorption is complete but when the rates of drug absorption and elimination are equal. Thus, two drugs with the same absorption rate will differ in t_{max} if elimination rates differ. Assessment of the rate of absorption can also be confounded by complex or slow drug distribution. For example, the calcium channel blocker

amlodipine has a much later t_{\max} than other similar drugs. This is not due to slow absorption but due to partitioning in the liver membrane with slow redistribution. A quantitative assessment of the rate of absorption can be obtained by deconvolution of plasma profiles following IV and oral administration.

30.1.1.1 Relating the Time Course of Plasma Concentrations to the Time Course of Effect A critical decision to be made after the first human study is whether the compound's speed of onset and duration of action are likely to be consistent with the desired clinical response. Speed of onset is clearly of interest for treatments which are taken intermittently for symptom relief, for example, acute treatments for migraine, analgesics, or antihistamines for hay fever. Duration of action is particularly important when the therapeutic effect needs to be sustained continuously, for example, anticonvulsants. The first information on the probable time course of action often comes from the plasma PK profile. However, it has become increasingly evident that the profile alone may be misleading, with the concentration–time and the effect–time curves being substantially different. Some reasons for this, with examples, include the following:

1. The effect may be delayed with respect to plasma concentration because of slow uptake into the target tissue from the plasma. A well-known example is digoxin, where there is a delay of several hours between peak plasma concentration and peak effect.
2. The effect may wane faster than the plasma elimination curve due to tolerance, for example, benzodiazepines and nitrates.
3. The effect may persist despite apparent elimination from plasma. This can occur with an irreversible effect of the drug (e.g., acetylation of platelet cyclooxygenase by aspirin). Another reason is very tight binding of the drug near the receptor (e.g., salmeterol) or concentration and trapping in the target tissue (omeprazole).
4. The formation of active metabolites may also contribute to a delay in onset and/or prolongation of action.

Some of these mechanisms may become apparent during animal pharmacology studies, but the clinical pharmacologist must always be aware of the possible discrepancy between concentration and effect–time curves. Clearly, if a relevant drug effect can also be measured in early human studies, establishing a relationship between plasma concentration and effect may be possible. If the desired clinical effect can be measured directly (e.g., blood pressure for an antihypertensive drug), the PK profile may not contribute greatly to the assessment of time course of action, but these circumstances are the exception rather than the rule. Because of the many causes of discrepancies between the time course of drug

concentrations and effect, and often the difficulty in measuring the clinical effects directly, a potentially useful approach comes from the use of surrogate markers of drug effect (discussed elsewhere in this book) combined with PK/PD modeling to explore the relationships between dose, plasma concentrations, and effects.

30.1.2 Safety of Clinical Trial Subjects

While there continues to be increased interest in and concern about the safety of marketed (“approved”) drugs (e.g., Ioannides and Lau (2001) have published a study showing that adverse safety findings is frequently low compared to actual numbers), as of this writing the public's confidence in the safety of participants in trials is at a low level (Lee et al., 2006). Certainly, the FIAU tragedy (Meinert, 1996) and the case of the death of a healthy volunteer in a Johns Hopkins trial brought this issue to the forefront of the public mind. Amid estimates of as many as 5000 subject deaths per year in federally funded clinical trials (out of seven million individuals enrolled in such trials) (Davis, 1998; Wilson, 1998; Association of American Universities, 2000; Henney, 2000; Shamoo, 2000), the current guidelines and procedures should be clearly understood and carefully adhered to, but continue to change. As a starting place, Table 30.9 presents a glossary of key terms employed in this discussion.

There are international regulations which govern (on a country-by-country basis) the conduct of clinical trials, with many national governments expecting researchers to follow specific guidelines, such as the International Conference on Harmonization (ICH) (1996 and 2006) Guideline for Good Clinical Practice (GCP). Regulations and guidelines are generally based on the principles of the Nuremberg Convention. The Nuremberg Code was written in 1946 in an effort to prevent recurrence of the human experimentation atrocities of World War II. This document states that all research in humans should be done with the well-being of the subject of primary concern (O'Donnell, 2005; Schmidt, 2001).

The 1964 Declaration of Helsinki includes significant detail about clinical trial practices and the rights of potential subjects to be informed about risks, benefits, and alternative therapies (World Medical Association, 2008). It has been amended several times, most recently in 2000, when the use of placebos in trials employing patients was pronounced to be unethical (Mackintosh, 2001). Together, several parts of the US Code of Federal Regulations (CFR) (21 CFR 50, 21 CFR 54, 21 CFR 56, 21 CFR 312) constitute the GCP regulations for studies conducted in the United States. The regulations detail the responsibilities of sponsors, investigators, and institutional review boards (IRBs) and also outline monitoring practices to ensure regulatory and study design compliance and subject safety. Similarly, the ICH guidelines on GCP provide detailed instructions for investigators, institutions, sponsors, and IRBs.

TABLE 30.9 Key Terms

Adverse event (or adverse experience): Any untoward medical occurrence in a patient or clinical investigation subject administered a pharmaceutical product and which does not necessarily have to have a causal relationship with this treatment

Adverse drug reaction (ADR): In the preapproval clinical experience with a new medicinal product or its new usages, particularly as the therapeutic dose(s) may not be established, “all noxious and unintended responses to a medicinal product related to any dose should be considered adverse drug reactions”

IND: Investigational New Drug application, filed with the FDA after preclinical testing, is complete asking for permission to proceed with human tests

Efficacy pharmacology: Evaluation of a drug’s characteristics, effects, and uses with regard to the target illness and its interactions with living organisms

Healthy volunteer: A healthy person who agrees to participate in a clinical trial for reasons other than medical and receives no direct health benefit from participating

Human subject: An individual who is or becomes a participant in research, either as a recipient of the test article or as a control. A subject may be either a healthy human or a patient (21 CFR 50.3)

Nonclinical studies: Studies in living systems (animals or cells) other than humans

Phase I: Initial safety trials on a new medicine in which investigators attempt to establish the dose range tolerance for single and multiple doses in about 20–80 healthy volunteers

Phase II: Pilot clinical trials to evaluate efficacy, safety, and therapeutic dose ranges in selected populations of about 100–300 subjects who have the disease or condition to be treated, diagnosed, or prevented

Phase III: Multicenter studies in populations of perhaps 100–3000 subjects (or more) for whom the medicine is eventually intended

Phase IV: Post marketing trials to provide additional details about the product’s safety, efficacy, and additional uses

Preclinical studies: Animal studies that support phase I safety and tolerance studies and must comply with good laboratory practice (GLP). Other preclinical studies are done in discovery research laboratories to support drug efficiency claims

Serious adverse event: A serious adverse event (experience) or reaction is any untoward medical occurrence that at any dose:

- Results in death
- Is life threatening
- Requires inpatient hospitalization or prolongation of existing hospitalization
- Results in persistent or significant disability/incapacity
- Is a congenital anomaly/birth defect

Subject/trial subject: An individual who participates in a clinical trial, either as recipient of the investigational product(s) or as a control. (ICH) See also healthy volunteers, human subject (ICH 1.57)

Unexpected adverse drug reaction: An adverse reaction, the nature or severity of which is not consistent with the applicable product information (e.g., investigator’s brochure for an unapproved investigational medicinal product)

Source: Data from Machin et al. (2007) and Edwards et al. (2010).

As with preclinical matters, during the 1990s, the ICH has brought together regulatory agencies and industry representatives from the United States, Europe, and Japan—and observers from all over the world—to agree to a single set of technical requirements for the registration of pharmaceuticals for human use. This process is now almost complete. The ICH Guideline for GCP has been adopted by the three lead regions and by many other countries (ICH, 1996). As developing nations begin establishing practices for the testing and registration of new molecular entities, many are using ICH guidelines as standards.

Thus, during the past 50 years, the conduct of clinical drug research has improved because of regulations, guidelines, and policies put in place to protect subjects. Individual pharmaceutical companies have used these guidelines and regulations as the basis for their standard operating procedures (SOPs), technical operations policies, and training programs to direct work processes and staff in their research. Most companies have created quality assurance (QA) units to oversee their

researchers’ adherence to agency guidelines and regulations and to their own company policies and practices.

In the United States, no clinical drug research can begin without prior FDA review of the IND application (with minor exceptions for research imaging agents and radiopharmaceuticals), which includes the human testing protocol and associated preclinical testing results. While formal FDA approval of such an application is not legally a requirement, a 30-day waiting period for FDA review before initiating clinical trials and assent before proceeding is a prudent goal. Regulators in some countries require only notification of intent to initiate first-in-human studies. Before moving on to phase II or phase III studies, pharmaceutical companies and other sponsors must submit the information gathered to date for agency reviews.

For new chemical entities (NCEs), new indications or new formulations companies must file an IND application, which must be approved by the FDA before a drug can be used in humans. The requirements for ADR reporting for INDs are

thus known as the IND regulations. Before a new product can be marketed, companies must file a new drug application (NDA) and have it approved by the FDA. The requirements for ADR reporting after marketing are thus known as the NDA regulations. Both sets of regulations can apply to a drug at the same time; for instance, the NDA regulations apply to any marketed forms, but the IND regulations apply to a new indication or formulation. At the time of writing, the current regulations are in Title 21 of the *CFR* (21 CFR) as follows:

- *21 CFR 312.32*: Safety reports for investigational products subject to an IND application (published 1987)
- *21 CFR 314.80*: Post-marketing reporting of ADEs (NDA) (published 1985)
- *21 CFR 600.80*: Post-marketing reporting of adverse experiences for licensed biological products (includes vaccines) (published 1994)

See also CFR website: <http://www.access.gpo.gov/nara/cfr/index.html>. An August 1997 guideline *Post-marketing Adverse Experience Reporting for Human Drug and Licensed Biological Products: Clarification of What to Report* defined the minimum data relevant for a safety report as:

- An identifiable patient
- An identifiable reporter
- A suspect drug or biological product
- An AE or fatal outcome

If any of these items remain unknown after being actively sought, a report should not be submitted to the FDA. The guideline also clarifies that adverse experiences derived during planned contacts and active solicitation of information from patients (e.g., company-sponsored patients support programs, disease management programs) should be handled as safety information from a post-marketing study (i.e., for expedited reporting, events must be serious and unexpected, with a reasonable possibility that the drug caused the event).

See also Center for Drug Evaluation and Research (CDER) guidance page <https://www.fda.gov/drugs/guidance-compliance-regulatory-information>. These regulations and the guidelines have most recently been extensively indexed in a publication in the *Drug Information Journal*: Curran and Sills (1997).

In the *Federal Register* of October 27, 1994, the FDA published a rule to amend the regulations to provide consistency with certain standardized definitions, procedures, and formats developed by the ICH and Council for International Organization of Medical Sciences (CIOMS) and finally published detailed amended expedited safety reporting regulations, implementing ICH in October 1997 (FDA, 1997a). A revision of the associated guideline has also been proposed by the FDA but was not available at the time of writing.

These new regulations for expedited reporting became effective 180 days later on April 6, 1998. Key points from the new regulations are described later. The amendments to the periodic post-marketing safety reporting regulations are delayed awaiting further consideration of the ICH E2C guideline. More recently, as of the start of 2008, all new drug clinical trials involving patients must be registered with ClinicalTrials.gov as part of the IND process. The form required to register, FDA-3674, is provided as Figure 30.3.

30.1.2.1 IND Regulations In 1994 the FDA proposed to amend requirements for clinical study design and conduct an annual sponsor reporting in the IND regulations as a result of events with fialuridine. In the light of comments received, the FDA withdrew the proposed amendments and will develop a guidance document with recommendations on study design and monitoring of investigational drugs used to treat serious and potentially fatal illnesses, with particular attention to detection of AEs similar to those caused by underlying disease.

30.1.2.2 Increased Frequency Reports The requirement for increased frequency reports for serious expected ADRs with marketed products is revoked. This was also published in FDA (1997b). The rationale for this was that despite receiving many such reports, only a small number of drug safety problems were identified.

30.1.2.3 Reporting Forms FDA form 3500/3500A (refer to Figure 30.1) is the standard form for notifying expedited reports and can also be used by companies to submit IND safety reports. Foreign cases may be reported on the CIOMS I form.

30.1.2.4 Definitions The definition of “serious” has been revised to make it consistent with ICH E2A and is the same for INDs and NDAs (see preceding text).

The definition of “unexpected” for IND reporting is “Any adverse drug experience, the specificity or severity of which is not consistent with the current investigator brochure; or if an investigator brochure is not required or available, the specificity or severity of which is not consistent with the risk information described in the general investigational plan or elsewhere in the current application, as amended. For example, under this definition, hepatic necrosis would be unexpected (by virtue of greater severity) if the investigator brochure only referred to elevated hepatic enzymes or hepatitis. Similarly, cerebral thromboembolism and cerebral vasculitis would be unexpected (by virtue of greater specificity) if the investigator brochure only listed cerebral vascular accidents. ‘Unexpected,’ as used in this definition, refers to an adverse drug experience that has not been previously observed (e.g., included in the investigator brochure) rather than from the perspective of such

Instructions for Completion of Form FDA 3674

Certification of Compliance, under 42 U.S.C. § 282(j)(5)(B), with Requirements of ClinicalTrials.gov Data Bank (42 U.S.C. § 282(j))
 Form 3674 must accompany an application/submission, including amendments, supplements, and resubmissions, submitted under §§ 505, 515, 520(m), or 510(k) of the Federal Food, Drug, and Cosmetic Act or § 351 of the Public Health Service Act.

1. **Name of Sponsor/Applicant/Submitter** - This is the name of the sponsor/applicant/submitter of the drug/biologic/device application/submission which the certification accompanies. The name must be identical to that listed on the application/submission.
2. **Date** - This is the date of the application/submission which the certification accompanies.
3. **& 4.** - Provide complete address, telephone number and fax number of the sponsor/applicant/submitter.
5. **Product Information - For Drugs/Biologics:** Provide the established, proprietary name, and/or chemical/biochemical/blood product/cellular/gene therapy name(s) for the product covered by the application/submission. Include all available names by which the product is known. **For Devices:** Provide the common or usual name, classification, trade or proprietary or model name(s), and/or model number(s). Include all available names/model numbers by which the product is known.
6. **Type of Application/Submission** - Identify the type of application/submission which the certification accompanies by checking the appropriate box. If the name of the type of application/submission is not identified, check the box labeled "Other."
7. **IND/NDA/ANDA/BLA/PMA/HDE/510(k)/PDP/Other Number** - If FDA has previously assigned a number associated with the application/submission which this certification accompanies, list that number in this field. For example, if the application/submission accompanied by this certification is an IND protocol amendment and the IND number has already been issued by FDA, that number should be provided in this field.
8. **Serial Number** - In some instances a sequential serial number is assigned to the application. If there is such a serial number, provide it in this field.
9. **Certification** - This section contains three different check-off boxes.
Box A should be checked if the sponsor/applicant/submitter has concluded that the requirements of 42 U.S.C. § 282(j), section 402(j) of the Public Health Service Act, do not apply because no clinical trials are included, relied upon, or otherwise referred to, in the application/submission which the certification accompanies.
Box B should be checked if the sponsor/applicant/submitter has concluded that the requirements of 42 U.S.C. § 282(j), section 402(j) of the Public Health Service Act, do not apply at the time of submission to any clinical trial that are included, relied upon, or otherwise referred to, in the application/submission which the certification accompanies. This means that, at the time the application/submission is being made, the requirements of 42 U.S.C. § 282(j), section 402(j) of the Public Health Service Act, do not apply to any of the clinical trials included, relied upon, or otherwise referred to, in the application/submission which this certification accompanies.
Box C should be checked if the sponsor/applicant/submitter has concluded that the requirements of 42 U.S.C. § 282(j), section 402(j) of the Public Health Service Act, do apply at the time of submission to some or all of the clinical trials that are included, relied upon, or otherwise referred to, in the application/submission which the certification accompanies. This means that, at the time the application/submission is being made, the requirements of 42 U.S.C. § 282(j), section 402(j) of the Public Health Service Act, apply to one or more of the clinical trials included, relied upon, or otherwise referred to, in the application/submission which this certification accompanies.
10. **National Clinical Trial (NCT) Numbers** - If you have checked Box C in number 9 (Certification), provide the NCT Number obtained from www.ClinicalTrials.gov for each clinical trial that is an "applicable clinical trial" under 42 U.S.C. § 282(j)(1)(A)(i), section 402(j)(1)(A)(i) of the Public Health Service Act, and that is included, relied upon, or otherwise referred to, in the application/submission which the certification accompanies. Type only the number, as NCT will be added automatically before number. Include any and all NCT numbers assigned to the clinical trials included, relied upon, or otherwise referred to, in the application/submission which this certification accompanies. Multiple NCT numbers may be required for a particular certification, depending on the number of "applicable clinical trials" included, relied upon, or otherwise referred to, in the application/submission which the certification accompanies.
11. **Signature of Sponsor/Applicant/Submitter or an Authorized Representative** - The person signing the certification must sign in this field.
12. **Name and Title of Person Who Signed in number 11.** - Include the name and title of the person who is signing the certification. If the person signing the certification is not the sponsor/applicant/submitter of the application/submission, he or she must be an authorized representative of the sponsor/applicant/submitter.
13. **& 14.** - Provide the full address, telephone and fax number of the person who is identified in number 11 and signs the certification in number 11.
15. Provide the date the certification is signed. This date may be different from the date provided in number 2.

Paperwork Reduction Act Statement

Public reporting burden for this collection of information is estimated to average 15 minutes and 45 minutes (depending on the type of application/submission) per response, including time for reviewing instructions. Send comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing this burden to the applicable address below.

Food and Drug Administration Center for Drug Evaluation and Research Central Document Room Form No. FDA 3674 5901-B Ammendale Road Beltsville, MD 20705-1266	Food and Drug Administration Center for Biologics Evaluation and Research 1401 Rockville Pike Rockville, MD 20852-1448	Food and Drug Administration Center for Devices and Radiological Health Program Operations Staff (HFZ-403) 9200 Corporate Blvd. Rockville, MD 20850

FIGURE 30.3 (Continued)

experience not being anticipated from the pharmacological properties of the pharmaceutical product.”

30.1.2.5 Time Frames The time period for submitting written IND safety reports has been revised from 10 working days to 15 calendar days. For telephone reports (fatal and life-threatening unexpected reactions), it has been revised from three working days to 7 calendar days. Such reports can also be made by fax. Telephone reporting was previously restricted to clinical studies conducted under the IND, but under the new rule, telephone reporting within seven calendar days applies to any unexpected fatal or life-threatening reaction from any source.

The time period for submitting NDA alert reports (serious and unexpected) has been revised from 15 working days to 15 calendar days.

Wherever human drug research is conducted, national regulations call for an independent ethical review of the study plan. In countries where a guideline on GCP is used, ethics review bodies are made up of medical professionals from the institution, nonmedical personnel, and community members. Sponsor companies and involved investigators have no voting representation on these review boards, nor may they be present during the voting on the research approval. The investigator conducting the study may, however, present the protocol and answer questions at the IRB review meeting. The company sponsoring the trial is not allowed to participate in IRB meetings as a matter of routine, although a representative might be invited to explain or clarify the protocol to the ethics review body.

Informed consent must be obtained from study participants—in writing—before any study-related activities are performed. Regulations clearly describe the required elements of the consent document and the consent process to be followed. A good informed consent process can help ensure that potential subjects understand the nature of the studies they will enter, the type of treatments they will undergo, alternative therapies currently available, and any particular hazards they might experience. They must be informed that they can withdraw from the study at any time without penalty. Subjects are to be asked for their consent to release information from their medical records and told that the medical information may be inspected by the sponsor, company, and regulatory agency representatives. They are to be informed that the results of the trials may be used publicly, but anonymously.

Drug supplies must be accounted for throughout the trial and reconciled at the end of the trial. These practices are designed to prevent the misuse or inappropriate redistribution of the investigational drug and to help ensure compliance with the protocol.

AEs, unexpected drug reactions, and drug side effects experienced and reported by subjects or observed by clinical investigators are all to be recorded and promptly reported to sponsor companies. It is clear, however, that there remain differences in

reporting standards between companies and between countries (Hayashi and Walker, 1996). There is also, however, a marked difference in reporting standards and rates in US clinical trials between different medical areas (Ioannides and Lau, 2001). The investigators involved with subject care and the pharmaceutical company sponsor must then analyze each event for “causality” and “relatedness” to administration of the drug—did this reaction occur because of the drug or because of something else such as the progression of the disease symptoms, other medications being taken, or unrelated causes? Bradford Hill’s criteria for causation (Hill, 1966), originally developed in conjunction with evaluating the relationship between smoking and cancer, is the accepted fundamental standard for such assessments (see Table 30.10) (Hill, 1966). Such safety information is then to be forwarded to the appropriate IRB or ethics committee and regulatory agencies. The sponsor company is to send periodic updates to investigators, alerting them to new serious or unexpected drug reactions.

Company physicians are expected to continuously analyze the adverse drug event data coming in from worldwide trials for trends and patterns that could foretell a drug safety problem. Drug companies frequently set up data and safety monitoring boards (DSMBs), composed of noncompany medical experts and statisticians who impartially evaluate safety as the study progresses and are responsible for alerting the sponsor to unanticipated problems. Regulatory agencies also watch for trends, because they are often in the best position to see safety trends across classes of drugs from any different companies.

Sponsor companies use QA units independent of the clinical research group to audit medical operations. Their role is to ensure that regulatory standards and company policies and procedures for clinical research are being followed in all countries where research is being conducted.

Regulatory agencies oversee sponsor organizations, clinical trial processes, and clinical trial sites to verify that sponsors are conducting trials appropriately. Existing FDA regulations are conforming to ICH guidelines. When deficiencies are noted, agency inspectorates can restrict and penalize the offending academic IRB, investigator, and/or the sponsor company. Investigator sites (including, in extreme cases, entire universities) can be prohibited from conducting clinical research. Company studies can be rejected by regulatory agencies.

30.1.2.6 Continuous Safety Monitoring Medical staff members at the clinical trial site and at the sponsor company are expected to be continuously alert to ADRs or unexpected and serious medical problems that might be attributed to the new medication being tested. The investigator and the site staff examine subjects and take vital sign measurements on the schedule designated by the protocol, the guide for study conduct. Each drug, as shown in its preclinical studies, has unique characteristics and the potential for AEs or side effects that investigators need to watch for during the clinical trial.

TABLE 30.10 Hill Criteria for Evaluation Causation

Consistency and Unbiasedness of Findings	Confirmation of the Association by Different Investigators, in Different Populations, Using Different Methods
Strength of association	Two aspects: the frequency with which the factor is found in the disease and the frequency with which it occurs in the absence of the disease. The larger the relative risk, the more the hypothesis is strengthened
Temporal sequence	Obviously, exposure to the factor must occur before onset of the disease. In addition, if it is possible to show a temporal relationship, as between exposure to the factor in the population and frequency of the disease, the case is strengthened
Biological gradient (dose–response relationship)	Finding a quantitative relationship between the factor and the frequency of the disease. The intensity or duration of exposure may be measured
Specificity	If the determinant being studied can be isolated from others and shown to produce changes in the incidence of the disease, for example, if thyroid cancer can be shown to have a higher incidence specifically associated with fluoride, this is convincing evidence of causation
Coherence with biological background and previous knowledge	The evidence must fit the facts that are thought to be related, for example, the rising incidence of dental fluorosis and the rising consumption of fluoride are coherent
Biological plausibility	The statistically significant association fits well with previously existing knowledge
Reasoning by analogy	Use of knowledge of other cases for which a high similarity occurs
Experimental evidence	This aspect focuses on what happens when the suspected offending agent is removed. Is there improvement? The evidence of remission—or even resolution of significant medical symptoms—following explanation obviously would strengthen the case

Note: It must be noted that not all criteria must be met to establish causality—indeed, such is a rare case.

Because of this, safeguard activities are built into the protocol, such as the time intervals between subject visits, how often subjects are to be questioned and examined, the specific medical tests to be run at various time points, and the special diagnostic tests or interviews to be conducted. Staff members at the clinical site must record the medical information from these tests and from interviews and medical histories. Site staff must also transfer information from the medical source documents to the case report forms (CRFs) specific to the study. The CRFs contain key information required for the protocol. Clinical research associates and physicians are required to review the information regularly and to immediately report anything alarming to the IRB and regulatory agencies for further evaluation.

30.1.2.7 Sponsor Pharmacovigilance Dedicated departments in pharmaceutical companies—often called pharmacovigilance groups—receive, review, analyze, follow up on, and appropriately distribute safety-related information from new drug trials. These groups sometimes staff hot lines and question and answer services to provide up-to-date answers to drug-related questions. Safety information is to be reported to regulatory agencies at specified intervals and at milestone time points throughout all phases of drug development. The post-approval aspects of this effort are the core of the subject of Chapter 29.

Sponsor monitoring is another important oversight process to ensure quality, compliance, and subject safety. Monitors may be employees of the sponsor’s medical staff, or

a contract research organization, or may be independent contractors. In each case, they represent the sponsor and visit investigator sites regularly, perhaps every 4–8 weeks. They examine subject records in detail and verify that the correct information was transferred to the clinical trial CRFs—a process called source data verification. During their site visits, monitors also examine administrative and regulatory documents, including drug supply and dosing records, AE documentation and reporting, the informed consent process and forms, and CRFs.

Ensuring subject safety must be of the foremost concern during the entire drug development process, especially in clinical trials. The gradual dosing of a drug candidate in healthy human volunteer subjects is performed under tightly controlled conditions and under the direction and scrutiny of physicians trained in clinical pharmacology. A drug candidate’s progress toward broader testing in a population of individuals with the disease or condition to be treated also moves prudently and in well-defined steps.

30.2 LIMITATIONS ON/OFF CLINICAL TRIALS

Before looking more closely at the definition, structure, and designs of trials, one should understand their limitations. These are regulatory, economic, legal, and due to custom.

First, the most recent (October 2008) revision of the Declaration of Helsinki (58th World Medical Association General Assembly) called for discontinuing the use of

placebo-controlled trials in patients. While this is not currently binding on US trials (the FDA has specifically said that they will not mirror this as a requirement) and is intended to protect the health of participating patient subjects by precluding having some denied existing efficacious treatments (which would be the effect in most—but not all—cases; see Al-Khatib et al., 2001), it will also likely cause the numbers of subjects required in a trial to increase. This will further stretch the economic aspects of limitations on the power of trials to assess potential drug safety in what will be the intended patient population. Trials are already very expensive—each additional subject enrolled costs US\$ 15 000 or more (potentially much more) in a phase II or III trial.

The legal (or rather, litigation) limitations are that any AE in a trial (or resulting from it) exposes a sponsor to potential litigation. Accordingly, trials are designed to exclude not only those individuals who are not in the precisely designed subject disease population but also those who represent potential additional risk subpopulations (the elderly, the young, those currently taking other drugs, minorities, and women who are or may become pregnant) are likely to eventually use the drug when it enters the marketplace.

Custom (continuing to do things as they have previously been done) also limits the power of trials to identify safety issues. While there are now regulatory inducements to include more women, the young, and ethnic minorities in trials, the first two groups still are not proportionately incorporated because of both the perceived risks of AEs that they represent and because historically they have not been. Ethnic minorities, particularly African Americans, present a different problem in that there is a historically based resistance to participation in such trials.

30.3 THE CLINICAL TRIAL PROCESS

While the numbers of animals involved in research is tracked closely and is well known, such is not the case for human subjects involved in clinical trials. We simply do not know how many are involved in such trials in the United States, much less worldwide. Though the National Institutes of Health (NIH) does track closely how many dollars and individuals are involved in research it funds (US\$ 18.0 billion and 8 million subjects in 1997), the same is not true for privately funded research (where the numbers are greater). And while there is now a website where one can examine the numbers and types of efficacy trials open, the same is not true for phase I tolerance and PK trials—where most potential drugs cease development.

Clinical drug development is often described as consisting of four distinct phases (phases I–IV). It is important to recognize that the phase of development provides an inadequate basis for classification of clinical trials because one type of

trial may occur in several phases (see Figure 30.4). Table 30.11 presents a preferable (objective based) classification of trial types. It is important to appreciate that the phase label is a description, not a set of requirements. It is also important to realize that these temporal phases do not imply a fixed order of studies since for some drugs in a development plan the typical sequence will not be appropriate or necessary. For example, although human pharmacology studies are typically conducted during phase I, many such studies are conducted at each of the other three stages, but nonetheless sometimes labeled as phase I studies. Figure 30.4 demonstrates this close but variable correlation between the two classification systems. The distribution of the points of the graph shows that the types of study are not synonymous with the phases of development.

Drug development is ideally a logical stepwise procedure in which information from small early studies is used to support and plan later larger, more definitive studies. To develop new drugs efficiently, it is essential to identify characteristics of the investigational drugs in the early stages of development and to plan an appropriate development based on this profile.

Initial trials provide an early evaluation of short-term safety and tolerability and can provide PD and PK information needed to choose a suitable dosage range and administration schedule for initial exploratory therapeutic trials. Later confirmatory studies are generally larger and longer and include a more diverse patient population. Dose–response information should be obtained at all stages of development, from early tolerance studies to studies of short-term PD effect to large efficacy studies. Throughout development, new data may suggest the need for additional studies that may commonly be part of an earlier phase. For example, blood-level data in a late trial may suggest a need for a drug–drug interaction study, or AEs may suggest the need for further dose-finding and/or additional nonclinical studies. In addition, to support a new marketing application approval for the same drug, for example, for a new indication, PK or therapeutic exploratory studies are considered to be in phase I or phase II of development (Stone, 2006; Green and Beneditti, 2012; Gallin and Ognibene, 2017).

Phase I starts with the first-in-man administration of an IND. Although human pharmacology studies are typically identified with phase I, they may also be indicated at other points in the development sequence. Studies in this phase of development usually have nontherapeutic objectives and may be conducted in healthy volunteer subjects or certain types of patients, for example, patients with mild hypertension. Drugs with significant potential toxicity (cytotoxic drugs) or risks due to route of administration (such as intrathecal) are usually studied in patients. Studies in this phase can be open or baseline controlled or may use randomization and blinding to improve the validity of observations.

FIGURE 30.4 Matrix illustrating relationship between phases of development and types of study by objective that may be conducted during each clinical development of new medicinal product. The shaded circles show the types of the study most usually conducted in a certain phase of development; the open circles show certain types of study that may be conducted in that phase of development but are less usual. Each circle represents an individual study. To illustrate the development of a single study, one circle is joined by a dotted line to an inset column that depicts the elements and sequence of an individual study.

TABLE 30.11 An Approach to Classifying Clinical Studies According to Objective

Type of Study	Objective of Study	Study Examples
Human pharmacology (phase I)	<ul style="list-style-type: none"> Assess tolerance Define/describe pharmacokinetics and pharmacodynamics Explore drug metabolism and drug interactions Estimate activity 	<ul style="list-style-type: none"> Dose tolerance studies Single- and multiple-dose PK and/or PD studies Drug interaction studies
Therapeutic exploratory (phase Ib/II)	<ul style="list-style-type: none"> Explore use for the targeted indication Estimate dosage for subsequent studies Provide basis for confirmatory study design, end points, and methodologies 	<ul style="list-style-type: none"> Earliest trials of relatively short duration in well-defined narrow patient populations, using surrogate or pharmacological end points or clinical measures Dose-response exploration studies
Therapeutic confirmatory (phase III)	<ul style="list-style-type: none"> Demonstrate/confirm efficacy Establish safety profile Provide an adequate basis for assessing the benefit/risk relationship to support licensing Establish dose-response relationship 	<ul style="list-style-type: none"> Adequate and well-controlled studies to establish efficacy Randomized parallel dose-response studies Clinical safety studies Studies of mortality/morbidity outcomes Large simple trials Comparative studies
Therapeutic use (phase III/IV)	<ul style="list-style-type: none"> Refine understanding of benefit/risk relationship in general or special populations and/or environment Identify less common adverse reactions Refine dosing recommendation 	<ul style="list-style-type: none"> Comparative effectiveness studies Studies of mortality/morbidity outcomes Studies of additional endpoints Large simple trials Pharmacoeconomic studies

Studies conducted in phase I typically may involve one or a combination of the following:

a. *Estimation of initial safety and tolerability:* The initial and subsequent administration of an IND into humans is usually intended to determine the tolerability of the

dose range expected to be needed for later clinical studies and to determine the nature of adverse reactions that can be expected. These studies typically include both single- and multiple-dose administration.

b. *PKs:* Characterization of a drug’s absorption, distribution, metabolism, and excretion continues throughout

the development plan. Such preliminary characterization is an important goal of phase I. PKs may be assessed via separate studies or as a part of efficacy, safety, and tolerance studies. PK studies are particularly important to assess the clearance of the drug and to anticipate possible accumulation of parent drug or metabolites and potential drug–drug interactions. Some PK studies are commonly conducted in later phases to answer more specialized questions. For many orally administered drugs, especially modified release products, the study of food effects on bioavailability is important. Obtaining PK information in subpopulations such as patients with impaired elimination (renal or hepatic failure), the elderly, children, women, and ethnic subgroups should be considered. Drug–drug interaction studies are important for many drugs and are generally performed in phases beyond phase I. But studies in animals and *in vitro* studies of metabolism and potential interactions may lead to doing such studies earlier.

- c. *Assessment of PDs*: Depending on the drug and the end points studied, PD studies and studies relating drug blood levels to response (PK/PD studies) may be conducted in healthy volunteer subjects or in patients with the target disease. In patients, if there is an appropriate measure, PD data can provide early estimates of activity and potential efficacy and may guide the dosage and dose regimen in later studies.
- d. *Early measurement of drug activity*: Preliminary studies of activity or potential therapeutic benefit may be conducted in phase I as a secondary objective. Such studies are generally performed in later phases but may be appropriate when drug activity is readily measurable with a short duration of drug exposure in patients at this early stage. Frequently such evaluations are done in what are called “phase Ib” studies.

Phase II is usually considered to start with the initiation of studies in which the primary objective is to explore therapeutic efficacy in patients. Initial therapeutic exploratory studies may use a variety of study designs, including concurrent controls and comparison with baseline status. Subsequent trials are usually randomized and concurrently controlled to evaluate the efficacy of the drug and its safety for a particular therapeutic indication. Studies in phase II are typically conducted in a group of patients who are selected by relatively narrow criteria, leading to a relatively homogeneous population, and are closely monitored.

An important goal for this phase is to determine dose levels and regimen for phase III trials. Early studies in this phase often utilize dose-escalation designs to give an early estimate of dose–response, and later studies may confirm the dose–response relationship for the indication in question by using

recognized parallel dose–response designs (could also be deferred to phase III). Confirmatory dose–response studies may be conducted in phase II or deferred until phase III. Doses used in phase II are usually but not always less than the highest doses used in phase I.

Additional objectives of clinical trials conducted in phase II may include evaluation of potential study end points, therapeutic regimens (including concomitant medications), and target populations (e.g., mild vs. severe disease) for further study in phase II or III. These objectives may be served by exploratory analyses, by examining subsets of data, and by including multiple end points in trials.

Phase III usually is considered to begin with the initiation of studies in which the primary objective is to demonstrate or confirm therapeutic benefit.

Studies in phase III are designed to confirm the preliminary evidence accumulated in phase II that a drug is safe and effective for use in the intended indication and recipient population. These studies are intended to provide an adequate basis for marketing approval. Studies in phase III may also further explore the dose–response relationship, or explore the drug’s use in wider populations, in different stages of disease, or in combination with another drug. For drugs intended to be administered for long periods, trials involving extended exposure to the drug are ordinarily conducted in phase III, although they may be started in phase III. ICH E1 and ICH E7 describe the overall clinical safety database considerations for chronically administered drugs and drugs used in the elderly. These studies carried out in phase III complete the information needed to support adequate instructions for use of the drug (official product information).

Phase IV begins after drug approval. Once rare, there are now commonly required therapeutic use studies that go beyond the prior demonstration of the drug’s safety, efficacy, and dose definition.

Studies in phase IV are all studies (other than routine surveillance) performed after drug approval and related to the approved indication. They are studies that were not considered necessary for approval but are often important for optimizing the drug’s use. They may be of any type but should have valid scientific objectives. Commonly conducted studies include additional drug–drug interaction, dose–response or safety studies, and studies designed to support use under the approved indication, for example, mortality/morbidity studies and epidemiological studies.

30.3.1 Development of an Application Unrelated to Original Approved Use

After initial approval, drug development may continue with studies of new or modified indications, new dosage regimens, and new routes of administration or additional patient populations. If a new dose, formulation, or combination is

studied, additional human pharmacology studies may be indicated, necessitating a new development plan.

The need for some studies may be obviated by the availability of data from the original development plan or from therapeutic use.

30.3.1.1 Special Considerations A number of special circumstances and populations require consideration on their own when they are part of the development plan.

Studies of drug metabolites: Major active metabolite(s) should be identified and deserve detailed PK study. Timing of the metabolic assessment studies within the development plan depends on the characteristics of the individual drug.

Drug–drug interactions: If a potential for drug–drug interaction is suggested by metabolic profile, by the results of nonclinical studies, or by information on similar drugs, studies on drug interaction during clinical development are highly recommended. For drugs that are frequently coadministered, it is usually important that drug–drug interaction studies be performed in nonclinical and, if appropriate, in human studies. This is particularly true for drugs that are known to alter the absorption or metabolism of other drugs or whose metabolisms or excretion can be altered by effects by other drugs.

Special populations: Some groups in the general population may require special study because they have unique risk/benefit considerations that need to be taken into account during drug development or because they can be anticipated to need modification of use of the dose or schedule of a drug compared to general adult use. PK studies in patients with renal and hepatic dysfunction are important to assess the impact of potentially altered drug metabolism or excretion. Specific ICH and FDA documents address such issues for geriatric patients and patients from different ethnic groups. The need for nonclinical safety studies to support human clinical trials in special populations is addressed in the ICH M3 document.

A key issue is thus when to perform kinetic studies in special patient groups (pediatrics, elderly, patients with renal or hepatic disease) and how. As the elderly are the majority users of many medicines, the subject of evaluating new drugs in the elderly is a major issue which is discussed in detail elsewhere. Unless a medication is unlikely to be used in the elderly, some data will be required by regulators for registration. However, an important issue in early phase development is whether to perform a separate elderly volunteer kinetic/tolerability study before elderly patients are included in later phase clinical trials. The major argument for doing so includes the possible reluctance of clinical investigators to enroll elderly patients

without such data being available because of safety concerns; however, the utility of such studies has been questioned. The subjects in elderly volunteer studies are usually in much better health than the general population they are intended to represent. Also, the elderly may differ from the young not so much in terms of mean kinetic parameters, but the variability in the elderly may be much greater. The relatively small sample size (typically 12–18) may not allow a good estimation of the variability within the elderly population. For these reasons the FDA have recommended that information about the kinetics of a drug in the elderly should come from a larger group representative of the target population, and this can be done in the efficacy clinical trials. Although these data are useful, it is not always an acceptable substitute for a specific elderly volunteer PK study because the information is only available after many patients have been exposed rather than before and clinical investigators may be reluctant to enroll patients without such data in advance. In practice, for a drug likely to be given to the elderly, an elderly volunteer study should be performed soon after a young healthy volunteer study to expand the potential population for efficacy studies as much as possible. If elderly patients are then included in the main efficacy/safety studies, the population approach can then be used to explore the PK variability in this subset of the population and whether this is associated with an altered clinical outcome.

A similar rationale can be used to decide whether special kinetic (and possibly dynamic) studies should be performed in patients with renal or hepatic disease. For example, if the compound is largely metabolized to inactive metabolites, renal function can reasonably be expected not to have a major effect on kinetics. However, regulators usually will want some information as some expectations do exist to the previous assumption. An example is the “futile cycle” involving some NSAIDs—where prolonged residence of inactive acyl glucuronide metabolites in the plasma in patients with renal disease allows breakdown back to the parent molecule resulting in accumulation (Sallustio et al., 1989). As outlined earlier, a population approach could be used to screen for an effect of disease on drug kinetics, but some investigators may need reassurance before enrolling patients in trials. A small study in patients with advanced renal disease may be able to provide this reassurance. Liver disease can be handled similarly for drugs which are primarily eliminated renally.

The safety of marketed drugs could be significantly improved if the subject groups involved in phase II and III trials better reflected the patient populations that will use drugs. By excluding “representatives” for what will clearly be subpopulations utilizing a drug (those using other drugs or with other diseases), many clear safety questions go unasked. The same is, to some degree, true about preclinical animal studies where only healthy young animals are employed rather than (perhaps) some disease model groups which might serve as better predictors of patient safety concerns.

30.4 INSTITUTIONAL REVIEW BOARDS (IRBS)/ ETHICS COMMITTEES IN THE CLINICAL TRIAL PROCESS

Clinical drug trials represent research with human subjects (Cato et al., 2002). All research involving human subjects that is supported by the federal government or the results of which are to be used in applications for drug or device approval must be conducted in accordance with regulations promulgated by the HHS (45 CFR 46) and the FDA (21 CFR 56). The regulations of both the HHS and the FDA require that an IRB “. . . shall review and have authority to approve, require modifications in (to secure approval), or disapprove all research activities covered by [the] regulations” (45 CFR 46, 21 CFR 56).

The review of clinical drug trials by IRBs raises a number of interesting and difficult issues. These relate to the origin and sponsor of the proposed trial, the nature of the institution the IRB serves, and the manner in which the norms for determining ethical conduct in clinical trials can be applied to specific trials.

Here the ethical principles underlying research involving human subjects, the legal authority for IRBs, and the regulatory requirements affecting the operations of IRBs are reviewed. It will then discuss the role of IRBs in reviewing clinical trials by examining how IRBs can assess the scientific design of trials, the competency of the investigator, the manner of selecting subjects for the trial, the balance of risks and benefits, informed consent, and provisions for compensating for research-related injuries.

30.4.1 Legal Authority and Responsibilities for IRBs

The legal authority for IRBs derives from two parallel sets of federal regulations. One set of regulations was promulgated by the HHS and implements the 1974 amendments to the Public Health Service Act (DHEW, 1974). These regulations are codified in Title 45 of the CFR, Part 46. The second set of regulations was promulgated by the FDA under the Federal Food, Drug, and Cosmetic Act (FD&C Act). These regulations are codified in Title 21 of the CFR; regulations pertaining to IRBs are in Part 50 and those pertaining to informed consent are in Part 56.

The FDA has the legal authority to regulate clinical investigations in the United States when the investigational products move across state or national boundaries. Under the FDA regulations, review and approval by an IRB are required for any experiment that involves a test article and one or more human subjects, either patients or healthy persons, and that is subject to the requirements for prior submission to the FDA (21 CFR 50.3). Such review is also required for any experiment, the results of which are intended to be submitted later to, or held for inspection by, the FDA. While there are as of this writing (December 2015) efforts to ease these requirements in

certain cases (the “Right to Try” movement) and some US states have passed law to this effect, a fundamental change remains unlikely.

The regulations of the FDA are identical or similar to those of the ICH and HHS in nearly all essential respects. Such differences as do exist reflect the different statutory authority under which the separate sets of regulations were promulgated and the difference in mission between the FDA and the NIH, the agency within HHS charged with overseeing the implementation and enforcement of the HHS regulations. The difference in mission between the FDA and the NIH is reflected in the FDA’s approach to compliance with its regulations utilizing its traditional tools of inspections and audits.

The FDA regulations specify requirements for IRB membership, function, and operation and the criteria according to which approval may be given for conducting research. Since these requirements are similar, a single committee should be established to undertake the activities required by both sets of regulations. Additionally, the FDA regulations allow a wide variety of ways in which private practitioners not affiliated with an institution can obtain necessary IRB review of their clinical research activities. The basic ethical tenets governing the actions of an IRB should include the following (Sharp, 2001):

1. Risks to subjects are minimized (i) by using procedures which are consistent with sound research design, and which do not unnecessarily expose subjects to risk and (ii) whenever appropriate by using procedures already being performed on the subjects for diagnostic or treatment purposes.
2. Risks to subjects are reasonable in relation to anticipated benefits, if any, to subjects, and the importance of the knowledge that may reasonably be expected to result. . .
3. Selection of subjects is equitable. . .
4. Informed consent will be sought from each prospective subject or the subject’s legally authorized representative. . .
5. Informed consent will be appropriately documented. . .

Additional requirements are that adequate provisions exist for monitoring the data collected, that adequate provisions exist to protect the privacy of subjects and maintain the confidentiality of the data, and that appropriate safeguards be included to protect the rights and welfare of subjects who are “. . . vulnerable to coercion or undue influence. . . or persons who are economically or educationally disadvantaged. . .” (45 CFR 46.1).

Before a trial initiates, formal review by an IRB that agrees to assume this additional function or by IRBs formed by a local or state health agency, a medical school, a medical society, a state licensing board, or a nonprofit or for-profit

independent group is required. All IRBs, regardless of sponsorship, that are assuming responsibilities for reviewing and approving clinical research protocols subject to FDA authority must comply with the IRB regulations set out by the FDA.

30.4.2 Duties of IRBs

IRBs are required to review and have the authority to approve, require modifications in, or disapprove all research activities covered by the regulations (45 CFR 46.109(b)). They must require that information given to subjects as part of informed consent is in accordance with the general requirements for informed consent that are set out in the regulations. Additionally, they may require that other information be given to subjects when they judge that such information would further protect the rights and welfare of the subjects (45 CFR 46.109(c)).

IRBs must require documentation of informed consent in all studies except those specified in the regulations in which documentation may be waived. Clinical drug trials are not among the classes of studies in which documentation of informed consent may be waived.

IRBs must provide written notification to investigators and institutions of their decisions to approve, require modifications in, or disapprove proposed research activities. Decisions to disapprove a proposed research proposal must be accompanied by a statement of reasons for the decision and provide the investigator an opportunity to respond in person or in writing.

IRBs must conduct continuing reviews of research they approve at least once each year. More frequent reviews may be required if the risk of a particular research project so warrants. IRBs have the authority to suspend or terminate approval of research that is not being conducted in accordance with their requirements or that has been associated with unexpected serious harm to subjects. Such action must be accompanied by a statement of reasons for it and be communicated to the investigator, appropriate institutional officials, and the Secretary of HHS.

The regulations require that IRBs must follow the written procedures that are set out in the assurances they have filed with HHS, review proposed research at convened meetings at which a majority of the IRB members are present, vote approval by a majority of members present at the meeting, and be responsible for reporting to the appropriate institutional official and the Secretary of HHS “. . . any serious or continuing noncompliance by investigators with the requirements and determination of the IRB.”

Institutions that are cooperating in multi-institutional studies, such as clinical drug trials, must each review and approve the proposed studies. Such institutions may, however, use joint review, rely on the review of another qualified IRB, or utilize similar arrangements to avoid duplication of efforts (Cato et al., 2002; Edwards et al., 2010).

30.4.3 Informed Consent

Assuring that adequate provisions exist for securing informed consent is a central duty of IRBs, and that which is seemingly the most visualized when it fails (Office of Inspector General, 2000a, b). The requirements for informed consent are specified in international guidelines and the federal regulations. These require that investigators “shall seek such consent only under circumstances that provide the prospective subject. . . sufficient opportunity to consider whether or not to participate and that minimize the possibility of coercion or undue influence. The information that is given to the subject. . . shall be in language that is understandable to [him]” (45 CFR 46.116). The regulations further stipulate that “No informed consent, whether oral or written, may include any exculpatory language through which the subject. . . is made to waive or appear to waive any of the subject’s legal rights, or releases or appears to be release the investigator, the sponsor, the institution or its agents from liability from negligence.”

The federal regulations specify the information that shall be provided to each subject:

1. A statement that the study involves research, an explanation of the purposes of the research and the expected duration of the subject’s participation, a description of the procedures to be followed, and identification of any procedures which are experimental
2. A description of any reasonably foreseeable risks or discomforts to the subjects
3. A description of any benefits to the subject or to others which may reasonably be expected from research
4. A disclosure of appropriate alternative procedures or courses of treatment, if any, that might be advantageous to the subject
5. A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained
6. For research involving more than minimal risk, an explanation as to whether any compensation and an explanation as to whether medical treatments are available if injury occurs and, if so, what they consist of, or where further information may be obtained
7. An explanation of whom to contact for answers to pertinent questions about the research and research subject’s rights and whom to contact in the event of a research-related injury to the subject
8. A statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled

In addition to these basic elements of informed consent, IRBs shall also require that information shall be provided, where indicated, to the effect that (i) the particular treatment or procedure being tested may involve risks to the subject that are currently unforeseeable, (ii) foreseeable circumstances may exist under which continued participation by the subject may be terminated by the investigator without regard to the subject's consent, (iii) additional costs to the subject may result from participation in the research, (iv) the consequences of a decision to withdraw, and (v) significant findings that may influence a subject's continued participation will be related to the subject.

In addition to the elements enumerated in the federal regulations, IRBs must consider whether consent forms should include the fact of randomization in the case of prospective randomized clinical trials.

Those who feel that the fact of randomization need not be disclosed to prospective subjects argue that since the alternative treatments to be tested are not known to produce significantly different results and since the physician would have to make an arbitrary selection of one treatment or the other for a particular patient, notification that selection of treatment is by computer rather than by the patient's own physician does not provide additional protection for the subjects and is unnecessary. The response to this contention is that a subject's ability to exercise full autonomy over what will be done with his or her own body is best served by notifying the subject as to how the treatment will be selected and by whom, even if the selection process is equally arbitrary whatever process is used.

The weight of the arguments favors the notion that for consent to be fully informed, subjects must be notified that their treatments will be allocated in a random manner, that is, selected by a process other than the judgment of their own physician. The meaning of the concept of randomization and the fact that it will be the manner by which treatment is selected is therefore considered to be an important and integral part of informed consent for participation in randomized clinical trials.

Implicit in the elements that comprise informed consent for subjects participating in clinical trials is that subjects will be notified of the nature of their disease. Current bioethical thinking views this to be essential in order for patients/subjects to give legally effective informed consent. The current practice in the United States is that informed consent to participate in clinical trials requires that patients be notified of their diagnosis. Accordingly, a statement regarding the diagnosis is required in consent forms for participation in clinical trials that are sponsored by national cooperative groups. The Tuskegee study on syphilis is an excellent example of the results of not informing patients (Jones, 1993). It is of interest that other Western countries do not feel that it is necessary or even appropriate to inform patients of their diagnosis as part of the consent process.

Increased incidents in clinical trials have led to recognition of the weaknesses of informed consent procedures (Bohazchuk, 1998). The FDA has reported that such deficiencies are the poorest area of GCP compliance for more than 12 years (FDC Reports, 2000).

30.5 DRUG FORMULATIONS AND EXCIPIENTS

It should never be lost sight that one of the major reasons for the 1938 FD&C Act was a public health disaster caused by a drug formulation mistake. In the 1930s, the Massengill Company's use of diethylene glycol in an elixir of sulfanilamide led to 105 deaths. This same disaster was, by the way, repeated in Haiti in 1995 and 1996 (O'Brien et al., 1998). Such considerations are also overlooked in clinical safety evaluations, though the history of them directly and indirectly causing problems, even to the current day, is extensive (Winek, 2000).

Preclinical animal studies are usually performed with simple formulations which are appropriate for the route investigated in the (nonhuman) species involved. While similar simple formulations or approaches (such as capsules) are also employed for first-in-man studies, as development proceeds, efforts are made to develop formulations which optimize bioavailability. This may lead to effects not seen in earlier animal (or, indeed, human) studies—a factor that should be kept in mind in both study design and interpretation.

It is essential that formulations used in clinical trials should be well characterized, including information on bioavailability wherever feasible. The formulation should be appropriate for the stage of drug development. Ideally, the supply of a formulation will be adequate to allow testing in a series of studies that examine a range of doses. During drug development, different formulations of a drug may be tested. Links between formulations, established by bioequivalence studies or other means, are important in interpreting clinical study results across the development program.

Safety limitations on formulations usually arise from sterility, purity (particularly acceptable levels of endotoxins), and local tissue tolerance concerns at the site of administration for drugs other than oral.

30.5.1 Route of Administration

Just as new drugs must be tested in animals by the route to be used in man, so must they be tested in volunteers using the intended route for patients. But there are clear benefits in testing all drugs when going into man for the first time using IV infusions, even if systemic exposure in patients will be achieved by another route. These benefits relate primarily to the fact that IV infusion allows for precise control of drug administration:

- In the event of a serious or otherwise distressing AE during the infusion, drug delivery can be halted.
- As the drug is delivered directly into the bloodstream, this ensures 100% exposure and overcomes problems relating to bioavailability which may occur with other routes, but in particular dosing by the oral route when the drug may be destroyed in the gastrointestinal (GI) tract or metabolized presystemically in the gut wall or in the liver.
- Delivery of the full dose into the bloodstream, coupled with a uniform delivery rate, results in less variability in plasma or tissue concentrations of drug than is possible using oral dosing, where not only the extent but also the rate of absorption from the GI tract can vary considerably between subjects. Less intersubject variability in plasma concentrations of drug in turn enables the study to be done using smaller numbers of subjects and also offers advantages for drugs anticipated to have narrow therapeutic ratios.
- IV dosing allows the true disposition kinetics of the drug to be evaluated and makes the assessment of PK/PD relationships easier to perform.
- PK scaling between species, that is, animals to man, is made simpler as fewer assumptions need to be made about extent and rate of exposure in man. This in turn helps in further dose selection for human studies.
- Blinding of studies is made easier when IV dosing is used, that is, there is no need to produce matching placebos, while IV dosing overcomes any problems relating to taste, which can make it difficult in blind studies involving oral dosing.

The primary disadvantage of using IV dosing for first-time-in-human studies is that additional resource will be needed to be spent in toxicology, establishing dosage form stability, and for mutation development on a drug which might fail at the first hurdle in man, as indeed many do. For this reason, investigators often prefer to administer drugs for the first time in healthy volunteers using the route to be used in patients and dose intravenously to establish the drugs' PK profile only when they feel reasonably certain that it is likely to be a candidate for further development.

30.6 PHASE I DESIGNS

Phase I clinical trials are the first studies in which a new drug is administered to human subjects. The primary purpose of phase I studies of new drugs is to establish a safe dose and schedule of administration (O'Grady and Linet, 1990; Gad, 2009). Other purposes are to determine the types of side effects and toxicity and organ systems involved, to assess evidence for efficacy, and to investigate basic clinical

pharmacology of the drug. Not all of these goals can be met completely in any phase I trial, in part because the number of patients treated is small. However, well-conducted phase I studies can achieve substantial progress toward each of these goals. Phase I trials are not synonymous with dose-response studies, but they have many characteristics in common.

The initial phase of clinical testing has the following objectives:

- a. Establish a dose-response PD profile by using initial doses projected to be therapeutic in humans. The dose required is predicted on the basis of blood levels found in animal screens.
- b. Determine the PK profile for initial titration and maintenance of steady state for chronically administered drugs.
- c. Design a safe dosage regimen for efficacy testing in adults, pediatric, or elderly.
- d. Estimate efficacy information necessary to make sample size determinations for phase II studies and establish adequate duration of treatment.
- e. Determine the drug interaction potential when concurrent medications are administered, as well as food interaction, assess the enzyme induction potential, and assess the need for therapeutic drug monitoring during efficacy testing.
- f. Establish the requirements for the final formulation.

The initial strategy for phase I is to conduct a single-dose safety study in normal volunteers. The first trial demands close 24h supervision in a clinical setting. Ethical considerations may, however, demand that only patients be used—for example, when evaluating an anticancer agent with predictable toxicity. A repeat-dose tolerance and PK study in normal or patient volunteers is then conducted for chronically administered drugs. These studies will provide the necessary safety information to support efficacy testing.

Sometimes investigators say that phase I studies are not “clinical trials” because there is no treatment comparison being made (except that frequently a placebo is employed). Such treatment comparisons are not a prerequisite for experiments. Because phase I trials rely on investigator-controlled treatment administration and subsequent structured observations, they are clinical trials.

In the development of cytotoxic drugs in oncology, dose finding usually means establishing a “maximum tolerated dose” (MTD). This is the dose associated with serious but reversible side effects in a sizable proportion of patients and the one that offers the best chance for a favorable therapeutic ratio. Side effects from cytotoxic drugs tend to be serious and are referred to as toxicities. Investigators are interested not only in the organ systems involved but also in the duration, reversibility, and probability of specific toxicities. In this

setting, evidence of efficacy is usually weak or nonexistent, because many patients receive what turn out to be subtherapeutic doses of the drug.

For all phase I studies, learning about basic PKs (clinical pharmacology) is important and includes measuring drug uptake, metabolism, distribution, and elimination. This information is vital to the future development and use of the drug and is helpful in determining the relationship between blood levels and side effects, if any. These goals indicate that the major areas of concern in designing phase I trials will be selection of patients, choosing a starting dose, rules for escalating doses, and methods for determining the MTD or safe dose.

If basic pharmacology were the only goal of a phase I study, the patients might be selected from any underlying disease and without regard to functioning of specific organ systems. However, phase I studies are usually targeted for patients with the specific condition under investigation. For example, in phase I cancer trials, patients are selected from those with a disease type targeted by the new drug. Because the potential risks and benefits of the drug are unknown, patients often are those with relatively advanced disease. It is usually helpful to enroll patients with a normal cardiac, hepatic, and renal function. Because bone marrow suppression is a common side effect of cytotoxic drugs, it is usually helpful to have normal hematologic function as well when testing new drugs in cancer patients. In settings other than cancer, the first patients to receive a particular drug might have less extensive disease or even be healthy volunteers.

30.6.1 First Administration: Single Dose Escalating (SDE)

First-time administration of single doses of new drugs is undertaken using a wide range of study design, but essentially there are several basic designs available which are modified to meet the needs of a given study. Fundamental to all designs is that in the interests of safety, successive subjects are exposed to increasing doses of the drug. The fact that doses are titrated upward either in the same subject or groups of subjects and not randomized to remove the potential for bias can be argued as a design weakness, but there is no alternative. Nevertheless, an ordered dose–response can be taken as reasonable evidence of a drug related effect. In addition, the use of placebo, which enables studies to be conducted on either a single- or a double-blind basis, will help to minimize bias. For this reason, placebo control is an integral part of a phase I study. Unwanted feelings or sensations are common occurrences in everyday life; hence it is to be expected that AEs will be encountered during phase I studies. AEs may be drug-related, study related, or result from something which has nothing to do with the drug or the study. They may act singly or in combination. For example, headache, which is one of the most common if not

the most common symptom reported by volunteers taking part in phase I studies, can result from any one of the following: fasting, caffeine withdrawal, feeling anxious about the study, an impending attack of influenza, or a combination of all four factors. Thus, without placebo control it becomes difficult to differentiate between headache which is drug related and headache which is nondrug related. A placebo is not only of value in helping to distinguish between drug- and nondrug-related subjective effects, but it also plays a role in the interpretation of results from laboratory and other safety tests and pharmacological tests which may be influenced by diverse factors such as diet, physical activity, mental state, circadian or other biological rhythms, and asymptomatic illnesses, for example, subclinical viral infections.

The different designs available for a first-time-inhuman study all have their own advantages and disadvantages (Fleiss, 1986; Spilker, 1991; Nysten, 2001; Gallin and Ognibene, 2017). At the end of the day, it is down to the investigator to weigh up the pros and cons of each and then to choose the design which best meets the aims of the study. In an attempt to examine their strengths and weaknesses, let us consider some designs open to an investigator who wishes to undertake a single rising dose safety and tolerability study with a new drug. A typical protocol might require:

- Placebo control
- The dose be increased from x (first dose) to $64x$ (top dose)
- Twofold increases in successive doses (within or between subjects)
- A 7-day within subject washout period
- A minimum of four subjects to receive each dose level

Some design options are shown in Tables 30.12–30.16, while the implications for going with one or other in terms of subject numbers, number of clinic visits, highest first dose given to a subject, biggest increment in dose, and time to complete the study are given in Table 30.17.

TABLE 30.12 Phase I Study—Type A

Group	Number of Subjects Who Received Each Treatment							
	Placebo	x	$2x$	$4x$	$8x$	$16x$	$32x$	$64x$
1	2	3						
2	2		3					
3	2			3				
4	2				3			
5	2					3		
6	2						3	
7	2							3

Note: x , first dose.

TABLE 30.13 Phase I Study—Type B

Group	Number of Subjects Who Received Each Treatment							
	Placebo	x	$2x$	$4x$	$8x$	$16x$	$32x$	$64x$
1	2	3	1					
2	2		2	1				
3	2			2	1			
4	2				2	1		
5	2					2	1

Times to do study	9 weeks	4 weeks	3 weeks	3–6 weeks ^a	3–6 weeks ^a

^aDependent upon whether dosing takes place once or twice weekly.

Design types A and B not only require more than threefold the number of volunteers needed for the other designs but also give the clearest picture of the PKs and tolerance of a single dose. This requirement is compounded by the fact that one-third of the volunteers will receive placebo. The number of volunteers on placebo in each group is open to the investigator's choice, but a balanced (even number of each) design again is easiest to interpret. Whichever way, types A and B require large numbers of subjects, which could present problems when recruiting suitable subjects. The situation is made more difficult when numbers on the volunteer panel are limited (which often is the case) and when one is attempting to recruit the best available volunteers who also satisfy the inclusion/exclusion criteria for a first-time-in-human study. It can also be argued that if the drug under test proved to be toxic, then more subjects would be exposed to its harmful effects. On the other hand, if the drug turns out to be well tolerated, it can be argued equally well that exposing a larger number of subjects is a better basis on which to proceed to the next study.

Types A and B, however, have two clear advantages over the other designs. First, as only one visit to the clinic is required, this will encourage the volunteer to take part in and complete the study. Second, they are ideal designs for drugs with long (or unclear) pharmacological, clinical, or chemical half-lives when a 7-day washout period is an inadequate time for the drug effects to disappear or for it to be cleared from the body.

In the interests of safety, the lower the dose the volunteer is given on the first exposure to the drug, the better. However, as it is impractical to start everyone off with dose x , the next best thing one can do is to keep the first dose given to a volunteer in each group as low as possible within the confines of the design of the study. In this respect, type E works best and types A and B do badly.

With types D and C, twofold increments in dose are uniformly made throughout the whole dose range. This is in

contrast to type E, in which the size of dosage increments over the dose range within subjects varies between 2- and 16-fold. Thus, type E might be an unwise choice for a drug anticipated to have a narrow therapeutic index or a steep dose–response.

Assuming the study goes according to plan (which is often not the case in first-administration studies) and depending upon the study design used, it will take between 3 and 9 weeks to complete. However, although type C (in which the dose is increased stepwise on the same study day) offers the advantage of speed, the fact that it can only really be used for drugs given by the IV route and for drugs with rapid onsets and offsets of action limits its usefulness in practice.

30.6.2 First Administration in Humans: Multiple Dose Escalating (MDE)

In clinical practice, drugs are often prescribed for illnesses which require regular treatment for days, weeks, months, or years. For drugs used in this way (or for which off-label use is likely to be this way), testing on a repeat-dose basis in volunteers is required to evaluate safety and tolerability before treating patients. As with first-time single-dose studies, first-time repeat-dose studies can be undertaken using different designs but with the emphasis again on safety and tolerability. The cornerstone design is a randomized, rising dose, placebo-controlled group comparative evaluation. Whichever design is used, the investigator has to decide upon an appropriate dosing schedule. The choice of a unit dose and dosing interval depends primarily upon the results from the single-dose study. To illustrate this point, if one assumes that the top dose (i.e., 64x) given in the previously described single-dose study proved to be well tolerated, then one might opt for the dosing schedule given in Table 30.18. Of course, the frequency of dosing will depend upon the PD and/or PK profile of the drug. Ideally, dosing should be continued until steady-state plasma concentrations of drug have been achieved, but this may not be practical for drugs with long half-lives. More often than not volunteers are dosed for 7–10 days, but in certain circumstances if toxicological clearance is available and there is a definite need to do so, volunteers may be dosed for 4 weeks. Even if the intent is to dose more than once daily (as in Table 30.18 where twice-daily [BID] dosing is required), giving single doses on the mornings of day 1 and the last day of dosing (i.e., day 7)

TABLE 30.18 Design and Dosing Schedule for a First Repeat-Dose Phase I Study

Group	Day 1	Day 2–6	Day 7
1	8x	8x b.i.d.	8x
2	16x	16x b.i.d.	16x
3	32x	32x b.i.d.	32x

Note: b.i.d., twice daily.

offers certain advantages. For example, it allows for a longer period to assess tolerability before the second dose of drug is given to a volunteer who more than likely will not have been exposed to the drug previously. It also enables comparisons to be made between drug plasma concentration time profiles over 24 h and the elimination kinetics of the drug at the start and end of dosing.

In the interests of safety, doses are increased between groups sequentially, and as a rule dosing is completed in the previous group before dosing is started in the next group. However, if groups are to be dosed for more than 7–10 days or a large number of increments in dose is planned, particularly if more than one dosing frequency is under test, the investigator might choose to overlap dosing between one group and the next, thus enabling the study to be completed in a reasonable time frame. Within each group, volunteers are randomly allocated to receive drug or placebo. The size of the groups usually varies between 6 and 12 with the numbers of subjects receiving drug and placebo in a group being subject to investigator preference.

30.6.2.1 Number of Subjects In a phase I trial, a sufficient number of subjects must be included in a study if valid conclusions are to be drawn from the results. Studies in healthy volunteers and patients are inherently flawed when it comes to assessing safety and tolerability because of the small numbers of subjects involved, and only the most guarded of conclusions are possible. It is easier to draw valid conclusions in respect to drug action involving PD, surrogate, or clinical end points because one is able to specify beforehand the magnitude of the difference which constitutes a useful drug effect and thus calculate the numbers of studies, except that regulatory authorities rather than the investigator specify the criteria which have to be met to enable different formulations to be judged bioequivalent.

30.7 CLINICAL TRIAL SAFETY INDICATORS

One major purpose of preclinical (animal) toxicity studies of a potential new drug is to identify the toxic effects which most commonly occur at doses nearest to those to be used in man. These observations serve to help ensure that care is taken to detect any such effects in humans. Additionally, a broad range of other indicators of adverse drug action may be identified to ensure that their occurrence is looked for. These are also commonly called safety parameters.

Because of the relatively small numbers of volunteers and patients involved, only the most common of drug-related AEs are likely to be detected during early studies (O’Grady and Joubert, 1997). For example, to have a 95% chance of picking up three subjects who have experienced an adverse reaction (with no background incidence) which occurs in 1 in every 100 subjects treated with the drug, it would need to be given

to 650 subjects. Matters are made worse when the AE in question also occurs in the general population, which is usually the case with the kind of symptoms reported by volunteers and patients taking part in drug studies. No matter how good the study design, nothing can compensate for this problem of inadequate numbers. In this respect, all of the study designs described earlier are more or less equally adequate or inadequate as the case may be.

Monitoring for drug-related AEs employs the same or similar methods in both volunteers and patients. In both cases assessments of tolerability and safety are based upon symptom reports, routine laboratory safety screens, electrocardiogram (EKG) monitoring, and on occasions special tests designed to detect unwanted effects associated with a particular class of drug. The chances of obtaining reliable information on a drug's safety profile are enhanced by detailed and careful monitoring, such as special biomarkers for cardiotoxicity (Braunwald, 2008). Symptoms may be reported spontaneously or elicited in reply to standard questions. Open questions such "how are you feeling?" are to be preferred to leading questions on the basis that they result in fewer reports of AEs. If leading questions are used, they need to be carefully worded. A certain amount of basic information is required on all AEs, that is, type, severity, time of onset in relation to time of dosing, duration, and causality. Attributing the cause of an unwanted effect to the drug or some other factor can be difficult particularly when little is known about the drug, as is often the case at the state of initial studies in volunteers or patients. Rechallenge with the drug ideally using the same dose or, if need be (because the event caused a degree of discomfort), a reduced dose is probably the single best way of proving or disproving a causal relationship. But if done the rechallenge procedure must be designed using placebo as comparator under double-blind conditions. Obviously rechallenges can be done only if the AE was reversible, did not cause excessive discomfort, and most importantly was not life threatening. The question of assessing attributions or causality is considered in detail later in this chapter.

30.7.1 Overall Approach to Assessing Safety

30.7.1.1 Choosing Safety Parameters Choosing the appropriate safety parameters for a clinical trial depends on a number of factors. A selected list of examinations and tests commonly used to assess the safety of medicines is given in Table 30.19. The majority of these tests will not be conducted in most drug trials. An assessment of the quantity and quality of prior experience and previous data obtained with the therapeutic is essential to enable one to decide which specific safety tests to incorporate in medicine trials. The choice of safety parameters requires both data in areas where there are indications of potential (or actual) safety problems to monitor and also additional experience and data with a new drug. Until a sufficient body of safety data has accumu-

TABLE 30.19 Selected List of Examinations and Tests Used to Evaluate Safety

A. Clinical examinations
1. Physical
2. Vital signs (usually considered as part of the physical examination)
3. Height and weight (state of dress is usually specified, e.g., socks)
4. Neurological or other specialized clinical examinations
B. Clinical laboratory examinations
1. Hematology (see Table 30.23)
2. Clinical chemistry (see Table 30.23)
3. Urinalysis (see Table 30.23)
4. Virology (viral cultures or viral serology)
5. Immunology or immunochemistry (e.g., immunoglobulins, complement)
6. Serology
7. Microbiology (including bacteriology and mycology)
8. Parasitology (e.g., stool for ova and protozoa)
9. Pulmonary function tests (e.g., arterial blood gas)
10. Other biological tests (e.g., endocrine, toxicology screen)
11. Stool for occult blood (specify hemoccult or guaiac method)
12. Skin tests for immunologic competence
13. Medicine screen (usually in urine) for detection of illegal or nonprotocol-approved medicines
14. Bone marrow examination
15. Gonadal function (e.g., sperm count, sperm motility)
16. Genetics studies (e.g., evaluate chromosomal integrity)
17. Stool analysis using <i>in vivo</i> dialysis
C. Probe for adverse reactions
D. Psychological and psychiatric tests and examinations
1. Psychometric and performance examinations
2. Behavioral rating scales
3. Dependence liability
E. Examinations requiring specialized equipment (selected examples)
1. Audiometry
2. Electrocardiogram (EKG)
3. Electroencephalogram (EEG)
4. Electromyography (EMG)
5. Stress test
6. Endoscopy
7. Computed tomography (CT) scans
8. Ophthalmological examination
9. Ultrasound
10. X-rays
11. Others

lated, more laboratory parameters of safety are generally included than will be needed at a later date. The nature of the clinical trials and efficacy tests used may dictate that certain safety parameters should or should not be included (e.g., in testing a new anticancer medicine, it may be necessary to perform a bone marrow biopsy and smear to confirm the lack of toxicity, and in assessing an agent in anesthetized

patients, the appropriate tests to ensure the patient's safety while under anesthesia must be performed). If, on the basis of preclinical pharmacological or toxicological data, any toxicity is either anticipated or considered possible, then an attempt should be made to evaluate patients for those possible problems. The anticipated use(s) of a therapeutic will also influence which safety parameters are chosen for evaluation (e.g., ophthalmological tests would be included for drugs intended for ocular use).

30.7.1.2 Measuring Safety Parameters After specific safety parameters are chosen, it is necessary to determine how thorough an evaluation of each parameter should be conducted. It is also possible that different types of examinations would be suitable at different points of a clinical trial. For example, a physical examination may be specified to include more or fewer measurements or facets, and a complete examination may not be necessary or even suitable during some periods of clinical trial.

Vital signs may be measured with the patient in a supine, seated, and/or erect position. Both supine and erect positions are usually used if orthostatic changes are being evaluated. The need for such data will depend on the situation, but the position of the patients for this examination, as well as the period of time desired for stabilization, should be noted in the protocol.

30.7.1.3 Parameters That Measure either Safety or Efficacy Certain parameters may, of course, be either safety or efficacy parameters, or both. The electroencephalogram (EEG) is an example. Blood pressure is another. It is thus important to establish clearly in the protocol whether each parameter is being incorporated in the protocol for safety or efficacy evaluations. Almost any safety parameter can be used for measuring efficacy.

30.7.1.4 Appropriateness of Each Parameter for the Clinical Trial and Patient There are four categories of appropriateness of safety tests used in clinical trials:

1. Appropriate for patients, but not necessary for the clinical trial. All of these tests should be included in the clinical trial. They indirectly benefit the trial because they may be monitored for progress or trends or they may simply ensure that patients are receiving appropriate care.
2. Appropriate for the clinical trial, but not necessary for the patients. These tests should be included in the clinical trial if they do not place the patient at unacceptable risk or discomfort. If any tests are deemed unethical in the context of the trials and the patients enrolled, then they should be excluded.
3. Appropriate for both patients and the clinical trial. All of these tests should be included in the clinical trial.

4. Appropriate for neither patients or the clinical trial. All of these tests should be identified and excluded from the clinical trial.

30.7.2 Precautions

Clinical laboratory parameters must be specified individually in the protocol. Abbreviations such as "SMA-6" or "SMA-12" are not acceptable, as different laboratories include different tests in their "SMA-6" (or "SMA-12") battery and using these abbreviations without an explanation can adversely affect the clarity of the protocol and possibly lead to the collection of data on divergent parameters at different sites. Other precautions to consider prior to initiating a clinical trial are to decide if (i) severely abnormal results should be routinely confirmed, (ii) samples should be divided and sent to two separate laboratories when specified abnormalities are determined, (iii) additional tests should be routinely requested if specified abnormalities are observed, (iv) medical consultants should examine patients whenever severe abnormalities are observed, and (v) aliquots of known concentrations of standard drugs should be sent to laboratories for confirmatory measurements and inter laboratory evaluation.

30.7.2.1 Summary of Tests Common dermatological tests are shown in Table 30.20 and ophthalmological tests in Table 30.21. Note that any of these tests could be utilized as measures of efficacy if they addressed the clinical trial objectives. Selected pointers are given in Table 30.22. Specific tests that may be used in hematology, clinical chemistry, and urinalysis are shown in Table 30.23, adult and pediatric behavioral rating scales in Tables 30.24 and 30.25, and psychometric and performance tests in Table 30.26.

30.7.2.2 Choosing Laboratory Tests There is no standardized series of laboratory parameters that are evaluated in all clinical trials, nor is there a single standard for drugs in phases I, II, or III. There are, however, broad general guidelines for laboratory tests that are performed at each stage of clinical development.

30.7.2.3 Tests in Phase I In phase I clinical trials, there is the greatest need to obtain a wide variety of laboratory evaluations as part of developing the safety profile on a new

TABLE 30.20 Selected Examples of Safety Measurements and Tests for a Specialized Dermatological Examination

-
1. Biopsy
 2. Erythema at site of lesion
 3. Absorption of medications systemically (e.g., blood levels)
 4. Signs and symptoms of absorption
 5. Interactions with standard treatment (e.g., ultraviolet light)
-

TABLE 30.21 Procedures and Tests Performed in Ophthalmological Examination

1. Ophthalmological history (attention is paid to patient family history plus patient's diseases and drug reactions)
2. Visual acuity corrected (i.e., with glasses present)
3. External ocular examination (i.e., check for inflammation, ptosis, nystagmus, tearing, proptosis, and other abnormalities)
4. Extraocular muscle testing
5. Pupil size and evaluation (in darkened room with controlled illumination)
6. Slit-lamp biomicroscopy (with dilated pupils)
7. Tonometry (ocular pressure)
8. Ophthalmoscopy with fundus photographs
9. Visual field testing and color vision testing
10. Gonioscopy^a
11. Lacrimation^a (Schirmer's test)

^aThese tests are of minimal value in determining ocular toxicity and are not recommended for routine use in ophthalmological examination to detect drug toxicities.

TABLE 30.22 Selected Considerations Pertaining to Laboratory Data

1. Ask the laboratory to maintain assayed samples that are of particular importance; if questions arise as to the accuracy of results, it might be possible to retest the original samples
2. If laboratory problems are anticipated, divide the initial (and subsequent) samples and send them to two different laboratories or to the same laboratory at two different times
3. If laboratory samples for a complete blood count are going to remain unexamined for a long period of time (e.g., sample obtained on Sunday), prepare a fresh smear so that a comparison may be made with one made 24 or more hours later, because abnormalities may occur when a sample lies around even when it is kept at an appropriate temperature

medicine. This entails an evaluation of the basic hematology, clinical chemistry, and urinalysis parameters (Table 30.23). There will never be 100% agreement among investigators and/or clinical scientists as to which specific tests constitute a "basic" workup.

30.7.2.4 Tests in Later Phases The total number of normal laboratory values that is sufficient to collect on a new drug to demonstrate safety is impossible to specify. Numerous factors must be considered, such as the toxicological profile on other safety parameters and the expected use of the drug in patients. It is important to determine if a therapeutic agent is to be used topically or parenterally, whether it is to be used in generally healthy patients or in seriously ill patients, whether it is a "me-too" drug or a totally novel drug chemically, and whether it will be lifesaving or provide a minimal therapeutic effect. The number of laboratory tests performed usually decreases as an investigational drug moves closer to the

market, but one or more tests may be added to the list in Table 30.23 and studied in great detail.

30.7.2.5 Tests in Medical Practice The ordering of laboratory tests in medical practice (as opposed to phase I clinical trials) is extremely inefficient and often irrational. This suggests the need in some clinical situations to develop logical protocols and algorithms for physicians to follow in ordering tests, particularly when the technology is changing (e.g., hepatitis), in therapeutic areas in which an excessive number of tests are often ordered (e.g., thyroid tests), or when hospitals have developed their own approaches to diagnosis (e.g., use of cardiac isoenzymes in diagnosing a myocardial infarction).

30.7.2.6 Less Commonly Used Methods Evaluations of virtually any biological fluid, tissue, or sense (taste, smell, hearing, sight, and touch) can be conducted to ascertain the safety of a drug (several have been reported to affect taste in some patients, and there are many other examples involving medicine-induced effects on one of the other senses). The choice of tests will depend on experience with the medicine and suspicions about possible problems. Drugs should also be reviewed for teratogenic potential, drug dependence, liability, and carcinogenicity.

30.7.2.7 Identifying the Most Important Laboratory Analytes to Monitor in a Clinical Trial A choice often must be made among the numerous laboratory analytes that could be measured in a clinical trial. This choice is based on (i) past experience with the treatment(s) being evaluated, (ii) therapeutic claim, (iii) cost of the tests, (iv) convenience of obtaining samples, (v) resources available, (vi) state-of-the-art concept of the data's importance, and (vii) the ability of data obtained to convince both regulators and medical practitioners. To arrive at a decision given these and other previously discussed factors may be difficult.

30.7.2.8 Uses of Specific Laboratory Tests to Discover, Confirm, and/or Exclude a Disease Some tests can confirm the diagnosis of a disease (e.g., tissue histology from a bronchoscopic biopsy to confirm lung cancer), but cannot be used to exclude the disease or discover the disease in routine screening. Other tests can be used both to confirm and to exclude the diagnosis of a disease (e.g., glucose tolerance test for diabetes mellitus) but are too inconvenient to be used to discover the disease in routine screening. The uses of each laboratory test to discover, confirm, or exclude a disease should be considered before a test is simply added to a clinical trial protocol. This ensures that the test is appropriate in the context of the planned clinical trial.

30.7.2.9 Hematology A basic hematology evaluation usually includes determination of hemoglobin, hematocrit, red blood cell (RBC) count, white blood cell (WBC) count,

RBC indices (mean corpuscular hemoglobin [MCH], mean corpuscular hemoglobin concentration [MCHC], and mean corpuscular volume [MCV]), and a platelet count. The WBC differential count is usually not required as part of a basic hematological workup unless a specific parameter of the differential count is being evaluated. Nonetheless, a WBC differential count is often obtained in phase I and generally provides useful (though often negative) information. Other hematological parameters (some of which are indicated in

Table 30.23) are not usually obtained unless there is a specific reason to do so.

30.7.3 Clinical Chemistry

A measurement of renal function (creatinine and/or blood urea nitrogen [BUN]) is an “essential” test for most clinical studies, as is the inclusion of a panel of liver function tests (serum glutamic oxaloacetic transaminase [SGOT], serum

what dependent on both the investigator's and/or clinical scientist's experiences and the characteristics of the drug. Other important parameters to measure include serum electrolytes and at least some of the tests listed in Table 30.23.

30.7.3.1 Drug Levels in Plasma Drug levels may also be measured in a clinical trial. Such levels are usually part of a PK analysis but also provide important safety data. This information would be particularly relevant in cases of suspected or actual drug overdose, drug interactions, to correlate medicine levels with toxic events, or in other situations. It must be clarified whether free levels of the drug and/or the protein bound will be measured by the laboratory.

As discussed before, plasma levels are a surrogate for drug levels in the body and may be misleading.

30.7.3.2 Total Blood That May Be Taken from Patients

The total amount of blood that may be taken from a subject in most therapeutic trials should be limited to one unit (about 460 mL) per 8-week period.

30.7.4 Urinalysis

Most clinical laboratories have established a standard battery of tests that includes most or all of the basic parameters listed in Table 30.23. If a dipstick is used to test the urine for several parameters, it is useful to use one that measures occult blood, even if a microscopic examination will count the number of RBC per high-power field. The means of obtaining the specimen should be indicated (i.e., normal

voiding sample, clean catch, midstream, catheterization, suprapubic tap, or cystoscopy), especially in clinical trials in which an antidiuretic or antibiotic (or other relevant drug) is being tested.

It is usually unnecessary to obtain a microscopic examination on all urinalyses unless there are reasons to believe that important information and data may be lost. This is particularly true after it has been demonstrated that the test treatment does not affect the parameters measured in the microscopic evaluation of urine.

30.7.5 Urine Screens

A urine screen can be used to confirm generally that patients being screened or entering the baseline period of the clinical trial are not using agents (legal or otherwise) contraindicated in the protocol. It can also be used on a scheduled or random basis during the study to confirm that patients are not using such agents. The urine screen is limited in that it is unable to detect positive compliance with the protocol and only measures certain aspects of compliance failure. If a urine test will be conducted at unannounced times in the clinical trial, then this point must be mentioned in the informed consent.

The number of agents tested in the urine screen is generally determined individually for each clinical trial, since there is a wide variety of possible drugs that may be measured. The choice of drugs to screen will be based on their relative importance for the trial plus the cost and reliability of the methodology. Results of urine screens are usually best viewed in qualitative (i.e., present, or absent) rather than quantitative terms. The identification of specific drugs in a patient's urine may help in explaining unusual adverse reactions, laboratory abnormalities, or other events. Urine screens may detect the presence of the therapeutic under study. If the urine screen is able to detect the presence of the study drug and this is reported as an unknown drug that is present or as a false positive for another drug, then it could essentially unblind a double-blind clinical trial. To prevent this situation from occurring, data from urine screens may be reported to a nonblinded monitor rather than to the investigator. If a sample of the study drug is put in urine at a physiological concentration and sent to the laboratory, the possibility of cross-reactivity with known agents may be assessed prior to initiation of the trial.

30.7.5.1 Type of Container to Be Used The specific type of container used to collect blood or urine samples is sometimes indicated in a protocol, especially if a special anticoagulant or additive is required or if other specific conditions of sample collection and handling are required. It is generally not necessary to provide this information for commonly requested laboratory tests.

30.7.5.2 Use of International System Units Although the international system of laboratory analyte units is almost

universally agreed upon, many people in the United States resist using it. Typically, these are physicians (and others) who desire to retain the system with which they were trained, which makes more sense to them.

30.7.6 Identifying New Diagnostic Laboratory Tests

Numerous laboratory tests are periodically performed as aids in the diagnosis of disease states. The standards that must be met before a new test is accepted are extremely high, particularly in terms of calculated rates of false-positive and false-negative results. A five-step process leading up to acceptance of a new diagnostic test is proposed.

30.7.7 Ophthalmological Examination

Various parts of the ophthalmological examination are shown in Table 30.21. The most important common ophthalmological test to evaluate patients for the occurrence of chronic drug-induced toxicity is slit-lamp examination. Specific types of drugs with known potential for ocular toxicity may require that special attention be directed to other evaluations shown in Table 30.21. Most drugs that are to be taken systemically require at least some evaluation of ocular safety prior to approval for marketing.

30.7.8 Dermatological Examinations

A few selected safety measurements and tests for specialized dermatological examination are listed in Table 30.20.

In evaluating the safety of drugs using laboratory or other tests, it is important to develop data that helps establish the nature and magnitude of any issue or problem (real or potential) that arises with abnormal laboratory data. Data obtained must also measure the strength of the association between the drug and the event noted or of the serial trends that are observed. While this information is being collected, the definitive courses of action in dealing with the issue or problem can be developed and evaluated. These countermeasures may take the form of (i) periodic monitoring (i.e., prothrombin [PT] or partial thromboplastin time [PTT] times for patients receiving anticoagulants), (ii) cessation of medicine treatment, (iii) decreasing the dose or changing the dose schedule, (iv) initiating counter treatment, (v) use of specific antidotes to counter or reverse medicine effects, (vi) increasing surveillance of the patient, or (vii) various other alternatives.

30.7.9 Cardiovascular Safety

As cardiovascular effects can be fatal or extremely debilitating, irreversible, and rapidly occurring, a number of steps are taken to allow prompt detection and evaluation of such effects. Functionally, blood pressure and heart rate and

cardiac electrophysiology (either episodically by EKG or continuously even when mobile by a Holter monitor) can now be supplemented by measuring a range of biomarkers (Table 30.27). Additionally, indicators of inflammation which are frequently associated with heart failure (Table 30.28) should be evaluated and screened for.

30.7.10 Deaths in Clinical Trials

Certain ADRs may be sufficiently alarming so as to require very rapid notification to regulators in countries where the medicinal product or indication, formulation, or population for the medicinal product are still not approved for marketing because such reports may lead to consideration of suspension of, or other limitations to, a clinical investigations program. Fatal or life-threatening unexpected ADRs occurring in clinical investigations qualify for very rapid reporting. Regulatory agencies should be notified (e.g., by telephone, by facsimile transmission, or in writing) as soon as possible, but no later than seven calendar days after first knowledge by the sponsor that a case qualifies, followed by a report that is as complete as possible within eight additional calendar days. This report must include an assessment of the importance and implication of the findings, including relevant previous experience with the same or similar medicinal products.

Determining the cause of deaths in clinical trials is extremely important, but this goal is often difficult or impossible to achieve. Investigators should be prepared to present reasons to family members to convince them of the importance of conducting an autopsy. Such an autopsy should include examination of the brain, whenever possible.

Any history of drug or alcohol abuse by a patient should trigger a request for appropriate blood and urine tests. Blood samples should always be taken to assess the levels of study drugs and any concomitant agents used. The drug containers should always be analyzed to confirm their contents. This usually entails sending these drugs to their manufacturer.

The circumstances surrounding the patients' death should be as well documented as possible, including a description of all possible influences of the clinical trial procedures on the death, even influences that are clearly independent of the medicine(s) being tested. Even procedures in a clinical trial apparently unrelated to a patient's death may have contributed to the death in some way. For example, these procedures could include (i) the requirement for excessive physical exertion, (ii) prolonged periods of psychologically difficult testing that lead to extreme fatigue, or (iii) giving patients many (e.g., 30) large capsules to ingest per day that lead to choking or aspiration.

Evaluation of the data surrounding the death by physicians who are unassociated with the clinical trial lends additional credibility to the report and conclusions. Physician biases probably will strongly influence their decision regarding the

association of a patient's death with the clinical trial, and this factor must be considered in interpreting their report. This is particularly true for developing survival curves in cancer or other often fatal diseases, when deaths unrelated to the disease or to the treatment are excluded from the analysis.

30.7.11 Behavioral Rating Scales, Performance, Personality, and Disability Tests

A number of behavioral ratings scales and psychometric and performance tests, listed in Tables 30.24–30.26, are briefly summarized in the following, since many of these scales and tests may be used to evaluate safety as well as efficacy. The following comments on the tests provide only a few highlights; readers who are interested in more details are advised to obtain additional information before choosing the tests that appear most relevant to be included in their particular protocol.

These scales may be used either as part of a clinical trial or as major end points in an efficacy trial. Here they are described as a means of obtaining ancillary data on psychological factors in a clinical trial. If these scales are used to demonstrate efficacy, it is mandatory to include only those scales known to be valid.

Unless otherwise noted, all of the adult and children’s behavioral scales are given once pretreatment and at least once posttreatment (depending on the trial design, subject drug PKs, and length of the trials). Investigators may schedule additional evaluations with these tests, but this is usually not done at less than weekly or biweekly intervals. Many tests provide data on both a total score and subtest (factor) scores. The times given to complete tests are subject to significant variation depending on the anxiety and characteristics of the patient and/or the experience of the professional. The times listed do not include either scoring or preliminary and/or necessary observations of the patient.

30.7.12 Adult Behavioral Rating Scales

30.7.12.1 Anxiety Status Inventory The Anxiety Status Inventory (ASI) scale is the professional-rated version of the Zung Self-Rating Anxiety Scale (SAS). Both tests (ASI and SAS) contain 20 items, each with a four-point scale, and are designed for use in adults diagnosed as having anxiety neu-

rosis. Both assess anxiety as a clinical disorder rather than a “feeling state.” The tests rate either the present time or the average status of the patient during the week preceding the evaluation. The ASI takes up to 15–20 min to complete and gives two scores: state anxiety and trait anxiety.

30.7.12.2 Beck Depression Inventory The Beck Depression Inventory (Beck) test may be used to measure the depth of depression as a rapid screen for depressed patients. It is a self-rating scale of 21 items (13 in a shortened form), with each item rated on a four-point scale. It measures the immediate present and has been used in antidepressant medicine trials. The original 21-item scale can be completed in about 10 min and the test is able to discriminate between anxiety and depression. No subtests are present in the Beck.

30.7.12.3 Brief Psychiatric Rating Scale The Brief Psychiatric Rating Scale (BPRS) is used primarily in adult inpatients to evaluate treatment response in medicine trials and in nonmedicine clinical treatment, but it is also used in some outpatient trials. Abbreviated instructions are printed on the form. Ratings are based on observations of patients. Originally developed for psychopharmacologic research, this test contains 18 symptoms, each rated on a seven-point severity scale. It requires approximately 20 min to complete and rates the period of time since the last test. If the test is being used for the first time, it rates the previous week. Five separate subscales are obtained: anxiety/depression, anergia, thought disturbance, activation, and hostility/suspiciousness.

30.7.12.4 Carroll Rating Scale for Depression The Carroll Rating Scale for depression (52-item self-rating scale) is scored with yes or no answers by patients. It was designed to match closely the information content and specific items included in the Hamilton Rating Scale. It has been validated by comparisons with both the Hamilton Depression Scale (HAMD) and Beck and requires approximately 20 min to complete. Seventeen components of depression are measured.

30.7.12.5 Clinical Global Impressions Although the *ECDEU Assessment Manual for Psychopharmacology* (Guy, 1976) provides a formal test for the Clinical Global Impression (CGI) Scale, numerous investigators have modified the three major questions as well as the scales used in order to fit this test to their own clinical trials. The three questions, which may be applied in almost all phase II and phase III clinical trials, are:

1. *Severity of illness:* “Considering your total clinical experience with this particular population, how mentally ill (the investigator may substitute a more

appropriate term if this is not applicable) is the patient at this time?"

2. *Global improvement*: "Rate total improvement, whether or not in your judgment it is due entirely to medicine treatment."
3. *Efficacy index*: "Rate this item on the basis of medicine effect only." This utilizes a rating of both efficacy and adverse reactions and divides the efficacy score by the adverse reaction score to form a ratio ("efficacy index").

Severity of illness is the only one of these three rated pre-treatment. All three questions may be rated posttreatment, and additional ratings are possible during a clinical trial. The CGI measure, which is widely used in all types of medicine trials, is generally well accepted.

A scale of two to nine gradations is usually used for questions 1 and 2, although five or so gradations are probably most common. A typical five-point scale for question 2 would be that the patient is rated as 1 (much worse), 2 (minimally worse), 3 (unchanged), 4 (minimally improved), or 5 (markedly improved).

30.7.12.6 Clyde Mood Scale The Clyde Mood Scale test may be used as either a self-rated or observer-rated scale. It contains 48 items to measure mood and has been shown to be sensitive to medicine effects. The test takes 5–15 min to complete and measures the immediate present in a patient or normal individual. The test gives six scores: friendly, aggressive, clear thinking, sleepy, unhappy, and dizzy.

30.7.12.7 Covi Anxiety Scale The Covi Anxiety Scale is a global observer's rating scale of patient anxiety. There were three items that are each rated on a 0–5 scale. The test is simple to use and requires only a few minutes to complete.

30.7.12.8 Crichton Geriatric Rating Scale The Crichton Geriatric Rating Scale test measures the level of behavioral function in elderly psychiatric patients using a five-point scale on 11 items. It rates either the present or the period within the last week and takes 5–10 min to complete.

30.7.12.9 Depression Status Inventory The Depression Status Inventory (DSI) Scale is the professional's version of the Zung Self-Rating Depression Scale (SDS). Each of the two scales (DSI and SDS) consists of the same 20 items rated on a four-point scale and is applied to adults with depressive symptomatology. The DSI is completed by the professional, and the SDS is completed by the patient. Both tests take about 5–10 min to complete. The DSI rates either the present situation or the last week prior to the test, and a total score is obtained.

30.7.12.10 Hamilton Anxiety Scale The Hamilton Anxiety Scale (HAMA) was designed to be used in adult patients who already have a diagnosis of anxiety neurosis rather than for making a diagnosis of anxiety in patients who have other problems. The test contains 14 items, each with a five-point scale, and is completed by a physician or psychologist. The test emphasizes the patient's subjective state. The two subscales determined are somatic anxiety and psychic anxiety.

30.7.12.11 Hamilton Depression Scale The HAMD is one of the most widely used tests to evaluate the severity of depressive illness quantitatively in adults. The most widely used form of this test contains 21 items covering a broad range of symptomatology, with a three- to five-point scale for most items. The minimum time required to complete this test is usually 10–20 min, and it requires a skilled interviewer. Either the present time or the period within the last week is rated. Six subscales are obtained in the HAMD: anxiety/somatization, weight, cognitive disturbance, diurnal variation, retardation, and sleep disturbance.

30.7.12.12 Hopkins Symptom Checklist The Hopkins Symptom Checklist (HSCL) is a scale that has been used to measure the presence and intensity of various symptoms in outpatient neurotic patients. It is a 58-item self-rating scale and has generally been replaced by the Self-Report Symptom Inventory (SCL-90). It measures the symptoms during the past week and requires approximately 20 min to complete. There are five subtests: somatization, obsessive/compulsive, interpersonal sensitivity, depression, and anxiety.

30.7.12.13 Inpatient Multidimensional Psychiatric Scale The Inpatient Multidimensional Psychiatric Scale (IMPS) is used to measure psychotic syndromes in hospitalized adults capable of being interviewed. The 89 items are rated on the basis of a psychiatric interview. This test has been well validated and requires 10–15 min following a 35–45 min interview. There are 10 scores: excitement, hostile belligerence, paranoid projection, grandiose expansiveness, perceptual distortions, anxious intro-punitiveness, retardation and apathy, disorientation, motor disturbances, and conceptual disorganization.

30.7.12.14 Nurses' Observation Scale for Inpatient Evaluation The Nurses' Observation Scale for Inpatient Evaluation (NOSIE) (30-item test) is used by nursing personnel to rate a patient's behavior on the ward, with a five-point scale for each item. This test is widely used and is well accepted for adult inpatients. The test, which rates the most recent 3 days, is relatively easy to use and requires 3–5 min to complete.

30.7.12.15 Plutchik Geriatric Rating Scale The Plutchik Geriatric Rating Scale (PLUT) (31-item test) is designed to measure the degree of geriatric functioning in terms of both physical and social aspects. The three-point scale for each item is completed on the basis of direct observation of the patient's behavior and takes 5–10 min to complete. The subscales measure overall dysfunction, aggressive behavior, sleep disturbance, social isolation, sensory impairment, work and activities, and motor impairment.

30.7.12.16 Profile of Mood States Profile of Mood States (POMS) self-rating scale is used in both normal and psychiatric outpatients to evaluate feelings, affect, and mood. It has been widely used in medicine trials. The 65 adjectives included in this test may be used to rate the present and/or previous week. This test requires approximately 5–10 min to complete and provides scores for six subtests: tension/anxiety, depression/dejection, anxiety/hostility, vigor, fatigue, and confusion.

30.7.12.17 Sandoz Clinical Assessment-Geriatric The Sandoz Clinical Assessment-Geriatric (SCAG) test measures 18 individual symptoms plus a global rating using a seven-point scale similar to those used in the BPRS. It measures the present period or that within the last week, requires about 10–15 min to complete, and does not contain subtests.

30.7.12.18 Self-Report Symptom Inventory Each of the 90 items in the SCL-90 uses a five-point scale of distress. It was designed as a general measure of symptomatology for use by adult psychiatric outpatients in either a research or clinical setting. It rates either the present or previous week. It requires about 15 min for the patient to complete this form and about 5 min for a technician to verify identifying information. This test is sensitive to drug effects and may be used with inpatients. Nine subscales are measured: somatization, obsessive/compulsive, interpersonal sensitivity, depression, anxiety, anger/hostility, phobic anxiety, paranoid ideation, and psychoticism.

30.7.12.19 Wittenborn Psychiatric Rating Scale The ECDEU version (Wittenborn Psychiatric Rating Scale [WITT]) is a 17-item test shortened from the original 72-item test. All but one item use a four-point scale, and the test takes 5–10 min to complete. It is used in both in- and outpatients and rates either the present or previous week. This test is not intended to make diagnoses but to reflect changes within one patient and to provide a basis for comparing different patients. This test provides descriptive, as opposed to etiological or prognostic, information on patients and includes the following subscales: anxiety, somatic/hysterical, obsessive/compulsive/phobic, depressive retardation, excitement, and paranoia.

30.7.12.20 Zung Self-Rating Anxiety Scale The SAS test requires approximately 5–10 min to complete.

30.7.12.21 Zung Self-Rating Depression Scale The SDS test requires approximately 5–10 min to complete.

30.7.13 Pediatric Behavioral Rating and Diagnostic Scales

Many of the behavioral rating scales described for adults are not suitable for use in the pediatric population. Special tests have been designed, and a number of pediatric behavioral rating scales are presented in Table 30.25. General comments on these tests are presented later. A further description of rating scales used in pediatric medicine trials is given in the *ECDEU Assessment Manual for Psychopharmacology* by Guy (1976). His article is a practical guide to identifying appropriate scales for a particular situation. Conners discusses the two broad approaches of many pediatric rating scales as either “rating current behaviors, symptoms or states; or . . . describing basic traits, dispositions, and personality characteristics.” The choice of one of these two approaches depends in part on the purpose of using a scale in a medicine trial. Three general purposes have been suggested for using a behavioral test (prediction, measurement of change, and classification). The choice of one of these three purposes usually implies that one of the two specific approaches implicit in the pediatric behavioral scales will be more appropriate:

1. To be able to predict something about a patient, choose a scale that rates basic traits.
2. To measure change in a patient, choose a scale that rates current symptoms.
3. To assess a patient's classification, choose a scale that rates either basic traits or current symptoms, depending on the purpose of the classification.

The type of patient population and the desired format of the test to be used in a clinical trial also influence the particular scale(s) chosen.

An evaluation system that can be used in a wide variety of pediatric inpatients is the Children's Behavior Inventory (CBI).

30.7.13.1 Children's Behavior Inventory The CBI is a 139-item, two-point (yes–no) scale to record maladaptive behavior in children aged 1–15 years. Relatively little training is needed to administer this test. It is easily used by nurses, teachers, graduate students, psychologists, and others. This test usually requires at least 2 h of observation of the child, but better reliability is achieved if behavior is observed over an 8 h period. Nine subtest scores are provided:

anger/hostility, conceptual dysfunctioning, fear and worry, incongruous behavior, incongruous ideation, lethargy/dejection, perceptual dysfunctioning, physical complaints, and self-deprecation.

30.7.13.2 Children's Diagnostic Classification

Children's Diagnostic Classification (CDC) test may be used instead of the Children's Psychiatric Rating Scale (CPRS) to arrive at a diagnosis. This differs from the CPRS in that it is highly directed and leads the observer to a diagnosis. It rates the current status of the child and may be used at pretreatment and/or the termination of the clinical trial.

30.7.13.3 Children's Diagnostic Scale

The Children's Diagnostic Scale (CDS) is used in children up to 15 years of age to assist in the diagnosis and classification of the child's condition. It contains 13 items, 8 of which have a seven-point scale. The others are specific diagnostic questions. It measures current status only and is mainly used at the start of a study, although it may be used at the termination of the study as well.

30.7.13.4 Children's Psychiatric Rating Scale

The CPRS is a comprehensive scale to assess a wide range of psychopathologies in children up to age 15. It contains 63 items, with a seven-point scale derived from the BPRS. This test rates 28 items by direct observation of the child based on behavior expressed during the interview and rates other items based on the child's reports of events that occurred either over the preceding week or that occurred during the interview. Scores of 15 separate clusters of the rated items are provided as well as the overall score.

30.7.13.5 Clinical Global Impression

See adult behavioral rating scale description of the CGI.

30.7.13.6 Conners Parent Questionnaire

The Conners Parent Questionnaire (PQ) is a 94-item checklist of symptoms that evaluates common behavior disorders using a four-point scale in children up to 15 years of age and takes 15–20 min to complete. It is used once pretreatment and may be repeated but is often replaced after the first use by the 11-item Conners Parent/Teacher Questionnaire (PTQ). There are eight subscales: conduct problem, anxiety, impulsive/hyperactive, learning problem, psychosomatic, perfectionism, antisocial, and muscular tension.

30.7.13.7 Conners Parent/Teacher Questionnaire

See previous descriptions for Conners PQ and below for the Conners Teacher Questionnaire (TQ). The PTQ is used in conjunction with either the PQ to TQ and yields a total score only (i.e., no subscales are given). The PTQ takes about 5 min to complete and is not used pretreatment.

30.7.13.8 Conners Teacher Questionnaire

The TQ form was designed to obtain teacher evaluations of children up to age 15 in terms of their interactions with peers and their ability to cope with the school environment and requirements. There are 41 items, and the first 39 have a four-point scale. Question 40 deals with the teacher's evaluation of the child's severity of illness, and question 41 deals with global improvement in four different areas. This test is used once at pretreatment and as needed afterward. It takes about 15 min to complete and covers either the present or any interval period up to 1 month. A shorter 11-item PTQ is often used after the initial use of the 41-item TQ. The five subscales included are conduct, inattentive/passive, tension/anxiety, hyperactivity, and social ability.

30.7.13.9 Devereux Child Behavior Rating Scale

The Devereux Child Behavior Rating Scale contains 97 items and is similar to the Devereux Teacher Scale. It is used for emotionally disturbed and mentally retarded children aged 8–12 years. Besides being easy to use, this scale is well researched and discussed in the literature. It requires 10–20 min to complete by clinicians, child care workers, parents, or others and gives 17 scores. There is a Devereux Adolescent Behavior Rating Scale for children from ages 13 to 18.

30.7.13.10 Devereux Elementary School Behavior Rating Scale

The Devereux Elementary School Behavior Rating Scale is a widely used test incorporating 47 items that have high test–retest reliability. It uses a checklist format and is easy to use (requires 10 min). There are 11 factor scores and 3 item scores.

30.7.14 Psychometric and Performance Tests

The psychometric and performance tests presented in Table 30.26 may be grouped as being applicable for use in either children or adults. In children, the tests measure intellect (Goodenough–Harris Figure-Drawing Test [GOOD], Porteus Mazes, Wechsler Intelligence Scale for Children [WISC], Peabody), achievement (Wide Range Achievement Test [WRAT]), and motor performance (vigilance tests, reaction time). There are other tests that may be used to measure learning, although many of these tests utilize equipment and are not described. All of these tests (unless otherwise noted) are given once pretreatment, at least once posttreatment, and at additional times if desired by the investigator. The contribution of learning in the scores obtained at second and third testings is usually unknown. The methods used to motivate patients to perform to the best of their ability in all tests must be standardized and reported.

30.7.14.1 Bender-Gestalt Test the Bender-Gestalt Test is a nonverbal performance test in which the individual copies a design shown on a card. It is often used to identify a problem of visual perception and/or motor performance or minimal brain dysfunction in children.

The scoring used for children (age 4 or 5–11 years) differs from that used for adults (age 15–adult). This test measures perceptual maturity, possible neurological impairment, and emotional adjustment in children. It measures maturation, intelligence, psychological disturbance, and cortical impairment in adults. The test requires 10 min to complete. Scores may fluctuate from test to test and thus must be interpreted carefully.

30.7.14.2 Conceptual Clustering Memory Test For the Conceptual Clustering Memory Test, patients are given a list of 24 specific words from a number of different categories such as birds, cars, or types of drinks. The words are presented one at a time over 2 min, after which patients are asked to recall as many of the specific words as possible. The test measures the total recall as well as the degree to which words of a specific category (e.g., animals) are recalled from the cluster of words given in that category (e.g., dog, cat, cow).

30.7.14.3 Digit Symbol Substitution Test A subtest of the Wechsler Adult Intelligence Scale (WAIS), the Digit Symbol Substitution Test, measures sensorimotor integration and learning relationships of symbols. It has been used in many psychopharmacological studies. Subjects are given different forms of this test at each session. The test requires the patient to match as many of 100 symbols to their respective numerals, found in a code key, as possible within 60 s.

30.7.14.4 Embedded Figures Test For the Embedded Figures Test, patients are shown a complex design and must identify as quickly as possible a simple figure that is “embedded” within the design. Twenty-four embedded figures are included, and a maximum of 3 min is allowed for each one.

30.7.14.5 Frostig Developmental Test of Visual Perception The Frostig Developmental Test of Visual Perception (FROST) measures the development of perceptual skills in children from 4 to 8 years of age or in older children with learning difficulties. It may be administered individually (requires 30–45 min) or to groups (requires 40–60 min).

30.7.14.6 Goodenough–Harris Figure-Drawing Test The GOOD is a brief (10–15 min) easy-to-use test for children 4–15 years of age to measure intellectual maturity.

30.7.14.7 Peabody Picture Vocabulary Test The Peabody Picture Vocabulary Test is a rapid 10–15 min intelligence test

for children aged 2.5–18 years that is useful when there is inadequate time to give the WISC.

30.7.14.8 Porteus Mazes The Porteus Mazes is a nonverbal test that has been shown to be sensitive to medicine effects in both children (over 3 years) and adults. The test has three series of mazes to prevent score improvement on retesting with the same test. It requires about 25 min and provides both a qualitative and quantitative score.

30.7.14.9 Reaction Time There are many different tests used to measure reaction time. These tests measure the period of time between the presentation of a stimulus to a patient and the onset of the resulting response. The signal is usually a visual or auditory stimulus, and the onset of a motor reaction, such as the lifting of a finger, arm, or leg or the pressing of a buzzer, is used to measure the speed of response.

In simple reaction times, a stimulus is presented that always requires the same response, even if the nature of the stimulus changes. A complex reaction time requires the patient to respond to some stimuli but not to others.

30.7.14.10 Vigilance Tests Numerous tests have been designed to measure vigilance. In these tests, patients are requested to respond in some manner to certain stimuli or occurrences but not to others. The stimuli may be controlled to present minimally perceived signals that require vigilance on the part of the patient.

30.7.14.11 Wechsler Adult Intelligence Scale The WAIS consists of 11 subtests—6 verbal tests and 5 performance tests. This provides an age-related IQ in adults from 16 to 75 years of age, that is, the test measures intelligence of the person in relation to their age group and not to the entire population. It may be used either as an initial assessment or as a tool to measure change. The test, which takes 40–60 min to complete, provides 13 scores in verbal and performance categories plus a total score.

30.7.14.12 Wechsler Intelligence Scale for Children The WISC was extensively revised in 1974, and it became the WISC-R, which requires 40–60 min to complete. This widely used scale in children from 6 to 16 years of age may be used for either screening or baseline data or as a measure of change. There is a “preschool and primary scale of intelligence” version that may be used in children from 4 to 6½ years of age (requires 50–75 min). The WISC-R has six verbal and six performance subtests.

30.7.14.13 Wechsler Memory Scale The Wechsler Memory (WMEM) Scale is a brief test that is used to measure memory deficits. There are two forms of the test, and they are generally alternated to avoid a training effect in children taking the test on two or more occasions.

30.7.14.14 Wide Range Achievement Test The WRAT is used in children from age 5 years to adults in college. It assesses basic skills in reading, spelling, and mathematics. It is simple, is easy to administer, and requires 20–30 min to complete.

30.7.15 Personality Tests

In addition to the aforementioned behavioral and performance tests, there are a number of well-known tests of personality that may provide useful information in select clinical studies. The most well known of these tests is the Minnesota Multiphasic Personality Inventory (MMPI). This test consists of 550 affirmative statements to which a true or false response is given and requires about 1 h to complete. It is given to adults over the age of 16 and is scored for 10 scales: depression, hysteria, hypochondriasis, psychopathic deviate, masculinity/femininity, paranoia, hypomania, schizophrenia, psychasthenia, and social introversion.

30.8 ASSESSMENT OF UNWANTED DRUG EFFECTS

Because of the relatively small numbers of volunteers and patients involved, only the most common of drug-related AEs are likely to be detected during early studies. For example, to have a 95% chance of picking up three subjects who have experienced an adverse reaction (with no background incidence) which occurs in 1 in every 100 subjects treated with the drug, it would need to be given to 650 subjects (Gad, 1998). Matters are made worse when the AE in question also occurs in the general population, which is usually the case with the kind of symptoms reported by volunteers and patients taking part in drug studies. No matter how good the study design, nothing can compensate for this problem of inadequate numbers. In this respect, all of the study designs described earlier are more or less equally adequate or inadequate as the case may be.

Monitoring for drug-related AEs employs the same or similar methods in both volunteers and patients. In both cases assessments of tolerability and safety are based upon symptom reports, routine laboratory safety screens, ECG monitoring, and on occasions special tests designed to detect unwanted effects associated with a particular class of drug. The chances of obtaining reliable information on a drug's safety profile are enhanced by detailed and careful monitoring. Symptoms may be reported spontaneously or elicited in reply to standard questions. Open questions such as "how are you feeling?" are to be preferred to leading questions on the basis that they result in fewer reports of AEs. If leading questions are used they need to be carefully worded. A certain amount of basic information is required on all AEs,

that is, type, severity, time of onset in relation to time of dosing, duration, and causality. Attributing the cause of an unwanted effect to the drug or some other factor can be difficult, particularly when little is known about the drug, as is often the case at the stage of initial studies in volunteers or patients. Rechallenge with the drug ideally using the same dose or if need be (because the event caused a degree of discomfort) a reduced dose is probably the single best way of proving or disproving a causal relationship; but if done the rechallenge procedure must be designed using placebo as a comparator under double-blind conditions. Obviously rechallenges can be done only if the AE was reversible, did not cause excessive discomfort, and most importantly was not life threatening.

30.8.1 Separation of Adverse Reactions from Placebo Reactions

Since adverse nondrug symptoms are common (Reidenberg and Lowenthal, 1968) and are not easily separated from drug-induced symptoms, both must be collected for analysis if a complete profile of adverse reactions is to be made. However, this technique can only be used in controlled studies, ideally with placebo, as well as with other standard drugs. The temptation to subtract the number of the particular AR in the placebo group from the number in the active drug group as follows:

Drug group – placebo group = number of adverse reactions to drugs should be resisted because:

- The difference may not be statistically significant and may have arisen by chance.
- Although the total number of events may be statistically different in the two treatment groups, it is also necessary to establish whether the numbers of patients afflicted with the AE are different and vice versa.
- Having established that there is a significant difference between the two treatment groups for the number of events and the number of patients afflicted, the severity of the ADRs in the two groups should be compared.

A further problem is that due to classification, some terms may include more than one type of abnormality (e.g., the incidence of "blurred vision" may be equal in both groups, but there may be several cases of tunnel vision with the trial drug, but because there is no code for tunnel vision it is coded under a more general terms). Another problem is that the symptoms forming a syndrome are often coded separately and individually there may be no difference between two drugs, but when the cases are examined, there may be a combination of symptoms with one drug that warrant being called a syndrome. It is therefore essential to read the individual original description of the AEs before making a judgment. This area has been

explored more fully by Bernstein, and he has added to the equation with the addition of bias:

$$\text{Attributable AEs} = \text{drug group AEs} - \text{placebo group AEs} \pm \text{bias}$$

Bias is equal to the baseline (*B*) frequency and severity of the AE multiplied by pharmacological clinical activity of the drug (AD) minus the pharmacological clinical activity of the placebo (AP):

$$\text{Bias} = B(\text{AD} - \text{AP})$$

The argument is that the disease or a symptom or sign of the disease and the drug ADR may interact as follows:

- Compliance—Early improvement may cause the patient to stop the drug, and the improvement of the ADR may be inappropriately assigned to tachyphylaxis of the ADR; failure of the disease to improve may persuade the patient to add a rescue drug or increase the dose of the study drug or even stop the drug; impaired mental or cognitive function due to the disease may affect compliance.
- The disease may alter the absorption, distribution, metabolism, or elimination of the drug (e.g., alteration of the blood–brain barrier by the disease may allow the drug to affect the brain).
- Observational bias of convalescence (e.g., severe pain causing insomnia may require morphine causing compensatory hypersomnia in excess of that caused by morphine alone).
- Observational bias by halo effects—Perception of an ADR may be swamped by the symptoms of the disease; thus, as the disease symptoms resolve, the ADR becomes apparent.
- Unblinding—If the patient or physician are unblinded due to rapid improvement of the disease or an ADR, they may be led to expect ADRs with the active treatment.
- Pharmacological clinical activity bias—An AE that is already present due to the disease may be increased if is also an ADR of the drug or vice versa. For example, the diarrhea of gastroenteritis may be alleviated by code in-containing preparations given to relieve pain, while the inertia of a severely depressed patient may be sufficiently resolved by an antidepressant to enable the patient to commit suicide.

ADRs that are similar to common nondrug AEs are rarely described or investigated sufficiently for a causal relationship for each individual event to be established. If they cannot be distinguished qualitatively, the correct quantitative procedure is to compare them using nonparametric statistics, giving the

confidence limits for the incidences of ADRs. Small studies ($n < 30$) have little chance of separating ADRs from placebo or nondrug events unless they are very common and specific to the drug. The situation is worsened by the fact that members of a placebo group have a tendency to “catch” AEs from the active drug group, therefore changing a relatively specific ADR to a nonspecific event.

30.8.1.1 Base-Case Causality of Single-Event Adverse Drug Reactions

The analysis and evaluation of ADRs is a major problem in both the development of new drugs and the postmarketing surveillance period. Just as there are standards and requirements established as guidelines in the chemical, pharmacological, and toxicological phases preceding the marketing of a new drug, there are also guidelines for causality assessment of individual human cases in both pre- and postapproval for new drugs.

The most common problem of assessment is the single-event ADR case. Presented here is an approach to such single-event ADR cases. This methodology, relating to the use of therapeutic-, diagnostic-, and prophylactic-type drugs in a clinical setting, should permit the diagnostician to make one of three responses after an assessment of an ADR case: an assured *yes*, a firm *no*, or a reasoned admission of *uncertainty*. The clinicopathological picture presented by the ADR case is often not readily distinguishable from nondrug-induced diseases. The clinical and morphologic findings of ADRs have the same limited number of final common paths that characterize these other (nondrug) human illnesses.

There are three major requirements for establishing the occurrence of an ADR:

1. The possibility and likelihood of a causal relationship between the drug and the ADR must be confirmed by establishing its eligibility.
2. Linkage of the drug with the clinicopathological findings made.
3. The degree of certainty of this drug linkage should be determined.

As an initial background for developing this algorithm or methodology, Figure 30.5 is offered for consideration and orientation. This figure has the basic elements of a “time flowchart,” which has considerable utility in evaluating ADR cases.

In this graphical representation of an ADR, the ordinate (*Q*) represents any of the findings of an ADR. *Specifically*, *Q* may be a symptom (pain, nausea, etc.), a sign, a clinical laboratory result, a radiological finding, a morphological finding, or any combination of these. Synonyms for *Q* include marker, disease marker, signal, indicator, parameter, detector, response, and effect.

FIGURE 30.5 Adverse drug reaction (curve Q) plotted against time (abscissa T). Dashed lines show three courses an ADR can take: increasing severity to death, leveling off to chronicity, or return to abscissa, indicating recovery. Four criteria that must be met before drug is eligible to be empiric correlate of Q (adverse drug reaction) are listed.

The abscissa is the time element (T), related to both the time of drug administration and the dating of disease marker data. Both are usually plotted on the same time flowchart in a particular case.

This graphical representation of an ADR case will be used frequently in the assessment of eligibility and linkage determinations of ADRs. The four eligibility criteria are also listed in Figure 30.5.

Administration of the drug: As it is with accurate identification of a drug, so it is that its “administration” must at times be held in question. Subject compliance with the study protocol is not a rare problem in clinical trials. Complete non-compliance sometimes occurs.

Temporal eligibility: The time factor in assessment of ADRs is a very important one and in some cases is of critical diagnostic importance. This is true not only in establishing “eligibility” of the drug but also in linking the drug to the reaction. On the other hand, the time element may be equally important in denying eligibility and also make linkage of the drug with the clinicopathological picture a most unlikely possibility.

It is quite apparent that a drug cannot be responsible for an ADR if the latter is already in progress before the drug is first administered. This dyssynchronicity is sometimes seen in both trials and later in the marketplace.

Latent period: Latent period refers to the time interval between the initial administration of the drug and the onset of the ADR (in Figure 30.6, it is the interval T_0 to T_1). The latent period is not rigidly fixed or exactly predictable, but it tends to fall within certain limits.

Characteristically, strychnine deaths occur in seconds to minutes. Most anaphylactic deaths occur within 20–30 min after contact with the lethal antigen, while jaundice associated with most drugs has its onset within 3 days to 3 weeks after the beginning of therapy. The fatal pancytopenia following chloramphenicol appears in 1–3 months, while hepatic angiosarcoma related to aflatoxin has a latent period of one to several decades. The ultimate in length of latency is one to several generations from a drug-induced mutational germ cell change to its manifestation in a conceptus.

Consideration of the latent period in an ADR is of use in an ADR assessment in one of two ways: the latent period may be too long, or it may be too short.

In summary, identification, administration, temporal eligibility, and latent period are the four criteria for establishing the eligibility of a drug to have caused an ADR. Emphasis should be placed on obtaining sufficiently detailed time-related data on drug administration and on the appearance of ADR markers. These data are a *sine qua non* in the assessment of drug eligibility.

Linking the Drug with the Clinicopathological Findings

The second major task in analyzing an ADR case is to establish a connection or linkage between the drug and the clinicopathological findings (making empiric correlates of the drug and these findings).

Figure 30.6 is a time flowchart representing an ADR that itemizes six ways of making this linkage.

Exclusion Exclusion consists of selecting one drug from a group of drug candidates by the use of the time flowchart.

FIGURE 30.6 Six methods of linking drug with adverse drug reaction.

The exclusion method also includes instances in which drug candidates are themselves excluded from causation status because a nondrug etiology is clearly demonstrable (environmental or occupational factors, radiation injury, the underlying disease of the patient, or a comorbid state) that can reasonably account for the clinicopathologic findings.

Dechallenge The principle involved in the dechallenge method of linkage is that if there is a reversible effect present, then removing the cause will eliminate the effect.

Rechallenge The principle involved in the rechallenge method of linkage of a therapeutic to an ADR is implied in the phrase *post hoc ergo propter hoc* (after this therefore because of this).

As applied, if a drug has been incriminated with a reaction and the ADR disappeared when the drug was discontinued, a rechallenge with this drug followed by a return of the ADR would increase the probability that the drug and the ADR were empiric correlates. While intentional challenge is not often done, such a rechallenge may occur inadvertently.

Singularity of the Drug The principle involved in the singularity method of linking a drug with an ADR is based on two assumptions: only one drug was administered, and there was no basic disease or comorbid state that could be related to the ADR marker being used in the assessment.

Pattern The pattern method of linking a drug with an ADR shifts the focus of attention to the clinicopathological findings in an ADR and away from the identification of the

causative drug. This shift of emphasis is necessary when detailed time-related drug and disease marker data are unavailable to the evaluator of the case. The site-process profile may then be used as a guideline for searching past experience and the literature for cases that have matching features. Matching features found in the literature may include associations with certain drugs or chemicals, which serves as a guideline for a focused examination of the patient's history for the causative agent.

This "pattern" method may also be used in excluding drugs. If the drugs or chemicals suggested by the morphologic findings are not identified or disclosed by historical or toxicological efforts, then the morphologic changes appear to remain nondrug or nonchemical related.

Quantitation of Drug Level Assessing an ADR case by quantitation of drug level brings our focus back to the search for and the identification of the causative agent by quantitative and objective data based on laboratory analysis of body fluids and/or viscera (Ozdemir et al., 2001). This method is applicable and strongest in the case of higher dose level. The feasibility of this approach is based on the availability of dependable information on lethal levels from past experience or preclinical work. Without this comparison information, there is no judgmental significance to toxicological levels in the case at hand.

Quantitated levels of drugs have limitations in diagnostic value. In adverse reactions in the hypersensitivity, idiosyncratic, and pharmacogenetic categories, drugs have been administered in therapeutic (not toxic) amounts, and blood and other body fluids and tissue levels have been found to lie

within therapeutic ranges. Such analyses will confirm any prior administration of the drugs, but the problem of the etiological differential diagnosis will still remain.

In addition to quantitative approach, qualitative identification can be of value in appropriate instances. In some cases of ADRs, more than one of the six methods of drug linkage that are listed in Figure 30.6 may be used in causation analysis. In fact, multiple methods in the same case strengthen the confirmation of the rejection of an ADR and its etiology.

Difficulties in Assessing ADRs Requirements for establishing eligibility and methods of linking a drug with an illness have been presented in the preceding discussion. This algorithm should constitute of blueprint for solving many if not most of the ADR problems in this area of medical diagnostics.

However, in the hands-on practice of the assessment of ADR cases, there are at least four major difficulties that stand in the way of such high diagnostic expectations. These four obstacles include the following:

1. *Incomplete information:* Incomplete information is not unique to ADR evaluation but is common to all areas of medical practice. The lack of sufficiently detailed time-related data on drug administration and disease markers may make it impossible to render a reasoned judgment on many ADR cases, leaving them in their original and unsatisfactory anecdotal status. Denial to the evaluation of access to these required facts makes it impossible to make judgments on latent period and temporal eligibility; time flowcharts cannot be utilized in exclusion, dechallenge, and rechallenge techniques. The diagnostic database should also include information on any other drugs being administered or taken, concurrent comorbid states, and the existence of any preexisting occupational and environmental hazards.
2. *Polypharmacy:* In recent times, polypharmacy is the rule rather than the exception. Patients with complicated and prolonged illnesses may have 20–30 medications in their medical background. Cases of this sort may be of such complexity that even with ideally complete drug and disease marker information, diagnostic success may be elusive.
3. *Lack of objective means of linking the drug to the ADR:* Tests and procedures that specifically and causally connect a drug to an illness are lacking. Our high-tech laboratory instrumentation is capable of identifying and quantifying extremely low levels of drugs and chemicals, but this type of information falls short of establishing causation.
4. *The limited number of toxicologic responses in human disease:* There are a limited number of generic

morphological reaction patterns that diseases fit into (inflammatory, congenital, neoplastic, degenerative, infiltrative, vascular, and functional). In parallel, there are also a rather limited number of clinical symptoms and signs (pain, nausea, fever, lumps, etc.) that come to the attention of the practicing physician. There are a multitude of causes and a multitude of clinical conditions that funnel into these clinicopathological “final common paths.” The algorithm previously described is an attempt to move from the generic to the specific in analyzing ADR causation.

Of the previous four difficulties, only the first (incomplete information) is subject to at least some degree of improvement.

Degree of Certainty The third major task in analyzing and assessing ADRs is determining the degree of certainty one has as to the causal relationship between the drug and the clinicopathological findings. Interposed between the definitive causative and negative categories are three shades of certainty (probable, possible, and coincidental) that titrate between these two extremes. These degrees of certainty are defined as follows:

1. *Causative:* Cases in this class are those in which there is no doubt that a drug has caused the reaction. This category is essentially limited to drug overdose cases or those cases in which the causative agent can be objectively identified (asbestos bodies, granuloma-encapsulated silica, etc.). Parenthetically, the overdose cases with drug levels in lethal ranges should have important negative findings: no anatomical cause of death at autopsy.
2. *Probable:* This term is equivalent to the phrase “consistent with,” and cases in this category of certainty fall short of the “causative” designation because they lack an objective and quantitative laboratory finding that is the sine qua non of the causative category. Cases placed in this category have the following characteristics
 - a. The criteria of temporal eligibility and appropriateness of latent period have been met.
 - b. The clinicopathological features are consonant with previous experience and literature precedent for the drug in question.
 - c. Other causes (the basic disease, comorbid states, and other modalities of therapy) have been eliminated from consideration.
 - d. One or several means of linkage of the drug to the ADR have been utilized: exclusion, dechallenge, rechallenge, singularity of the drug, and pattern.

TABLE 30.29 Major Causes of Acute Functional Adverse Drug Reactions

Acute Adverse Drug Reaction	Example
Augmented (“supratherapeutic”) effect of interaction with the primary molecular target	Pronounced bradycardia with a β-blocker; pronounced hypotension with an angiotensin II receptor antagonist
Interaction with the primary molecular target present in nontarget tissues	Sedation caused by antihistamines
Interactions with secondary molecular targets	Interactions with the hERG cardiac channel leading to QT interval prolongation (e.g., some antipsychotics and antihistamines drugs)
Nonspecific effects	
Pharmacologically active metabolites	Inhibition of the hERG channel transcription by desmethylamiodarone, metabolite of amiodarone

Source: Adapted from Gad (2009).

3. *Possible*: Cases are put in this category when the relationship between the drug and the clinicopathological findings can be neither confirmed nor denied. There are three subdivisions in this category:
 - a. Cases with potential causes other than the drug in question. The clinicopathological picture could have been produced by the basic disease, a comorbid state, or some other modality of therapy.
 - b. Cases in which some of the criteria for eligibility and linkage have been met, but some have not because of lack of adequate information. Such a case could be put in this category temporarily while awaiting more information or placed here permanently if it were evident that further data would not be forthcoming.
 - c. Cases that have met all the criteria of eligibility and linkage but for which there is no known precedent literature. Such a case might be a new and emergent ADR. It could be placed in the “possible” group, awaiting the appearance of similar cases for cluster studies at a later time.
4. *Coincidental*: Cases in this category include those that were indeed exposed to the drug in question but in which assessment of the case clearly reveals only an anecdotal association.
5. *Negative*: This category applies to those cases in which the alleged drug was not or could not have been in the patient’s system at the time of the ADR. This circumstance could be related either to noncompliance, mislabeling of the drug, or historical misinformation.

Clinical trials are the final step in the drug development process and are the slowest to evolve and integrate new technology. The paradigms of plasma levels being directly relate to (and predictive of) efficacy and safety are only slowly being supplanted by understanding molecular and receptor occupancy-based correlations. Table 30.29 provides a classification of such relationships to AEs.

30.9 RECENT CHANGES IN SAFETY RELATED REQUIREMENTS FOR INITIAL CLINICAL REQUIREMENTS

FDA has been working external to their offices and without ready access to their electronic resources. In response, several additional requirements have been incorporated into first-in-human studies.

1. Separation of SAD and MAD studies.

As opposed to conducting a single study to evaluate single and then multiple dose phases under a single protocol, FDA at present frequently requires two separate studies. While patient exposures and actual procedures are not changed, to conduct these separately does prolong the time required to conduct phase I studies, and adds approximately 150k or more to cost.
2. Use of sentinel subjects for each cohort

For each cohort a single individual is dosed a day (or more) before the rest of the members of the cohort are dosed.
3. Equal numbers of males and females in each cohort

For each cohort, equal numbers of males and females are included.
4. Review of results by DSMB between each cohort.

As treatment of each cohort is completed, a data safety management board needs to review safety and PK data to verify safety before proceeding to the next cohort.

POSTMARKETING SAFETY EVALUATION: MONITORING, ASSESSING, AND REPORTING OF ADVERSE DRUG RESPONSES (ADRs)

Once a new drug is approved, it proceeds to market either with or without mandated postmarketing evaluation requirements. While this represents the end of a long road, it is also the start of yet another. While careful work during development (both in animals and humans) serves to provide the tools to greatly reduce the potential safety issues around a new drug, it cannot totally eliminate them. One needs only to look at Table 31.1 to appreciate the history of market withdrawals due to safety issues in the modern era (1961–2001) or turn to Table 31.2 to verify that the problem is still present in the first decade of the twenty-first century, though with lower incidence of individuals severely affected in each case. The exceptions are accelerated approvals for which a marketing approval NDA is granted with post approval study requirements. Now with Covid-19, EUA (Emergency Use Authorization) which due to critical public health needs a drug can be marketed and used for the length of the need. An EUA does not constitute a NDA which additional clinical trial data and other data are required to support filing and receiving an NDA (FDA 2014,2017).

Tracking and continuing to evaluate the safety of a therapeutic agent once it is on the market are a complex task, and now the field of the discipline (and regulations) called pharmacovigilance (PV). Philosophically, PV represents a special case of the general risk assessment model (the steps of which are summarized in Table 31.3). The World Health Organization (WHO) established the precursor for these efforts as the Programme for International Drug Monitoring in response to the thalidomide disaster detected in 1961.

More explicitly, PV (or postmarket clinical drug safety) is the discipline dedicated to the collection, detection, assessment, monitoring, and prevention of adverse effects with pharmaceutical products. The etymological roots for

the word “PV” are *pharmakon* (Greek for drug) and *vigilare* (Latin for to keep watch). As such, PV heavily focuses on adverse drug reactions (ADRs) which are defined as any response to a drug which is noxious and unintended, including lack of efficacy, which occurs at doses normally used for prophylaxis, diagnosis, or therapy of disease, or for the modification of physiological function. Medication errors such as overdose and misuse and abuse of a drug are also of interest because they may result in an ADR.

Information received from patients and healthcare providers, as well as other sources such as the medical literature, plays a critical role in providing the data necessary for PV to take place. In fact, in order to market or to test a pharmaceutical product in most countries, adverse event (AE) data received by the license holder (usually a pharmaceutical company) must be submitted to the local drug regulatory authority (FDA, 2005; Mann and Andrews, 2006; Strom et al., 2019).

For the WHO drug safety reporting system (now participated with by more than 134 countries), Figure 31.1 summarizes the growth in number of event reports through 2012. The minimum requirements that the WHO and partners agree should be present in any national PV:

1. A national PV center with designated staff (at least one fulltime), stable basic funding, clear mandates, well defined structures, and roles, and collaborating with the WHO Programme for International Drug Monitoring
2. The existence of a national spontaneous reporting system, with a national individual case safety report (ICSR) form, that is, an ADR reporting form
3. A national database or system for collating and managing ADR reports

TABLE 31.1 Therapeutic Products Withdrawn from the Marketplace Due to Safety Reasons in the United Kingdom and/or the United States 1961–2001

Drug (INN)	Trade Name	Therapeutic Class	Reason(s) for Withdrawal/ Suspension of Product License	Launch Date	Countries	License Suspension or Market Withdrawal	Years on Market
Acetylsalicylic acid (pediatric)	Aspirin	Analgesic	Reye's syndrome	1899	United Kingdom	1986	87
Alclofenac	Prinalgin	Nonsteroidal antiinflammatory drug (NSAID)	Skin and renal reactions Mutagenic metabolite	1972	United Kingdom	1979	8
Alfaxalone	Althesin	Anesthetic	Allergic-type reaction	1972	United Kingdom	1984	12
Aminoglutethimide	Elipten	Anticonvulsant	Endocrinological Reintroduced—Cushing's syndrome	1960 1978	United States United States	1966	6
Aminopyrine		Analgesic	Hematological	1900 1900	United States United Kingdom	1970 1975	70 75
Astemizole	Hismanal	Antihistamine	Drug–drug interaction	1988	United States	1999	11
Azaribine	Triazure	Antipsoriatic	Neuropsychiatric coagulation disorders	1975	United States	1976	1
Benoxaprofen	Opren	NSAID	Cholestatic jaundice Photosensitivity	1980 1982	United Kingdom United States	1982 1982	2 <1
Benziodarone	Amplivix	Uricosuric Coronary dilator	Hepatic	1962	United Kingdom	1964	2
Bithionol	Actamer	Anthelmintic	Dermatological	?	United States	1967	?
Bromfenac sodium	Duraet	NSAID	Liver damage	1996	United States	1998	3
Cerivastatin sodium	Baycol	Cholesterol lowerers	Muscle weakening	1999	United States	2001	2
Chlormadinone	Normenon	Hormone	Animal carcinogenicity	1965 1966	United States United Kingdom	1970 1970	5 4
Cisapride	Propulsid	Heartburn	Cardiovascular irregularities	1993	United States	2000	
Clioquinol	Enterovioform	Antidiarrheal	Neuropsychiatric	1930 1930	United Kingdom United States	1981 1973	51 43
Centoxin	HA-1A	Hu-anti-lipid A IgM monoclonal	Gram-negative septicemia	1990	United Kingdom	1992	2
Danthron	Dorbanex	Laxative	Animal carcinogenicity Reintroduced with restrictions	1959 1964	United States United Kingdom	1987 1987	28 23
Desensitizing vaccines	Various	Vaccine	Allergic-type reactions	?	United Kingdom	1989	
Diamthazole	Asterol	Antifungal	Neuropsychiatric	?	United States	1970	17
Dihydrostreptomycin		Antibiotic	Neuropsychiatric	?	United States	1970	?

TABLE 31.2 List of Drugs Withdrawn Since 1990

Year	Drug	Indication/Class	Causative Side Effect
1991	Enkaid (4 years on market)	Antiarrhythmic	Cardiovascular (sudden cardiac death)
1992	Temafloxacin	Antibiotic	Blood and kidney
1997	Fenfluramine/dexfenfluramine (combo used since 1984) (24 years on market)	Diet pill	Heart valve abnormalities
	Seldane (terfenadine)	Antihistamine	Ventricular arrhythmias
1998	Posicor (mibefradil) (1 year on market) (inhibited liver enzymes)	Ca ²⁺ channel blocker	Lethal drug interactions
	Duract (bronfemic sodium) (early approval warnings of ↑ liver enzymes)	Pain relief	Liver damage
1999	Trovan (use severely restricted)	Antibiotic	Liver/kidney damage
2000	Hismanal	Antihistamine	Drug–drug interactions
	Rotashield	Rotavirus vaccine	Bowel obstruction
	Rezulin (approved December 1996)	Type 2 diabetes	Liver damage
	Propulsid	Heartburn	Cardiovascular irregularities/death
	Lotronex ^a	Irritable bowel syndrome	Ischemic colitis/death
2001	Phenylpropanolamine (ppa)	Otc ingredient	Hemorrhagic stroke
	Baychlor (baycol)	Cholesterol reducing (statin)	Muscular weakness/death
	Alatrofloxacin	Antibiotic	Liver toxicity
2002, 2003	None	None	None
2004	Serzone	Antidepressant	Liver failure and injury
	Vioxx ^b	Arthritis (cox-2 inhibitor)	Heart attack/cardiovascular (thrombosis)
2005	Tysabri ^a	Ms (multiple sclerosis)	Pml (progressive multifocal leukoencephalopathy)
	Bextra	Arthritis (cox-2 inhibitor)	Cardiovascular safety, skin reaction (sometimes fatal)
2006	Dolophine (methadone hydrochloride)	Treatment of moderate to severe pain	Respiratory depression and cardiac arrhythmias
2007	Zelnorm	Constipation	Cardiovascular safety
	Permax	Parkinson’s disease	Heart valve damage
2008	Trasylol	Bleeding	Increased risk of death
	Acomplia	Weight loss	Severe depression/suicide
2009	Raptiva	Psoriasis	Pml
2010	Meridia	Weight loss	Cardiovascular safety
	Avandia	Diabetes	Cardiovascular safety
	Darvon and darvocet	Pain	Addiction, cardiovascular safety
	Mylotarg	Aml	Veno-occlusive disease, risk for death
2011	Vivaglobin	Primary immune deficiencies	Thrombolytic adverse extents (cv)

^aLimited return to market in 2003. The new labels will also include a detailed warning on the “well-described, serious, and potentially life-threatening GI bleeding,” as well as GI ulceration and perforation. These products should be used with “extreme caution” in patients with a prior history of ulcer disease or GI bleeding, the warnings section will state, and although the risk of these problems increases with duration of use, even short-term therapy is not without risk.

^bThe possibility of skin reactions is also part of the warnings section: “NSAIDs including [brand name] can cause serious skin adverse events including exfoliative dermatitis, Stevens–Johnson syndrome, and toxic epidermal necrolysis.” These reactions played a big part in the FDA’s decision to ask Pfizer to suspend Bextra—the product had “no added advantage” and a “special risk” of serious skin reactions, the agency said.

TABLE 31.3 A Special Case of the General Risk Assessment Model in a Regulated Environment

Identify potential hazards (signals)
Collect signal data (ADRs)
Classify/categorize/assess signals (assign causality)
Code and analyze signals (ADR reports)
Report population ADR data
Perform risk/benefit assessment and then risk management
A similar approach used for medical devices

4. A national ADR or PV advisory committee able to provide technical assistance on causality assessment, risk assessment, risk management, case investigation, and, where necessary, crisis management including crisis communication
5. A clear communication strategy for routine communication and crises communication

Manufacturers are legally required to collect, analyze, and report such data both nationally (by the Food and

CASE STUDY: THALIDOMIDE

Thalidomide, α -N-[phthalimido] glutarimide, was introduced into the market in 1957 by the Chemie Grünenthal Company in Germany. A derivative of glutamic acid, it exists in humans in two concurrent, interchangeable, and optical isomeric forms (enantiomers), *S*(-) and *R*(+). Despite research showing its safety, the drug caused horrific birth defects when taken by pregnant women after it was approved for market use. The detrimental effects of thalidomide led Congress to pass the Kefauver-Harris amendment to the FD&C Act in 1962 which required far greater PV. The amendment also required proof of safety before any clinical trials (the current IND process) can be initiated.

The nonclinical testing for thalidomide included overdose experiments in rodents, which produced neither death nor congenital defects in offspring. Marketing therefore asserted that thalidomide had no toxic effects in humans. They advertised it as a sedative, hypnotic, and antiemetic, with particular emphasis on the reduction of symptoms related to morning sickness. By 1961 thalidomide was marketed in 46 countries under a variety of names. The increase in distribution was followed by an increase in severe, and somewhat unique, deformities in newborn children, though the causal relationship was far from obvious.

In 1961 a German doctor, Widukind Lenz, cast suspicion on thalidomide as the cause of the deformities, which was quickly and independently confirmed that same year by an Australian doctor, William McBride. Withdrawal of the drug from the market began in the late 1961. This was the first instance of a drug confirmed to have teratogenic effects. Previously, researchers and scientists assumed that the placenta protected the fetus from this type of harm entirely. Unfortunately, the removal of the drug from the market was slow. Children were born with deformities due to its use even 2 years after the recall began. By current estimates, thalidomide caused over 10000 children to be born with birth defects.

The human fetus proved very vulnerable to the effects of thalidomide. Multiple studies indicate that exposure to a single 50 mg tablet raises the likelihood of teratogenic effects as high as 50%. There is, however, a limited time window in which thalidomide must be administered in order to cause teratogenic effects: between 20 and 36 days postfertilization or 34 and 50 days since the last menstrual period. Before this window, exposure to thalidomide generally causes miscarriage and afterwards causes no morphological effects. In contrast, rats (the original animal model tested) are relatively insensitive to the developmental effects of thalidomide. However, rabbits and especially macaques are sensitive models for these effects.

Morphological effects induced by fetal exposure to thalidomide include defects to the limbs, eyes, ears, internal organs, nerves, and CNS. Limb defects are the most common, occurring in over 90% of the cases. Effects are generally reductive in nature and symmetrical. Deformities ranged from absence of digits to complete absence of limbs (amelia). Phocomelia is the classic image of the thalidomide tragedy, a shortening of the long bones which can leave “flippers.” Ocular effects include cataracts, microphthalmos, anophthalmos, and colobomas. They usually occur in only one eye, though the other eye may be affected independently. Ocular effects generally occur simultaneously with aural effects and changes to facial musculature. Aural effects are generally symmetrical and include anotia and microtia. Internal organs which are affected include the heart, kidneys, genitals, and bowels. Many of the defects in internal organs do not develop until later in life, and therefore incidence is unknown as many patients die. CNS effects can include facial palsies, cranial nerve conduction problems, and later in life autism and epilepsy.

Drug Administration (FDA) in the United States and by equivalent organizations in other countries—but here the emphasis will be on the US situation) and internationally (by WHO). There are regulatory reporting systems (that is, where the reports go directly to government agencies) and organizational reporting systems (organized around method of distribution—such as hospital pharmacies (Hunziker et al., 1977; ASHP, 1995) or by product type, such as radiopharmaceuticals). Poison control centers also monitor ADR cases and rates (Chyka, 1999; Chyka and McEommon, 2000). The regulatory systems for such PV in the United States are MedWatch (for human drugs), vaccine adverse event reporting system (VAERS) (for human vac-

cines) (Niu et al., 1998, 1999; Varrinocchio, 1998), and the FDA-CVM system (for veterinary drugs) (Bukowski and Wartenberg, 1996; Keller et al., 1998). One key difference of the US systems from those in other countries is that they are (and remain) voluntary (largely a reflection of the primarily private—that is, not national government—healthcare system in the United States). The US regulatory requirement for PV was promulgated in March of 2005, *FDA Guidance for Industry: Good Pharmacovigilance Practices and Pharmacoepidemiologic Assessment* (part of PDUFA IIIa) (FDA, 2005), and then continued as new technologies are added to therapeutic medicines and new challenges (and surprises) arise:

FIGURE 31.1 Global drug safety reports.

- 1993: Tambocor (flecainide) as signal case for class IC antiarrhythmic drugs (~50 000 deaths due to cardiac arrest caused by hypokalemia and *torsades de pointes*) induced by these drugs
- Principal cause of International Conference on Harmonization (ICH) preclinical safety pharmacology testing requirements for drugs
 - Revealed cardiac arrhythmia suppression trial (CAST) (Moor, 1995)

There is no compulsion for physicians, hospitals, or individuals to report AEs to either the manufacturer or the government (though the marketing companies for a therapeutic are required to periodically summarize all reports of AEs that they know of on to the federal government). It is widely held that it is this voluntary (or “spontaneous”) aspect which limits the effectiveness of the US systems (Piazza-Hepp and Kennedy, 1995; Kennedy and Goldman, 1997; Goldman, 1998; Sharpe, 1998; White and Love, 1998; Brewer and Colditz, 1999). Studies have identified factors which influence (and limit) physician use of such systems (LaCalamita, 1995; Figueras et al., 1999), and newly marketed drugs are subject to a higher rate of underreporting of ADRs than are established drugs (Martin et al., 1998). It should be kept in mind that what we are considering here are adverse effects caused by the use of a drug as intended and not by a medication error. Medication errors are at least as serious a problem (and complex an issue) as ADRs (Antonow

et al., 2000) but are beyond the scope of this volume. Both companies and the regulatory agencies must collect reports of AEs, evaluate them, and then decide on a correct course of action (ranging from doing nothing through improving labeling then on to restricting access and/or requiring ongoing or increased medical surveillance of patients and then to withdrawing the drug from the market).

For while new medications can save or mostly improve lives, once on the market side effects—harmful ones—are virtually certain to occur and must be promptly recognized.

ICH has sought to harmonize global PV efforts by promulgating a series of guidances:

- ICH E1: *The Extent of Population Exposure to Assess Clinical Safety for Drugs Intended for Long-Term Treatment of Non-Life Threatening Conditions*
- ICH E2C (R1): *Clinical Safety Data Management: Periodic Safety Update for Marketed Drugs*
- ICH E2C (R2): *Period Benefit–Risk Evaluation Report*
- ICH E2D: *Post-Approval Safety Data Management: Definitions and Standards for Expedited Reporting*
- ICH E2E: *Pharmacovigilance Planning*
- ICH E2F: *Development Safety Update Report*

Actual regulatory authority comes with implementation by regional authorities:

- *European Union*: adopted by CHMP, December 1, 2004, issued as CPMP/ICH/571603

- *MHLW*: Adopted September 16, 2005, PFSB/ELD Notification No. 0916001 and PFSB/SD Notification No. 0916001
- *FDA*: Published in the Federal Register, April 1, 2005, Vol. 70, No. 62, p. 16827–16828

31.1 CAUSES OF SAFETY WITHDRAWALS

It would be comforting to be able to state that the causes of post-marketing withdrawals from drugs were substantially different from those of the failure of drugs in clinical trials. While the last few years (refer back to Table 31.2) are seemingly somewhat different from those in the past (carcinogenic is no longer necessarily a big, marketed drugs problem), the historic causes for the modern era (the last 40 years) are lead off by hepatic toxicity—also the primary cause for safety faced failure in early clinical trials (see Table 31.4).

While the proximal wake-up call was Tambocor in 1993, Fung et al. (2001) have done an extensive assembly and analysis of safety withdrawal data through 1999, and Ajayi et al. (2000) have also analyzed factors increasing likelihood of safety problems. Table 31.4 presents this author’s extension of their work through of the time of this writing (late in the third

TABLE 31.4 Characteristics of Drug Safety Withdrawals (1960–August 2001)

	Drugs	% of Total
A. Most common classes		
NSAIDs	16	13

Anesthetics	4	3
Antihistamines	4	3
Antibiotics	3	2
B. Most common causes of withdrawal		
Hepatic toxicity		26
Hematologic toxicity (bone marrow suppression)		10
Cardiovascular toxicity		6
Carcinogenicity		6
Renal toxicity		5
Drug interactions		4
Neurotoxicity		4
Behavioral effects		4
Abuse potential		4

quarter of 2001), which changes the results but a little. It should be noted that the rank order of these two lists is different than the rank orders based on the numbers of AEs (see Holland and DeGruz, 1997). AEs can have a wide range of causes which may not even be done to unanticipated effects of a drug but due to a medication error or something as mundane as the discrepancies between doses recommended in *The Physician’s Desk Reference* and those recommended or reported in the medical literature (Cohen, 2001).

In 2005, Schuster et al. published an analysis that shared that cardiovascular toxicity was accounting for 40% of current (2000–2005) safety withdrawals and hepatotoxicity for 27% (leaving all others to share 33% of the total) (Schuster et al., 2005). Failure to identify these largely predictable causes of failures in new therapeutic entities largely reflects both a continuing lack of recognition of the actual patient populations utilizing drugs with their existing pathophysiological characteristics (Table 31.5) and the limitations of the currently employed clinical trial scheme (Table 31.6). While such efforts as mandatory assessment of safety pharmacology features will serve to improve the situation, for the foreseeable future it remains vital to ensure that our PV systems identify problems as soon as possible.

31.2 REGULATORY REQUIREMENTS

A “case” is a basic unit of drug safety surveillance. It is used to assure, to the greatest extent possible, the safety of approved drug products that are still in use. The basic unit of all post-marketing safety submissions is the adverse drug experience “case,” which is an individual adverse drug experience.

FDA has explicit requirements for reporting of AE cases for drugs. A post-marketing adverse drug experience source

TABLE 31.5 Factors That Increase Patient Risk for Adverse Drug Interactions

Factor	Group/Disorder
Age	Neonates, elderly
Gender	Women
Genetic phenotype	Slow metabolizers
Chronic disease	Moderate/severe renal or hepatic impairment, CHF, cirrhosis
Acute illness	Pneumonia, influenza
Metabolic disturbances	Hypothyroidism, hypoxia
Multiple drug use	Elderly, HIV patients
Multiple prescribing physicians	Elderly
Use of drugs with a low therapeutic index	
Use of drugs that are enzyme inhibitors or inducers	

TABLE 31.6 Limitations of the FDA’s Current Clinical Trials

1. Too few	Prior to approval, most drugs are administered to 2000–3000 patients. (To obtain an 80% probability of detecting an adverse drug event that occurs in one out of every 10000 recipients, 16000 patients must receive the drug)
2. Too simple	Premarketing trials often exclude patients with complicated medical histories or medication regimens. It is easier to demonstrate efficacy without including these complex patients
3. Too median	Most premarketing trials exclude patient populations such as pediatric, geriatric, and lactating and pregnant patients
4. Too narrow	Premarketing trials are generally intended to investigate a drug for a single indication. After release to the market, the drug may be used to treat other conditions in different populations with varying medical histories
5. Too brief	Adverse drug events that occur only with chronic use will not be detected in the relatively short clinical trial

Source: Data from Rogers (1987, pp. 915–920).

can be categorized into the several sample categories: clinical trial, nonclinical trial/regulatory authority, nonclinical trial/literature, and nonclinical trial/all other. This chapter only deals with spontaneous experiences—nonclinical trial adverse drug experiences reported to the industry any time after a marketed drug product achieves marketing approval from FDA (Adams et al., 1997).

When one looks at a typical case folder, he or she notices that certain types of information are on the folder:

- The outside of a folder is identified by a (alpha) numeric code.
- There is an “initial” report.
- There is either at least one letter requesting additional information regarding the initial report or documentation reflecting the failed attempts to obtain additional information.
- There is at least one “follow-up” report.
- The spontaneous report event is categorized as serious or nonserious, expected or unexpected.
- The source is either literature, regulatory authority, or spontaneous.
- There is at least one MedWatch form or Council for International Organization of Medical Sciences (CIOMS) I form for each report.

Everything in a given case folder is present because of an FDA regulation requirement or a related company-written standard operating procedure.

TABLE 31.7 How a Spontaneous Drug Case is First Submitted to the Food and Drug Administration

Case Source/Case Type	Report Submitted
Foreign literature/not both serious and unexpected	Not 15 days, not periodic
Foreign literature/serious and unexpected	15 days
US consumer/not both serious and unexpected	Periodic
US consumer/serious, unexpected	15 days
Foreign consumer/not both serious and unexpected	Not 15 days, not periodic
Foreign consumer/serious, unexpected	15 days
FDA, initial/serious and unexpected	15 days
FDA, initial/serious and unexpected	Periodic, not 15 days
International regulatory authority/serious and unexpected	15 days
International regulatory authority/not serious and unexpected	Not 15 days, not periodic

The number on the outside of the case is required to be numeric or alphanumeric as opposed to the name of the patient. Patient names are not permitted to be publicly disclosed in the context of a MedWatch report per 21 CFR 21.63(f). The initial report is the first reported information received by the company about an individuals’ adverse drug experience. There must be a “prompt” attempt to obtain follow-up information about each initial report. The attempt(s) are made per company’s written procedures. If the written safety procedures are not followed, the safety reports are not appropriately submitted, or the safety records are not appropriately kept, the FDA has the authority under section 80 of Part 315 to withdraw the market NDA. The follow-up report is the format for submitting additional information about an experience. Each case regards only one individual unless the experience is both temporally and clinically unrelated to a second event experienced by the same person taking the same drug product.

Table 31.7 summarizes FDA reporting requirements of spontaneous reports in terms of how the case event is first submitted to the agency. The definitions of serious, unexpected, etc., are in 21 CFR 314.80(a) (CFR, 1994; FDA, 2005).

31.2.1 The 15-Day Report Versus the US Periodic Report

Post-marketing adverse drug experiences are reported to a drug company by the public via regulatory authorities, literature, attorneys, consumers, and health professionals. Sometimes a company receives a report of an adverse experience someone had after taking its drug product not from the public but from FDA because instead of submitting the report to the company, the report was submitted directly to FDA. When FDA sends the applicant an initial MedWatch

report, the information does not have to be resubmitted to FDA in an initial 15-day report if the information is serious and unexpected. This is because FDA already has knowledge of the report. However, MedWatch and its information are incorporated into the next periodic report of the product. Follow-up to such an FDA MedWatch, obtained from a non-FDA source, would be submitted as a follow-up, expedited 15-day report (and should reference the source of the initial report). When FDA sends the applicant an initial MedWatch that is not both serious and unexpected, the applicant incorporates the information into the next periodic report, under the normal procedure for submitting follow-up information.

If an initial 15-day report was submitted, and the first follow-up information reflects that the event is no longer classified as a 15-day report (never was serious and unexpected), the first follow-up report describes the change in the report classification but is a (first) follow-up 15-day report. Subsequent additional information is not submitted in the form of a 15-day report.

A periodic report contains certain information, such as the event terms submitted during the period, the dates that events of the period were submitted, an event term count by body system, and labeling changes made due to the period's adverse experiences. In addition to (and prior to) being incorporated into a periodic report, 15-day reports are submitted within 15 calendar days of the date the applicant received the data. All 15-day reports contain serious, unexpected events. Non-15-day reports are submitted periodically in FDA periodic reports.

If on a given day a serious, unexpected domestic report is received, it is submitted first on an FDA Form 3500A, within 15 calendar days of receipt, via the 15-day report and subsequently is incorporated (not in the form of an FDA Form 3500A) into a periodic report. If a report is received, that is, domestic but not both serious and unexpected, it is not submitted in a 15-day report but rather in the US periodic report. A US periodic report is submitted quarterly for the first 3 years after the date the product was approved by the FDA for marketing (21 CFR 314.80). However, the March 2001 FDA guidance allows an applicant to request a 21 CFR 314.90 waiver of the US periodic report reporting period and base the report not on the date of FDA marketing approval but instead on the international birthdate (the first date the product was approved in the international community). The request for such a waiver should be submitted to the Director, Office of Post-marketing Drug Risk Assessment, CDER, FDA, 5600 Fishers Lane, HFD-400, Rockville, MD 20857. The request should include the product's name, the date of FDA marketing approval, and the product's approved application number. In addition, an applicant may request a 21 CFR 314.90 waiver of the 21 CFR 314.80©(2)(ii) format of the periodic report submitted. If the waiver is granted, the ICH E2C Periodic Safety Update Report format may be used provided that the content of the Section 80 ©(2)(ii) information that is not in the body of the ICH E2C periodic report is found in appendices, that is, certain reports

from consumers that are not in the body of the ICH E2C periodic report submission. 21 CFR 314.90 states that, among other things, the applicant may request FDA to waive any of the post-marketing requirements under 21 CFR 314.80.

ICH E2C and the FDA March 2001 draft guidance *Post-marketing Safety Reporting for Human Drug and Biological Products Including Vaccines* are available online, when searching browse for "case" requirements are accessible in 21 CFR 314.80.

The major change over the past few years has been a significant attempt to harmonize regulations under the aegis of the ICH, and this is covered in some depth later. The latest response to the ICH in its three participating regions (Europe, the United States, and Japan) is also described together with an update on the current UK regulations. The ICH potentially offers real advantages to the pharmaceutical industry, but the process takes time, and countries have adopted and implemented the guidance in slightly different ways and at different times. National regulations and guidelines are therefore bound to change in the near future as each country embraces the ICH.

The ICH of Technical Requirements for Registration of Pharmaceuticals for Human Use has brought together as equal partners the regulatory authorities of Europe, Japan, and the United States and experts from the pharmaceutical industry in these regions to discuss scientific and technical aspects of product registration. The WHO, European Free Trade Area (EFTA), and Canada are observers, and the International Federation of Pharmaceutical Manufacturers Association (IFPMA) ensures contact with the research-based industry outside the ICH regions.

The aim of the ICH is to achieve greater harmonization in the interpretation and application of technical guidelines and requirements for product registration and reduce or eliminate duplicate testing. This should result in better use of resources and eliminate unnecessary delay in the global development and availability of new medicines while maintaining safety guards on quality, safety, and efficacy.

There are four broad topic areas within the ICH:

- S—Safety (animal toxicology and pharmacology)
- Q—Quality (pharmaceutical and analytical)
- E—Efficacy (clinical)
- M—Multidisciplinary topics

Timely, complete reporting of ADRs and medical device problems is essential to an effective national system of post-marketing surveillance (PMS). Pharmaceutical manufacturers are required by federal regulations to report all ADRs of which they are aware to the FDA. However, many healthcare professionals do not think to report AEs either to the manufacturers or to FDA. To encourage and facilitate the reporting of serious AEs, FDA launched the MedWatch reporting program in June 1993. The MedWatch reporting form is used by healthcare

professionals to voluntarily report ADRs and other problems with all FDA-regulated products used in medical therapy (drugs, biologics, medical devices, and special nutritional agents). The reporting of ADRs associated with vaccine products is the only exception, since reporting of those ADRs is mandatory. The form used for vaccines is the joint FDA/Centers for Disease Control and Prevention (CDC) VAERS form. For drugs and therapeutic biologics, the MedWatch (3500A) form replaces the 1639 reporting form.

FDA does not want reports on every AE observed; that would not be practical for reporters or FDA because of the sheer volume of AE reports already being sent to the agency each year (about 130 000 in 1994). While 80–85% of these reports are submitted by the manufacturer, 10–15% are received by MedWatch directly from physicians, pharmacists, other healthcare professionals, and consumers. MedWatch encourages reporters to be selective by limiting their reports to events for which the outcome was serious. This enables FDA to focus on those events with potentially the largest public health impact. Reporters are encouraged to fill out the reporting form as completely and accurately as possible.

From 1978 through 1990, the CDC and the FDA divided the responsibility for PMS of vaccines in the United States. The FDA received reports of AEs after vaccines were administered in the private sector; events occurring after the administration of vaccines purchased with public funds were reported to the monitoring system for AEs following immunization.

The monitoring system was a stimulated passive surveillance system. In other words, when vaccines purchased with federal funds were administered in the public sector, “important information” forms were given to recipients or their parents or guardians instructing them to report any illnesses requiring medical attention that occurred within four weeks of vaccination. System coordinators at each immunization project/grantee site and the state health department completed standardized forms that were reviewed for consistency and completeness and then forwarded to the CDC for data entry and analysis.

In response to the National Childhood Vaccine Injury Act of 1988, which required health workers to report vaccine AEs, the CDC and the FDA collaborated in 1990 to implement the VAERS to monitor the safety of vaccines in both sectors. Healthcare professionals and parents/caretakers are *encouraged* to report all clinically significant vaccine AEs. Narrative diagnostic reports are reviewed and assigned standard codes using Coding Symbols for a Thesaurus of Adverse Reaction Terms. The source of the vaccines (public vs. private provider) is recorded on the form.

The WHO system, created in response to the thalidomide disaster, seeks to capture adverse worldwide AEs and identifies problems (WHO, 1975, 2010; Olsson, 1998). It is proposed that all such gathered reports should first be analyzed

for mortality effects and trends (Rose and Elnis, 2000) as such would identify the most critical trends and be easiest to evaluate.

31.3 MANAGEMENT OF ADR AND ADE DATA

In monitoring the safety of products, pharmaceutical companies need to comply with worldwide regulations as well as the primary requirement of helping doctors to prescribe safely. It is not intended to provide a comprehensive review in this chapter but to provide an insight into the methods of managing ADR data.

31.3.1 Sources of Data

There can be an enormous variation in the nature and quality of data depending upon the source, and this must be considered when the data is processed, computerized, and analyzed. Safety data may come from any of the sources described later.

31.3.2 Clinical Trials

In Phase I studies, good documentation and additional investigations should be a standard practice. Serious reactions are pretty unusual in these studies, which will detect only very common ADRs, in particular those that are pharmacologically mediated (e.g., bradycardia with beta-adrenergic receptor antagonists).

Good documentation and follow-up should be possible in Phase II studies, but rare reactions will not be identified due to the small numbers of patients involved. The larger numbers in Phase III trials can pose problems, but these can be minimized by careful choice of investigators, good case report form design, and procedures for follow-up. Phase IV studies are designed to test the efficacy and safety of the drug in clinical practice and often share the same constraints in patient numbers as premarketing trials.

31.3.3 Post-marketing Surveillance Studies

Any surveillance of safety of a drug after marketing is PMS (now often referred to as a post-authorization safety study). In practice the distinction between Phase IV studies and PMS is blurred (e.g., German drug experience studies).

31.3.4 Spontaneous Reports

Spontaneous reports are the most effective means of identifying rare, serious adverse reactions (usually idiosyncratic or Type B) after marketing despite the underreporting that exists. Spontaneous reports are an unsolicited communication

to a company, regulatory authority, or other organization that describes an AE in a patient given one or more medical products. These reports do not originate from a study or from any organized data collection scheme. Unless indicated otherwise by the reporter, all spontaneous AEs are assumed to be possible ADRs. The quality and completeness of spontaneous reports are often inadequate. Pharmaceutical companies or regulatory authorities can only achieve good case documentation through effective data collection, detailed follow-up, and use of field workers for complex cases. The quality of spontaneous reports also varies from country to country. Some countries do not have a regulatory reporting form for ADRs. There are differences among countries in publicity of drug safety issues, and drug regulations differ regarding the format, content, and submission time frames for ADR reporting.

Reports received by companies via regulatory authorities are often edited and poorly documented, but they cannot be ignored and should be handled alongside reports received directly. The FDA implemented the Medical Products Reporting Program (MedWatch) in 1993, which encourages healthcare providers to regard reporting as a fundamental professional and public health responsibility and submit serious AE reports directly to the FDA on the FDA 3500A form. The FDA forwards these reports to the manufacturer, who is obliged to follow up with those reporting such events and submit any relevant information obtained to the FDA and other regulatory agencies worldwide as required. It is currently proposed that regulatory agencies (FDA) should take a more direct hand in these activities (Snidermann, 2000).

31.3.5 Literature

The publication of case reports in medical and scientific journals is an important primary source of information on ADRs. Many ADRs are noted in medical and scientific journals before they become well known. For example, the association of thalidomide with birth defects was first noted in a letter to the *Lancet* in 1961. The quality of ADR reports in the published literature can be variable and has been the subject of much criticism and correspondence, though guidelines have been promulgated for these (Jones, 1982).

Despite the anecdotal nature and sometimes poor documentation, publication of case reports in journals remains one of the most useful primary sources of information on ADRs. ADR reports in the literature can be identified in several different ways. Prepublication manuscripts describing a spontaneous case report or an event from a clinical trial are sometimes provided by authors to the manufacturer of the drug and the regulatory authority in that country. Pharmaceutical companies are required to be aware of the literature as to the safety of their approved therapeutic products and are assumed (by law) to be cognizant of such.

31.3.6 Searching for ADRs in the Literature

With the increasing number of scientific and biomedical journals, there are more sources of ADR data on many drugs. Conversely, for some drugs, particularly those recently marketed, there is a scarcity of clinical publications, and frequently there is an inadequate account of the adverse reaction profile. Searching for ADRs in the literature may be assisted by online databases such as MEDLINE (Index Medicus), EMBASE (Excerpta Medica), and secondary sources such as SEDBASE (Meyler's side effects of drugs) and ADIS online services such as REACTIONS. Many journals contain relevant information, but some specific ADR-related journals may assist in the search for information. Increasingly, the use of high-capacity storage systems such as compact disks (CD-ROM) has led to stand-alone systems for storage and search of the literature other than online systems. Integrated dictionaries have allowed the development of user-friendly information; however, due to the anecdotal nature of these reports, pharmaceutical companies should have a clear policy on how to handle them.

31.3.7 Information Required for Reports

In order to draw a conclusion about the possible relationship between a drug and an AE, certain minimal information elements are required. Points considered essential for literature reports have been proposed (Jones, 1982), and some journals issue guidelines or checklists for potential authors. These can be adapted as a potential checklist for information that should be included in any ADR report as follows:

- Patient demography—age, sex, body weight, height, race, and pregnancy.
- Medical history—previous medical history and concurrent conditions, known allergies (including ADRs with similar drugs), and previous experience with drug.
- Timing—duration of treatment with the suspect drug before AE.
- Concurrent medications—details of other drugs including formulation, dose, and duration.
- Dechallenge—action taken with the suspect drug (stopped, continued, and dose reduction).
- Outcome—outcomes of the AEs.
- Alternative causes—what other factors could have accounted for the AE (diet, occupations exposure) and which were excluded?
- Rechallenge—was the patient rechallenged, and, if so, what was the result?
- Relevant additional data—blood levels, laboratory data, biopsy data, and, where relevant, postmortem findings.

31.3.8 Adverse Drug Reaction Forms and Form Design

Many forms are used by different organizations to collect ADR information. Most regulatory authorities have their own form (see Figure 31.2—the FDA 3500A). Although the content of these forms is similar, little attempt has been made to standardize the design other than by CIOMS.

In order to design the best form for their needs, users must first define what data they wish to collect and which factors are of the greatest importance. In addition, all the usual factors in form design need to be considered (e.g., size, layout, color, print type, spacing, flow of questions, boxes, language, and instructions). A pilot to test the form should be carried out before formal introduction and use.

Consideration should be given to what happens to the form once it is returned. Form design will be affected depending upon whether it is intended to serve as a direct entry document (i.e., the data elements closely match the data entry screens) or whether a transcription document will be used.

The key factor in ADR form design is the compatibility with other forms required for output, most importantly regulatory authority forms. The FDA, for example, required ADR reports to be submitted on an FDA3500A (Figure 31.2). If the pharmaceutical company does not wish to collect data on an FDA3500A but must submit reports to the FDA, it will need to design a form that collects the same information. AE report forms generally collect the basic data elements outlined in the following text:

- Patient demography
- Relevant medical history and allergies
- Suspect and concurrent drugs, route, and indication
- AE(s)
- Treatment and management of AE
- Dechallenge, rechallenge, and outcome
- Relevant laboratory data
- Reporter's opinion of causality
- Report's source of information

The form can be printed as a folding postage prepaid envelope for domestic use to encourage a reply. The pharmaceutical company must be able to demonstrate due diligence in seeking relevant follow-up information on each AE report.

Within the next 2 years, several key regulatory authorities including the MCA and FDA will require electronic data submission by companies for both expedited and nonexpedited case reports. The compatibility between the company and the regulatory authority's databases with regard to content and format of the key data elements for transmission is a critical factor to success of these initiatives. The adoption of internationally sanctioned standards such as a dictionary of medical terms, various code lists (e.g., countries,

routes, and units), file formats, and periodic safety update reports is essential to enable efficient and accurate transmission. The ICH guideline (ICH E2B) defines data elements for transmission of ICSRs. The guidelines aim to standardize the data elements for all ICSRs regardless of source and destination and cover reports for both preapproval and post-approval periods. It also defines the minimum information for a report and the requirements for proper processing of the report. The medium for electronic submissions will be electronic data interchange (EDI)-encrypted transmissions over the internet.

31.3.9 Computerization of Drug Safety Data: Data Collection and Input

“Rubbish in, rubbish out” applies to safety data as to any other computerized data. The enforced control of terms at entry can be linked to checking of data, which should form part of the quality control procedures. Such controls should be driven by the business so that clinical trial data, free from all errors and needed for statistical analysis, will probably involve double data entry, whereas single data entry is generally considered adequate for AE databases used for signal generation and regulatory reporting.

Data are still generally typed into a database rather than electronically loaded from other systems. The first step of any data entry process should involve a check for duplicate cases. The need for decision making at the data entry stage will depend upon the type of database design. In all cases, there should be clear rules on how data should be entered into each field to ensure consistency and aid subsequent searching and outputting. This is particularly important when there are multiple users distributed over a number of international sites. Use of electronically available field specific lists of value and well-defined coding conventions will help with this.

In the future, data will increasingly be captured electronically. Image processing and developments in optical character recognition are already proving useful. Electronic data capture (using fax- or pen-based methods) is used to collect data in some clinical trial.

With the increase in licensing agreements between pharmaceutical companies, safety data frequently needs to be exchanged between one or more parties. If the case volume is sufficient, it is worth considering electronic data exchange between the databases involved. In addition to preventing rekeying of data, this minimizes discrepancies between the data sets. With the adoption of proposed ICH standards in the future, this will become a much simpler process.

31.3.10 Medical and Drug Terminology

Medical and drug terminology is at the heart of the ADR systems. Accurate and consistent input of terms is critical for

Domain Facsimile of FDA Form 3500A

Submission of a report does not constitute an admission that medical personnel, user facility, distributor, manufacturer or product caused or contributed to the event

FIGURE 31.2 FDA form 3500A. Source: FDA 3500 A / U.S. Department of Health and Human Services.

retrieval and analysis of ADR information. An integrated dictionary allows the capture of original text, which is automatically encoded against the dictionary to retrieve the correct code for that piece of text. Coded information allows

easy retrieval and analysis. The dictionary structure should allow different ways of grouping and analyzing data encompassing body systems at the highest level to specific reporter's wording that should meet the following needs:

- Acceptable to all users of the system.
- New terms can be easily added.
- Specificity of the reported term preserved.
- Hierarchical structure to group terms at various levels of specificity.
- Logical groupings so similar terms are not scattered.
- A default grouping for each term.
- Unambiguous to enable autoencoding on input.

31.3.11 Dictionaries

This section compares commonly used dictionaries in monitoring drug safety. As electronic exchange of ADR data between industry and regulatory authorities in different countries increases, so does the need for standardization of terminology (Benichou et al., 1991). Medical Dictionary for Regulatory Activities (MedDRA) has completed development with version 4.0 just being available and is discussed later in this chapter. Table 31.5 presents a summary of its structure. (Gruchalla, 1995; Brown et al., 1999).

31.3.12 Medical Term Coding Dictionaries

It is logical to deal with AEs, indications, diseases, surgeries, and procedures using one system for the following reasons:

- ADRs frequently mimic spontaneously occurring diseases; hence, the same diagnosis or symptom could appear as an AE or disease.
- In the identification of new ADRs, it is important not to separate a possible side effect from a disease.
- Separate classifications can lead to confusion and add a layer of complexity when developing ADR systems.

Meaningful codes may or may not be needed for modern dictionaries. For example, the new Adverse Drug Reactions Online Information Tracking (ADROIT) dictionaries do not use meaningful codes but rely on linkage of related terms and effective text processing. Where codes are considered necessary, they should be as short as possible (Westland, 1991). Whenever a system is used for AEs from the literature, spontaneous reports, clinical trials, or a combination of these, the needs of the users of the system will influence the selection of the dictionary.

31.3.13 Medical Dictionary for Regulatory Activities

MedDRA is a medical dictionary encompassing terms relevant to pre- and post-marketing phases of the regulatory process. It was developed by the MCA to support its information systems and has subsequently been further developed by the MCA to support its information systems and medical termi-

nology working group. The objective is to harmonize on standards for electronic submissions among regulatory authorities, between authorities, and industry within and across regions. The aims of the dictionary are:

- To address pre- and post-marketing AE reporting
- To cover multiple medical product areas
- To be available in multiple languages
- To be available in multiple formats and platforms
- To be well maintained

The guiding principles are:

- To build from existing terminologies to maximize compatibility
- To focus on the international community need rather than optimizing on individual countries
- To ensure worldwide use through collaboration and participation in development
- To ensure mechanisms and structures are in place for translation into many languages
- To ensure long-term maintenance

The scope of MedDRA is as follows:

- Disease
- Diagnoses

There is a dual classification for some terms (e.g., 573.1 “Hepatitis in viral diseases classified elsewhere”), but this is not extensive. The dictionaries are very comprehensive with the exception of symptoms, which tend to be scattered. They have been widely used in coding patient histories and hospital charts.

ICD-9 CM is a clinical modification of ICD-9 and offers some advantages, particularly the inclusion of synonyms, but is constrained by systems that have used the older versions of ICD-9. ICD-10 is more comprehensive than any ICD revision to date (see websites). It extends well beyond the traditional causes of death and causes of hospitalization. The content has been expanded to include symptoms, signs, abnormal findings, factors related to lifestyle, and other factors causing contact with health services:

- Signs and symptoms
- Therapeutic indications
- Investigation names and qualitative results
- Medical and surgical procedures
- Medical, social, and family history
- Terms from COSTART, WHO-ART, ICD-9, HARTS, and J-ART

The current structure of MedDRA is defined in Table 31.8. There will be a central maintenance organization responsible for development, user support, implementation, and communication as well as an international user group. A management board will oversee the activities of the central maintenance organization with direction provided by the ICH steering committee. A standard medical dictionary will facilitate electronic data exchange between industry and regulatory authorities worldwide, as recommended by the ICH.

31.3.13.1 FDA Under the March 2001 draft guidance *Post-marketing Safety Reporting for Human Drug and Biological Products including Vaccines* (FDA, 2001), FDA will accept SAEs coded with either MedDRA, COSTART, or WHO-ART. MedDRA has been implemented for SAE coding in FDA’s Adverse Event Reporting System (AERS) program. While FDA encourages companies to use MedDRA, the deadline for full MedDRA implementation is still pending.

31.3.13.2 European Union The European Agency for the Evaluation of Medical Products (EMA) established January 2002 as the deadline for all electronically filed single case reports to be coded in MedDRA. All ADR drug reporting must be coded in MedDRA by January 2003.

31.3.13.3 Japan MedDRA/J, the Japanese version of MedDRA, officially was issued on December 28, 1999 and the Ministry of Health highly recommended its use for ADR reporting beginning at the end of March 2000. However, J-ART terms are still applicable and upon submission to the ministry are being converted to MedDRA/J terms. No firm deadline for full implementation has been issued.

MedDRA is available in English and Japanese only. The Maintenance and Support Services Organization (MSSO) is working on translations in French, Portuguese, German, Greek, and Spanish. With their annual dues, subscribers can get

MedDRA in English and one other European language (when available). Japanese or additional European languages will need to be purchased separately. The German and Portuguese translations were recently submitted to MSSO for review.

The most current version of MedDRA, 11.0, was released in March 2008. The cost of the dictionary depends on the type of organization and annual revenue. An annual subscription provides a company with all versions of MedDRA released during the year. All regulators are provided MedDRA free of charge. Otherwise, costs are as follows.

31.3.14 Periodic Reports

Many regulatory authorities require detailed summary reports on groups of cases on a regular basis. The FDA requires annual progress reports for investigational compounds and periodic reports for marketed drugs either quarterly or annually depending upon the length of time the product has been on the US market. CIOMS II guidelines recommend submission of line listings of serious, unlabeled spontaneous cases in conjunction with a summary of the drug safety profile on a 6-monthly basis. These reports are well defined in format, content, and submission time frame. Most major pharmaceutical companies produce them electronically.

The regulatory requirements, particularly regarding frequency of submission and content, differ in the three regions (Europe, Japan, and the United States). In order to avoid duplication of effort and to ensure that important data are submitted with consistency to regulatory authorities worldwide, the ICH3 Topic E2C Guideline on the format and content for comprehensive periodic safety update reports (PSURs) (1996) of marketed medicine products has been developed. The general principles of this guideline include:

- One report is submitted for one active substance. All dosage forms as well as indications for a given active substance should be covered in one PSUR.

TABLE 31.8 MedDRA Structure

Level of Hierarchy	Approximate Number of Terms	Definition	Example
System organ class	26	Broadest collection of concepts for retrieval; grouped by anatomy or physiology	Cardiac disorders
High-level group term	333	Broad concepts for linking clinically related terms; can be linked to one or more SOCs	Cardiac rhythm disorders
High-level term	1685	Groups of preferred terms related by anatomy, pathology, physiology, etiology, or function; can be linked to one or more high-level groups terms or SOCs	Tachyarrhythmia
Preferred term	14,287	International level of information exchange; single, unambiguous clinical concept	Ventricular tachycardia
Lowest-level term	51,083	Synonyms and quasisynonyms; help define scope of preferred terms	Praxysmal ventricular tachycardia

- The focus is on ADRs, which include all spontaneous reports and all drug-related clinical trial and literature reports.
- An international birthdate and frequency of review and reporting are defined. The international birthdate is the date of the first marketing authorization for the product granted to any company in any country in the world. Preparation of PSURs should be based on data sets of 6 months or multiples thereof. The PSUR should be submitted within 60 days of the data lock point.
- The reference safety information is the company core data sheet to determine whether an ADR is listed or unlisted.
- ADR data are presented in line listings and/or summary tabulations.

31.4 CAUSALITY ASSESSMENT

Decisions have to be made by pharmaceutical companies and regulatory authorities about whether a drug can cause a particular AE so that an appropriate action can be taken. What does “can cause” mean? Does it imply certainty? In many cases to wait for “certainty” before taking action would entail many patients suffering unnecessarily. The degree of certainty or “probability” required will vary according to the situation.

There are, nearly always, many factors other than the administration of a drug that can cause an AE and will determine whether the AE will occur in a particular patient. The drug may be “the last straw that broke the camel’s back.” If an AE would not have occurred as and when it did but for the drug, then the drug “caused” the AE (Hutchinson, 1992). So with an adverse drug interaction, both drugs “caused” the AE. Using this definition the drug may only be a minor factor.

Certainty is rarely obtainable; perhaps an AE with a positive rechallenge where there is objective evidence and an absence of confounders in an individual case would be considered as certainty due to the drug. In the majority of cases, action is needed before there is absolute certainty that a drug can cause an AE. This lack of certainty in individual cases has been described using rather vague terms such as “almost certain,” “probably,” “possible,” “unlikely,” etc. These terms have also been defined, but each author has a slightly different definition (Venulet et al., 1982; Stephens et al., 2011).

Again, in epidemiological studies or clinical trials, there is nearly always a degree of uncertainty due to bias, chance, and confounders. In these studies uncertainty is measured in terms of *p* values, odd ratios, relative risks, etc.

The differential diagnosis of AEs associated with a drug or drug(s) is an everyday part of a practicing clinician’s life (Rogers, 1987). However, the term “causality assessment” is reserved for a similar process performed at one or more stages

removed from the patient and with some important differences. Clinicians do not necessarily need to find out whether a drug caused an AE in order to satisfy themselves and their patients. They will be more interested in resolving the event as quickly as possible. If there is a possibility that the event might be an ADR, it may be resolved by either reducing the dose or stopping the drug or by treating the ADR while waiting for tolerance to develop, or it may resolve if any of the underlying factors are altered. The resolution of the AE might be because the event has been caused by the drug or it may have been a transient natural occurrence; either way the patient and doctor will welcome its disappearance. If, however, the doctor is interested in knowing whether it was an ADR, further investigations can be undertaken, as long as the patient is willing, until it is established or refuted.

When causality assessment is undertaken by a regulatory authority or a scientist/physician in industry, it is unlikely that the full details known to the clinical treating the patient will be reported, even after further inquiry is made. The only way to obtain all available data is usually by visiting the physician and, with permission, reading the notes and discussing the case with him or her.

31.4.1 Aims of Causality Assessment

Of the many similar events on an AE database, only a few have sufficient and relevant data to enable the assessor to decide that the AE was more likely caused by the drug than by any other cause or vice versa. A preliminary assessment (sometimes referred to as a “triage”) can be made by placing the event into a category (e.g., probably, possible or unlikely, or using the EEC classification of A, B, or O) (Meyboom and Royer, 1992). This will enable the company to extract the probable cases at regular intervals in order to consider whether there is a “signal.” The possible and unlikely cases will probably not contribute much to this signal.

This preliminary assessment will need to be updated as and when further information becomes available. It should favor sensitivity over specificity so that a borderline possible/probable case is classified as probable rather than possible to make certain that the case is not lost when at a later stage the probable cases are picked out as a signal. A full assessment when all the information is available can then rectify any misclassifications.

31.5 COURSES OF CORRECTIVE ACTION

Identification of a safety issue with a marketed drug does not necessarily (or even usually) lead to the withdrawal of that therapeutic agent from the market. As noted at the beginning of this chapter, there is a range of possible actions. These include:

- Change in dosage or dose form (reformation)
- Change in labeling (warnings)
- Restriction of situation of use (from open prescription to either clinician administration or hospital use only)
- Monitoring of patients during use
- Restriction on use (that is, of patients allowed to use)
- Withdrawal from the market (usually a permanent step but not always)

Which action(s) are taken depends on severity and incidence rates of the adverse response, technical details, the existence of alternative therapies, and the benefit of the use of the drug.

31.6 LEGAL CONSEQUENCES OF SAFETY WITHDRAWAL

Although in the context of personal injury claims an HMO and other parties (e.g., doctors, hospital) may all be the target of proceedings, it is usually the pharmaceutical company, perceived as having “deep pockets,” that is the prime target for claimants. Claims for negligence based upon a failure to act with reasonable care (e.g., to obtain or act upon PV data) and/or the supply of a product that is “defective” in legal terms (e.g., because its labeling was not amended, pursuant to the receipt and review of PV data so as to give adequate warnings and precautions) are always possible.

Tables 31.9 and 31.10 set out in very simple terms the necessary “ingredients” for establishing product liability, either in negligence or under statute: so-called strict liability.

All of the elements of each of these legal wrongs must be present in a given situation for liability to be established. In negligence therefore, where the claim is made against the

TABLE 31.9 Criteria for Negligence—D+L+F+C = N

D: duty of care	Owed to the claimant; easy to establish in the case of the supplier/manufacturer <i>vis-à-vis</i> the patient who uses the product
L: lack of reasonable care	Evidenced by a failure to conduct operations according to accepted standards applicable at the time—that is, a breach of regulatory requirements or possibly failure to take account of or apply (industry) guidelines
F: foreseeable injury	Of the type likely to occur following failure (e.g., side effect of the drug)
C: causation	The lack of reasonable care must have caused/contributed to the injury; if a label would not have been read by the patient in any event, an omission from it might not have caused injury

TABLE 31.10 Criteria for Strict Liability—D+D+C = SL

D: defect	Widely defined—product design defect, manufacturing error (so that the product is less safe than persons generally would be entitled to expect), deficiency in “presentation”
D: damage	To person or property flowing from the defect
C: causation	See Table 26.7

person alleged to owe the duty of care (in the context of this chapter, this will be the company putting the product on the market), proof of causation, without a lack of reasonable care having occurred, will not afford the claimant a remedy. However, the chief distinction between negligent liability and so-called strict liability is that in the case of the latter, fault is not required to be shown. To establish strict liability, the claimant must establish against the “producer” (manufacturer/importer) that the product was “defective” (for the purpose of the law, this could refer to shortcomings in its presentation, design, or manufacture) and that it caused the injury suffered.

It would not be at all unusual for claimants in personal injury actions to look for a regulatory compliance failure on the part of a company defendant. The demonstration of a regulatory breach will significantly assist the plaintiff in establishing lack of reasonable care (i.e., conduct falling below acceptable standards). In fact, whether the failure is alleged to be directly relevant to the injury or not, it can be used to demonstrate a general lack of care in the operation of corporate systems with prejudicial effect. Failure to warn is a common element of many pharmaceutical product liability cases, where the pleadings (of negligence and strict liability) might be expected to assert that had the labeling accurately dealt with contraindications, precautions, and/or warnings, the patient would have avoided the injury allegedly suffered, either because the product would not have been used/administered at all, or the patient would have been monitored, advised (by the treating doctor), or managed differently so as to avert injury.

In a case where PV omissions are identified that can be said to lead to no/or an insufficient response being adopted by the manufacturer (especially where the regulatory authorities have taken some form of action or simply criticized a company), the plaintiff is a significant way toward establishing a case for lack of reasonable care in negligence, or that the product was defective in strict liability terms, because it was not presented accurately and was therefore less safe than persons were entitled to expect, given the content of the labeling.

31.6.1 FDA Tools for Risk Management

The FDA Amendments Act of 2007 (PDUFA IV) gives FDA an array of new regulatory tools to exert tighter controls over prescription drugs in the post-marketing setting (McCaughan, 2008).

The centerpiece of the new authorities is included in the section of the law allowing FDA to impose risk management plans on new drugs, under the new acronym Risk Evaluation and Mitigation Strategies (REMS). But the spirit of the REMS lives throughout the new law, providing the FDA with new authority providing direct onset of consumer ads, a proposed active surveillance system, mandatory post-marketing study provisions, and new safety labeling procedures. Fundamentally, these arise from the belief that product labeling alone is not sufficient to ensure the safe, appropriate use of prescription drugs.

This belief that top FDA officials have expressed publicly for a decade grew out of the agency's frustration over a series of earlier product withdrawals like the type 2 diabetes drug troglitazone (Rezulin) and the cholesterol agent cerivastatin (*Baycol*).

In both those cases (and several less prominent examples), FDA officials believed that the product could be safely marketed if only prescribers followed appropriate use instructions already included in labeling. But such labeling actions did not and the drugs ultimately were taken off the market for safety reason:

Such concerns gave rise to the voluntary risk management plans that serve as the models for the REMS. The amendment makes REMS the new *de facto* baseline for drug approvals, setting a formal mechanism for FDA to impose the programs.

The standard for FDA to impose REMS is quite low: it can do so if a program "is necessary to ensure the benefits of a drug outweigh the risks." That, of course, is the standard FDA already applies for any new drug approval decisions.

That does not mean FDA will impose REMS for every new drug but rather that it can. So sponsors need to anticipate that every new drug review will involve a discussion of whether REMS is necessary, in essence forcing sponsors to work with FDA to define a program up front or prove that one is not necessary for a new drug.

Not all REMS are created equal. Instead, the new law allows FDA to impose different degrees of control depending on the profile of the product under consideration.

31.6.1.1 The Regulatory Pyramid FDA's new regulatory tools can be envisioned as forming a pyramid, with the base representing a relatively small increase in the regulatory burdens already imposed on sponsors in the postmarketing setting and the tip of the pyramid representing the strictest distribution controls that essentially require patients to be identified and screened individually before the medicine is administered.

Though it is not explicitly defined in law, each tier of the pyramid layers new regulatory controls on top of those used in the lower tiers. The result: products regulated on the lower tiers can reach a larger share of the potential patient population for the medicine, while products regulated on higher tiers are limited to narrower and narrower slices.

Here is one approach to arranging FDA's new regulatory authorities that may be useful in drug development planning, along with some examples of currently marketed products that already have these kinds of restrictions in place.

31.6.2 Tier 1: Mandatory Studies

The lowest tier in the new regulatory system will be products for which FDA does not impose REMS at all but does mandate post-marketing studies. FDA's authority to mandate studies is independent of the new REMS provisions in FDAAA, and it is broadly crafted. FDA can mandate studies (i) to assess a known safety risk identified prior to marketing, (ii) to investigate a safety signal about a product, or (iii) to identify "an unexpected serious risk when available data indicates the potential for a serious risk."

Those criteria suggest that FDA will have the ability to argue for mandatory studies for essentially any drug.

The mandatory study authority also interacts with the separate provisions of the law directing FDA to create an active surveillance system via a public/private partnership.

The law stipulates that FDA is not to impose a clinical trial requirement if the active surveillance system can answer a safety question. On the other hand, the active surveillance network will be certain to generate plenty of safety signals that could serve as justification for FDA to impose Phase IV trials.

Still, products in the lowest tier of FDA's new regulatory authority will have no special limits on their distribution or the potential access to patients. Indeed, there is nothing in the law that prevents sponsors from using studies of new indications—trials that could expand use of their medicines—to answer safety questions about existing uses.

Any product marketed with a voluntary *Phase IV* commitment can serve as an example for this tier and, in particular, products approved under FDA's accelerated approval mechanism, which face the threat of a streamlined withdrawal process if the sponsor fails to complete a post-marketing trial or if the trial fails to prove clinical benefit.

But even accelerated approval medicines are not perfect examples of the new regulatory reality, since FDA has not so far used its enhanced power to pull a product from the market for failure to complete trials. There is one pending case where FDA may be considering using that authority: the agency has written to generic drug manufacturers who market versions of Shire PLC's orthostatic hypertension therapy midodrine (*ProAmatine*), pointing out that the required post-marketing studies are not yet complete and inviting comments on proposals from some of the generic manufacturers to do the trials themselves.

One of the first high-profile examples of a sponsor preparing for the new reality of mandatory post-marketing commitments for already marketed products is Amgen Inc., which will be further refining its post-marketing research program for darbepoetin alfa (*Aranesp*).

31.6.3 Tier 2: Labeling and Assessment

The next tier up the pyramid is the first layer of the new REMS authority. The law says that the minimal requirement of REMS is a periodic assessment of a product's post-marketing safety profile. In other words, everything about the drug would be the same as a non-REMS product, but there would be predefined timelines to assess how effective the labeling is working to ensure safe use.

FDA's separate authority to dictate labeling changes will also come into play in this tier. After 18 months on the market (the first predefined assessment point), FDA and the sponsor would review AE reports and other new data (eventually including the active surveillance system). The new information would be added to labeling, and warning statements might be revised. But in the event of a disagreement about the interpretation of the data, FDA now has the upper hand—the agency can force a change (subject to due process provisions in the law).

In principle, there is nothing new about the idea that FDA will be analyzing post-marketing safety reports for new drugs. But the deadline for a formal rereview makes a profound difference in the impact of those analyses.

FDA is already pilot testing this authority via a series of planned drug safety “report cards” for new molecular entities. The agency published its first review in September, looking at spontaneous AE reports for oral chelating agent deferasirox (Exjade). The review prompted a new round of media coverage about acute renal failure and cytopenia associated with the drug; Novartis alerted prescribers to the issue in May.

Going forward, sponsors will have to be cognizant of the deadlines for reassessment and wary of FDA's ability to dictate new labeling.

At a minimum, sponsors will need to enhance their own postmarketing monitoring of products regulated under this tier to prevent any surprises in their interactions with FDA. And in some cases sponsors may decide to take voluntary steps on their own to further restrict use if they believe the alternative will be facing an unworkable warning in labeling.

31.6.4 Tier 3: Enhanced Communication

The REMS authority allows FDA to require consumer medication guides and enhanced communications for doctors or other tools to communicate appropriate use information more effectively. Current examples of risk management tools that would fall under this authority might include special stickers to be affixed to prescriptions, agreements to limit sampling, enhanced patient compliance programs, or voluntary agreements not to advertise to consumers.

FDA's new direct-to-consumer ad review user fee program and its separate authority to require disclaimers in broadcast ads also should be considered as part of this regulatory tier. Though not part of the REMS, the DTC provisions will work in the same way by giving FDA a stronger hand in shaping the final version of safety messages included in broadcast ads.

The enhanced communication provisions obviously place a higher regulatory burden on the sponsor. Sponsors operating under an enhanced communication plan may find themselves in jeopardy if there is significant, measurable use of the product in a setting that FDA considers inappropriate.

The agency will consider imposing more restrictive REMS in that situation; it could also seek to hold the company accountable for the failure of the program. The new law makes REMS mandatory with potentially significant penalties for violations. A sponsor that willfully promotes a product in a manner that runs counter to the enhanced communication plan is obviously in jeopardy. But FDA may also view the failure of the plan as suspicious in itself, triggering a deeper investigation of a company's marketing activities.

There are quite a few examples of products marketed with enhanced communication plans. Amylin Pharmaceuticals Inc.'s type 2 diabetes therapy pramlintide (*Symlin*) is noteworthy as an early example of a manufacturer voluntarily agreeing not to advertise directly to consumers.

Another instructive example is AstraZeneca PLC's rosuvastatin (*Crestor*). Developed as a “superstatin,” *Crestor* had the misfortune to be pending at FDA at the time of the *Baycol* withdrawal. In response to concerns about potential toxicity from high-potency statins, AstraZeneca agreed not to sample the high dose of *Crestor*. The product also underwent an unplanned safety reassessment after approval thanks in part to a petition filed by a public citizen seeking *Crestor*'s withdrawal. The result was a relabeling with stronger warnings, followed by the resumption of direct-to-consumer advertising and the emergence of *Crestor* as a brand approaching \$3 billion in annual sales.

Two recent Pfizer Inc. approvals also used enhanced communication plans. In the case of the inhaled insulin brand *Exubera*, the program was part of an effective regulatory strategy to resolve safety issues that long delayed its launch. (See “Pfizer's *Exubera*: Breathing New Life into Inhaled Insulin,” *IN VIVO*, October 2005). But getting the product to market turned out to be the easy part: after dismal uptake, Pfizer is giving up on the brands and writing off almost \$3 billion as a result.

A happier example is the smoking cessation agent varenicline (*Chantix*). Pfizer markets the drug in conjunction with a voluntary patient support program and also delayed the launch of DTC advertising as part of its commitment to principles established by the Pharmaceutical Research and Manufacturers of America. Now the brand is one of the rising stars of the company's commercial portfolio, with sales jumping almost 10-fold to \$241 million in the third quarter of 2007.

31.6.5 Tier 4: Safe Use Restriction Defined by Provider

The next level up the pyramid is when the REMS really start to pinch market sizes. The law gives FDA the authority to set

distribution restrictions on a drug if “necessary to assure safe use of the drug because of its inherent toxicity or potential harmfulness.” FDA is supposed to apply the restrictions only when a drug could not be marketed (or would be withdrawn) without them or if less restrictive REMS fail to assure appropriate use.

The safe use authority is one section of the law, but it really represents two tiers of regulation.

The lower tier is a restriction based on the providers. That restriction could be to allow use only by providers who complete a special training program—a burden to the sponsor, to be sure, but one with a clear upside in promoting a new medicine.

Or the restriction could be defined by physician specialty or practice setting. FDA could allow use of a medicine only in hospitals, for example, as was the case for Praecis Pharmaceuticals’ abarelix (*Plenaxis*). The restriction essentially killed the product; Praecis withdrew it and was itself acquired by GlaxoSmithKline PLE.

In other cases, such as with Genentech Inc.’s omalizumab (*Xolair*), the distribution restriction can serve more as an opportunity. *Xolair*’s labeling stipulates that the asthma drug must be administered in a physician’s office to monitor for acute adverse reactions. The product did not initially meet Genentech’s expectations but is now emerging as a prime example of the “minibuster” model that will be critical to the industry in the future.

Still, restricted access provisions place a significant burden on sponsors, typically requiring specialized distribution systems and close coordination with providers. In other words, the primary care blockbuster model that built the modern Big Pharma business does not apply.

31.6.6 Tier 5: Safe Use Restriction Defined by Patient

The highest tier on the pyramid involves the other elements of restricted distribution programs, ones that define the limits by patient-specific criteria.

The law allows FDA to require distribution only to patients with a documented lab test, or to require special monitoring of each patient given the drug, or to mandate patient registries for recipients. This tier represents the tip of the regulatory pyramid, where FDA’s authority dictates the conditions for administering the drug to individual patients.

But even at this layer of regulation, commercial success is possible. Biogen Idec Inc.’s *Tysabri* is marketed under the most restrictive distribution plan approved by FDA. The product is not at the level the sponsor hoped for when it was first launched for MS—but the company believes it could still be a billion-dollar brand.

Or consider Celgene Corp.’s thalidomide (*Thalomid*), the drug that ushered in the modern era of risk management plans when it was approved in 1998. The program has been so successful that it has essentially defined Celgene’s business

model—an approach that many other companies are likely to want to imitate post-FDAAA.

There is an even earlier example: Novartis’ atypical antipsychotic clozapine (*Clozaril*) which was sold with a requirement for blood monitoring, initially tied to a single lab test provider (Caremark). *Clozaril* has been surpassed by many newer atypicals, but it is worth remembering that one of the biggest blockbuster classes of the past two decades began as a prototype for the era of restrictive distribution plans.

STATISTICS IN PHARMACEUTICAL SAFETY ASSESSMENT

32.1 INTRODUCTION

Modern nonclinical safety assessment is heavily dependent on the use of multiple tools, some that generate data, and others (such as statistical analysis) that help to evaluate and understand data. This chapter is meant to serve the practicing toxicologist and pathologist, as a practical guide to the common statistical problems encountered in drug safety assessment and the methodologies that are available to solve them. The chapter also includes discussions of why a particular procedure or interpretation is recommended, by the clear enumeration of the assumptions that are necessary for a procedure to be valid and by discussion of problems drawn from the actual practice of toxicology and toxicological pathology. Studies are frequently over- or misused in the place of knowledgeable and critical integration and analysis of data.

Studies continue to be designed and executed to generate increased amounts of data. The resulting problems of data analysis have then become more complex, and toxicology has drawn more deeply from the well of available statistical techniques. Statistics has also been very active and growing during the last 35 years—to some extent, at least, because of the parallel growth of toxicology. These simultaneous changes have led to an increasing complexity of data and, unfortunately, to the introduction of numerous confounding factors which severely limit the utility of the resulting data in all too many cases.

A major difficulty is that there is a very real necessity to understand the biological realities and implications of a problem, as well as to understand the peculiarities of toxicological data before procedures are selected and employed for analysis. These characteristics include the following:

1. The need to work with a relatively small sample set of data collected from the members of a population (laboratory animals) which is not actually our populations of interest (i.e., humans or a target animal population).
2. Dealing frequently with data resulting from a sample which was censored on a basis other than by the investigators as a design. By censoring, of course, we mean that not all data points were collected as might be desired. This censoring could be the result of either a biological factor (the test animal being dead or too debilitated to manipulate) or a logistic factor (equipment being inoperative or a tissue being missed in necropsy).
3. The conditions under which our experiments are conducted are extremely varied. In pharmacology (the closest cousin to at least classical toxicology), the possible conditions of interaction of a chemical or physical agent with a person are limited to a small range of doses via a single route over a short course of treatment to a defined patient population. In toxicology, however, all these variables (dose, route, time span, and subject population) are determined by the investigator.
4. The time frames available to solve our problems are limited by practical and economic factors. This frequently means that there is no time to repeat a critical study if the first attempt fails. So a true iterative approach is not possible.

The training of most pathologists in statistics remains limited to a single introductory course which concentrates on some theoretical basics. As a result, the armamentarium of

TABLE 32.1 Sample Size Required to Obtain a Specified Sensitivity at $p < 0.05$

Background Tumor Incidence	P^a	Treatment Group Incidence

	0.50	3	3	5	5	6	8	10	13	25	56

^a P = Power for each comparison of treatment group with background tumor incidence.

statistical techniques of most toxicologists is limited, and the tools that are usually present (*t*-tests, chi-square, analysis of variance [ANOVA], and linear regression) are neither fully developed nor well understood. It is hoped that this chapter will help change this situation.

As a point of departure toward this objective, it is essential that any analysis of study results be interpreted by a professional who firmly understands three concepts: the difference between biological significance and statistical significance, the nature and value of different types of data, and causality.

For the first concept, we should consider the four possible combinations of these two different types of significance, for which we find the relationship shown in the succeeding text.

		Statistical Significance	
		No	Yes
Biological Significance	No	Case I	Case II
	Yes	Case III	Case IV

Cases I and IV give us no problems, for the answers are the same statistically and biologically. But cases II and III present problems. In case II (the “false positive”), we have a circumstance where there is a statistical significance in the measured difference between treated and control groups, but there is no true biological significance to the finding. This is not an uncommon happening, for example, in the case of clinical chemistry parameters. This is called type I error by statisticians, and the probability of this happening is called the alpha (α) level. In case III (the “false negative”), we have no statistical significance, but the differences between groups are biologically/toxicologically significant. This is called type II error by statisticians, and the probability of such an error happening by random chance is called the beta (β) level. An example of this second situation is when we see a few of a very rare tumor type in treated animals. In both of these latter

cases, numerical analysis, no matter how well done, is no substitute for professional judgment. Along with this, however, one must have a feeling for the different types of data and for the value or relative merit of each. Note that the two error types interact and in determining sample size, we need to specify both α and β levels. Table 32.1 demonstrates this interaction in the case of tumor or specific lesion incidence.

The reasons that biological and statistical significance are not identical are multiple, but a central one is certainly causality. Through our consideration of statistics, we should keep in mind that just because a treatment and a change in an observed organism are seemingly or actually associated with each other does not “prove” that the former caused the latter. Though this fact is now widely appreciated for correlation (e.g., the fact that the number of storks’ nests found each year in England is correlated with the number of human births that year does not mean that storks bring babies), it is just as true in the general case of significance. Timely establishment and proof that treatment causes an effect are required for an understanding of the underlying mechanism and proof of its validity. At the same time, it is important that we realize that not finding a good correlation or suitable significance associated with a treatment and an effect likewise does not prove that the two are not associated—that a treatment does not cause an effect. At best, it gives us a certain level of confidence that under the conditions of the current test, these items are not associated.

These points will be discussed in greater detail in “Assumptions and Limitations” for each method, along with other common pitfalls and shortcomings associated with the method. To help in better understanding the chapters to come, terms frequently used in discussion throughout this book should first be considered. These are presented in Table 32.2 later.

Each measurement we make—each individual piece of experimental information we gather—is called a datum. However, we gather and analyze multiple pieces at one time, the resulting collection being called data.

TABLE 32.2 Some Frequently Used Terms and Their General Meanings (Marriott, 1991)

Term	Meaning
95% CI	A range of values (above, below, or above and below the sample) (mean, median, mode, etc.) have a 95% chance of containing the true value of the population (mean, median, and mode). Also called the fiducial limit equivalent to the $p < 0.05$.
Bias	Systemic error as opposed to a sampling error. For example, selection bias may occur when each member of the population does not have an equal chance of being selected for the sample.
df	The number of independent deviations, usually abbreviated df.
Independent variables	Also known as predictors or explanatory variables.
p value	Another name for significance level, usually 0.005.
Power	The effect of the experimental conditions on the dependent variable relative to sampling fluctuation. When the effect is maximized, the experiment is more powerful. Power can also be defined as the probability that there will not be a type II error ($1 - \beta$). Conventionally, power should be at least 0.07.
Random	Each individual member of the population has the same chance of being selected for the sample.
Robust	Having inferences or conclusions little effected by departure from assumptions.
Sensitivity	The number of subjects experiencing each experimental condition divided by the variance of scores in the sample.
Significance level	The probability that a difference has been erroneously declared to be significant, typically 0.005 and 0.001 corresponding to 5% and 1% chance of error.
Type I error (false positives)	Concluding that there is an effect when there really is not an effect. Its probability is the α level.
Type II error (false negatives)	Concluding there is an effect when there really is an effect. Its probability is the β level.

Data are collected on the basis of their association with a treatment (intended or otherwise) as an effect (a property) that is measured in the experimental subjects of a study, such as body weights. These identifiers (i.e., treatment and effect) are termed variables. Our treatment variables (those that the researcher or nature control and that can be directly controlled) are termed independent variables, while our effect variables (such as weight, life span, and number of neoplasms) are termed dependent variables—their outcome is believed to be dependent on the “treatment” being studied.

All the possible measures of a given set of variables in all the possible subjects that exist are termed the population for those variables. Such a population of variables cannot be truly measured—for example, one would have to obtain, treat, and measure the weights of all the Fischer 344 rats that were, are, or ever will be. Instead, we deal with a representative group—a sample. If our sample of data is appropriately collected and of sufficient size, it serves to provide good estimates of the characteristics of the parent population from which it was drawn.

32.1.1 Bias and Chance

Any toxicological study aims to determine whether a treatment elicits a response. An observed difference in response between a treated and control group need not necessarily be a result of treatment. There are, in principle, two other possible explanations—*bias*, or systematic differences other than treatment between the groups, and *chance*, or random differences. A major objective of both experimental design and analysis is to try to avoid bias. Wherever possible, treated and control groups to be compared should be

alike in respect of all other factors. Where differences remain, these should be corrected for in the statistical analysis. Chance cannot be wholly excluded, since identically treated animals will not respond identically. While even the extreme difference might in theory be due to chance, a proper statistical analysis will allow the experimenter to assess this possibility. The smaller the probability of a “false positive,” the more confident the experimenter can be that the effect is real. Good experimental design improves the chance of picking up a true effect with confidence by maximizing the ratio between “signal” and “noise.”

32.1.2 Hypothesis Testing and Probability (p) Values

A relationship of treatment to some toxicological end point is often stated to be “statistically significant ($p < 0.05$).” What does this really mean? A number of points have to be made. *First*, statistical significance need not necessarily imply biological importance if the end point under study is not relevant to the animal’s well-being. *Second*, the statement will usually be based only on the data from the study in question and will not take into account prior knowledge. In some situations, for example, when one or two of a very rare tumor type are seen in treated animals, statistical significance may not be achieved, but the finding may be biologically extremely important, especially if a similar treatment was previously found to elicit a similar response. *Third*, the p value does not describe the probability that a true effect of treatment exists. Rather, it describes the probability of the observed response, or one more extreme, occurring on the assumption that treatment actually had no effect whatsoever.

A p value that is not significant is consistent with a treatment having a small effect, not detected with sufficient certainty in this study. *Fourth*, there are two types of p value. A “one-tailed (or one-sided) p value” is the probability of getting by chance a treatment effect in a specified direction as great as or greater than that observed. A “two-tailed p value” is the probability of getting, by chance alone, a treatment difference in either direction which is as great as or greater than that observed. By convention, p values are assumed to be two-tailed unless the contrary is stated. Where, which is unusual, one can rule out in advance the possibility of a treatment effect except in one direction, a one-tailed p value should be used. Often, however, two-tailed tests are to be preferred, and it is certainly not recommended to use one-tailed tests and *not* report large differences in the other direction. In any event, it is important to make it clear whether one- or two-tailed tests have been used.

It is a great mistake, when presenting results of statistical analyses, to mark, as do some laboratories, results simply as significant or not significant at one defined probability level (usually $p < 0.05$). This poor practice does not allow the reader any real chance to judge whether or not the effect is a true one. Some statisticians present the actual p value for every comparison made. While this gives precise information, it can make it difficult to assimilate results from many variables. One practice I recommend is to mark p values routinely using plus signs to indicate positive differences (and minus signs to indicate negative differences) as follows: $+++$, $p = 0.001$; $++$, $0.001 \leq p < 0.01$; $+$, $0.01 \leq p < 0.05$; \pm , $0.05 \leq p < 0.1$. This highlights significant results more clearly and also allows the reader to judge the whole range from “virtually certain treatment effect” to “some suspicion.” Note that using two-tailed tests, bracketed plus signs indicate findings that would be significant at the conventional $p < 0.05$ level using one-tailed tests but are not significant at this level using two-tailed tests. This “fiducial limit” ($p < 0.05$) implies a false-positive incidence of 1 in 20 and, though now imbedded in regulation, practice, and convention, was somewhat an arbitrary choice to begin with. In interpreting p values, it is important to realize they are only an aid to judgment to be used in conjunction with other available information. One might validly consider a $p < 0.01$ increase as chance when it was unexpected, occurred only at a low-dose level with no such effect seen at higher doses and was evident in only one subset of the data. In contrast, a $p < 0.05$ increase might be convincing if it occurred in the top dose and was for an end point one might have expected to be increased from known properties of the chemical or closely related chemicals.

32.1.3 Multiple Comparisons

When a p value is stated to be less than 0.05, this implies that, for that particular test, the difference could have occurred by chance less than 1 time in 20. Toxicological

studies frequently involve making treatment–control comparisons for a large number of variables and, in some situations, also for various subsets of animals. Some statisticians worry that the larger the number of tests, the greater is the chance of picking up statistically significant findings that do not represent true treatment effects. For this reason, an alternative “multiple comparison” procedure has been proposed in which, if the treatment was totally without effect, 19 times out of 20 *all* the tests should show no significance when testing at the 95% confidence level. Automatic use of this approach cannot be recommended. Not only does it make it much more difficult to pick up any real effects but also there is something inherently unsatisfactory about a situation where the relationship between a treatment and a particular response depends arbitrarily on which other responses happened to be investigated at the same time. It is accepted that in any study involving multiple end points that there will inevitably be a gray area between those showing highly significant effects and those showing no significant effects, where there is a problem distinguishing chance and true effects. However, changing the methodology so that the gray areas all come up as nonsignificant can hardly be the answer.

32.1.4 Estimating the Size of the Effect

It should be clearly understood that a p value does not give direct information about the size of any effect that has occurred. A compound may elicit an increase in response by a given amount, but whether a study finds this increase to be statistically significant will depend on the size of the study and the variability of the data. In a small study, a large and important effect may be missed, especially if the end point is imprecisely measured. In a large study, on the other hand, a small and unimportant effect may emerge as statistically significant.

Hypothesis testing tells us whether an observed increase can or cannot be reasonably attributed to chance, but not how large it is. Although statistical theory relates to hypothesis testing, current trends in medical statistics are toward confidence interval (CI) estimation with differences between test and control groups expressed in the form of a best estimate, coupled with the 95% CI. Thus, if one states that treatment increases response by an estimated 10 units (95% CI 3–17 units), this will imply that there is a 95% chance that the indicated interval includes the true difference. If the lower 95% confidence limit exceeds zero, this implies the increase is statistically significant at $p < 0.05$ using a two-tailed test. One can also calculate, for example, 99% or 99.9% confidence limits, corresponding to testing for significance at $p < 0.01$ or $p < 0.001$.

In screening studies of standard design, the tendency has been to concentrate mainly on hypothesis testing. However, presentation of the results in the form of estimates with CI can be a useful adjunct for some analyses and is very important in studies aimed specifically at quantifying the size of an effect.

Two terms refer to the quality and reproducibility of our measurements of variables. The first, accuracy, is an expression of the closeness of a measured or computed value to its actual or “true” value in nature. The second, precision, reflects the closeness or reproducibility of a series of repeated measurements of the same quantity.

If we arrange all of our measurements of a particular variable in order as a point on an axis marked as to the values of that variable, and if our sample were large enough, the pattern of distribution of the data in the sample would begin to become apparent. This pattern is a representation of the frequency distribution of a given population of data—that is, of the incidence of different measurements, their central tendency, and dispersion.

The most common frequency distribution—and one we will talk about throughout this book—is the normal (or Gaussian) distribution. The normal distribution is such that two-thirds of all values are within one standard deviation (SD) (to be defined in Section 32.2) of the mean (or average value for the entire population), and 95% are within 1.96 SD of the mean. Symbols used are μ for the mean and σ for the SD. Other common frequency distributions include the binomial, Poisson, and chi-square.

In all areas of biological research, optimal design and appropriate interpretation of experiments require that the researcher understand both the biological and technological underpinnings of the system being studied and of the data being generated. From the point of view of the statistician, it is vitally important that the experimenter both know and be able to communicate the nature of the data and understand its limitations. One classification of data types is presented in Table 32.3.

The nature of the data collected is determined by three considerations. These are the biological source of the data (the system being studied), the instrumentation and techniques being used to make measurements, and the design of the experiment. The researcher has some degree of control over

TABLE 32.3 Types of Variables (Data) and Examples of Each Type

Classified By	Type	Example
<i>Scale</i>		
Continuous	Scalar	Body weight
	Ranked	Severity of a lesion
Discontinuous	Scalar	Weeks until the first observation of a tumor in a carcinogenicity study
	Ranked	Clinical observations in animals
	Attribute	Eye colors in fruit flies
	Quantal	Dead/alive or present/absent
<i>Frequency distribution</i>		
	Normal	Body weights
	Bimodal	Some clinical chemistry parameters
	Others	Measures of time-to-incapacitation

each of these—least over the biological system (he or she normally has a choice of only one of several models to study) and most over the design of the experiment or study. Such choices, in fact, dictate the type of data generated by a study.

Statistical methods are based on specific assumptions. Parametric statistics—those that are most familiar to the majority of scientists—have more stringent underlying assumptions than do nonparametric statistics. Among the underlying assumptions for many parametric statistical methods (such as the ANOVA) is that the data are continuous. The nature of the data associated with a variable (as described in the preceding text) imparts a “value” to that data, the value being the power of the statistical tests which can be employed.

Continuous variables are those which can at least theoretically assume any of an infinite number of values between any two fixed points (such as measurements of body weight between 2.0 and 3.0 kg). Discontinuous variables, meanwhile, are those which can have only certain fixed values, with no possible intermediate values (such as counts of five and six dead animals, respectively).

Limitations on our ability to measure constrain the extent to which the real-world situation approaches the theoretical, but many of the variables studied in toxicology are in fact continuous. Examples of these are lengths, weights, concentrations, temperatures, periods of time, and percentages. For these continuous variables, we may describe the character of a sample with measures of central tendency and dispersion that we are most familiar with—the mean, denoted by the symbol \bar{X} and also called the arithmetic average, and the SD, which is denoted by the symbol σ and is calculated as being equal to

$$\sqrt{\frac{\sum X^2 - (\sum X)^2 / N}{N - 1}}$$

where X is the individual datum, and N is the total number of data in the group.

Contrasted with these continuous data, however, we have discontinuous (or discrete) data, which can only assume certain fixed numerical values. In these cases, our choice of statistical tools or tests is, as we will find later, more limited.

32.1.5 Functions of Statistics

Statistical methods may serve to do any combination of three possible tasks. The one we are most familiar with is hypothesis testing—that is, determining if two (or more) groups of data differ from each other at a predetermined level of confidence. A second function is the construction and use of models which may be used to predict future outcomes of chemical–biological interactions. This is most commonly seen in linear regression or in the derivation of some form of correlation coefficient. Model fitting allows us to relate one variable (typically a treatment or “independent” variable) to another. The third function, reduction of dimensionality,

continues to be less commonly utilized than the first two. This final category includes methods for reducing the number of variables in a system while only minimally reducing the amount of information, therefore, making a problem easier to visualize and to understand. Examples of such techniques are factor analysis and cluster analysis. A subset of this last function, discussed later under descriptive statistics, is the reduction of raw data to single expressions of central tendency and variability (such as the mean and SD).

There is also a special subset of statistical techniques which are part of both the second and third functions of statistics. This is data transformation, which includes such things as the conversion of numbers to log or probit values.

32.1.6 Descriptive Statistics

Descriptive statistics are used to summarize the general nature of a data set. As such, the parameters describing any single group of data have two components. One of these describes the location of the data, while the other gives a measure of the dispersion of the data in and about this location. Often overlooked is the fact that the choice of which parameters are used to give these pieces of information implies a particular type of distribution for the data.

Most commonly, location is described by giving the (arithmetic) mean and dispersion by giving the SD or the standard error of the mean (SEM). The calculation of the first two of these has already been described. If we again denote the total number of data in a group as N , then the SEM would be calculated as

$$SEM = \frac{SD}{\sqrt{N}}$$

The use of the mean with either the SD or SEM implies, however, that we have reason to believe that the sample of data being summarized is from a population which is at least approximately normally distributed. If this is not the case, then we should rather use a set of statistical descriptions which do not require a normal distribution. These are the median, for location, and the semiquartile distance, for a measure of dispersion. These somewhat less familiar parameters are characterized as follows:

32.1.6.1 Median When all the numbers in a group are arranged in a ranked order (i.e., from smallest to largest), the median is the middle value. If there is an odd number of values in a group, then the middle value is obvious (in the case of 13 values, e.g., the seventh largest is the median). When the number of values in the sample is even, the median is calculated as the midpoint between the $(N/2)$ th and the $((N/2) + 1)$ th number. For example, in the series of numbers 7, 12, 13, and 19, the median value would be the midpoint between 12 and 13, which is 12.5.

The SD and the SEM are related to each other, but yet are quite different.

The SEM is quite a bit smaller than the SD, making it very attractive to use in reporting data. This size difference is because the SEM actually is an estimate of the error (or variability) involved in measuring the means of samples, and not an estimate of the error (or variability) involved in measuring the data from which means are calculated. This is implied by the *central limit theorem*, which tells us three major things:

1. The distribution of sample means will be approximately normal regardless of the distribution of values in the original population from which the samples were drawn.
2. The mean value of the collection.
3. The SD of the collection of all possible means of samples of a given size, called the SEM, depends on both the SD of the original population and the size of the sample.

The SEM should be used only when the uncertainty of the estimate of the mean is of concern—which is almost never the case in toxicology. Rather, we are concerned with an estimate of the variability of the population—for which the SD is appropriate.

32.1.6.2 Semiquartile Distance When all the data in a group are ranked, a quartile of the data contains one ordered quarter of the values. Typically, we are most interested in the borders of the middle two quartiles Q_1 and Q_3 , which together represent the semiquartile distance and which contain the median as their center. Given that there are N values in an ordered group of data, the upper limit of the j th quartile (Q_j) may be computed as being equal to the $((jN/1)/4)$ th value. Once we have used this formula to calculate the upper limits of Q_1 and Q_3 , we can then compute the semiquartile distance (which is also called the quartile deviation and as such is abbreviated as the QD) with the formula $QD = (Q_3 - Q_1)/2$.

For example, for the 15-value data set 1, 2, 3, 4, 4, 5, 5, 5, 6, 6, 6, 7, 7, 8, 9, we can calculate the upper limits of Q_1 and Q_3 as

$$Q_1 = \frac{1(15+1)}{4} = \frac{16}{4} = 4$$

$$Q_3 = \frac{3(15+1)}{4} = \frac{48}{4} = 12$$

The 4th and 12th values in this data set are 4 and 7, respectively. The semiquartile distance can then be calculated as

$$QD = \frac{7-4}{2} = 1.5$$

There are times when it is desired to describe the relative variability of one or more sets of data. The most common way of doing this is to compute the coefficient of variation (CV), which is calculated simply as the ratio of the SD to the mean or

$$CV = \frac{SD}{\bar{X}}$$

A CV of 0.2 or 20% thus means that the SD is 20% of the mean. In toxicology, the CV is frequently between 20% and 50% and may at times exceed 100%.

32.2 EXPERIMENTAL DESIGN

Toxicological experiments generally have a twofold purpose. The first question is whether or not an agent results in an effect on a biological system. The second question, never far behind, is how much of an effect is present. It has become increasingly desirable that the results and conclusions of studies aimed at assessing the effects of environmental agents be as clear and unequivocal as possible. It is essential that every experiment and every study yield as much information as possible and that the results of each study have the greatest possible chance of answering the questions it was conducted to address. The statistical aspects of such efforts, so far as they are aimed at structuring experiments to maximize the possibilities of success, are called experimental design (Cochran and Cox, 1975).

The four basic statistical principles of experimental design are replication, randomization, concurrent (“local”) control, and balance. In abbreviated form, these may be summarized as follows:

Replication Any treatment must be applied to more than one experimental unit (animal, plate of cells, litter of offspring, etc.). This provides more accuracy in the measurement of a response than can be obtained from a single observation, since underlying experimental errors tend to cancel each other out. It also supplies an estimate of the experimental error derived from the variability among each of the measurements taken (or “replicates”). In practice, this means that an experiment should have enough experimental units in each treatment group (i.e., a large enough “*N*”) so that reasonably sensitive statistical analysis of data can be performed. The estimation of sample size is addressed in detail later in this chapter.

Randomization This is practiced ensuring that every treatment shall have its fair share of extreme high and extreme low values. It also serves to allow the toxicologist to proceed as if the assumption of “independence” is valid. That is, there is no avoidable (known) systematic bias in how one obtains data.

Concurrent Control Comparisons between treatments should be made to the maximum extent possible between experimental units from the same closely defined population. Therefore, animals used as a “control” group should come from the same source, lot, age, and so on, as test group animals. Except for the treatment being evaluated, test and control animals should be maintained and handled in exactly the same manner.

Balance If the effect of several different factors is being evaluated simultaneously, the experiment should be laid out in such a way that the contributions of the different factors can be separately distinguished and estimated. There are several ways of accomplishing this using one of several different forms of design, as will be discussed in the succeeding text.

There are 10 facets of any study which may affect its ability to detect an effect of a treatment. The first six concern minimizing the role of chance and the last four relate to avoidance of bias.

32.2.1 Choice of Species and Strain

Ideally, the responses of interest should be rare in untreated control animals but should be reasonably readily evoked by appropriate treatments. Some species or specific strains, perhaps because of inappropriate diets (Roe, 1989; Gad, 2015), have high background tumor incidences which make increases both difficult to detect and difficult to interpret when detected.

32.2.2 Sampling

Sampling—the selection of which individual data points will be collected, whether in the form of selecting which animals to collect blood from or to remove a portion of a diet mix from for analysis—is an essential step upon which all other efforts toward a good experiment or study are based.

There are three assumptions about sampling which is common to most of the statistical analysis techniques that are used in toxicology. These are that the sample is collected without bias, that each member of a sample is collected independently of the others, and that members of a sample are collected with replacements. Precluding bias, both intentional and unintentional, means that at the time of selection of a sample to measure, each portion of the population from which that selection is to be made has an equal chance of being selected. Ways of precluding bias are discussed in detail in the section on experimental design, Section 32.2.

Independence means that the selection of any portion of the sample is not affected by and does not affect the selection or measurement of any other portion.

Finally, sampling with replacement means that in theory, after each portion is selected and measured, it is returned to

the total sample pool and thus has the opportunity to be selected again. This is a corollary of the assumption of independence. Violation of this assumption (which is almost always the case in toxicology and all the life sciences) does not have serious consequences if the total pool from which samples are sufficiently large (say, 20 or greater) is such that the chance of reselecting that portion is small anyway.

There are four major types of sampling methods—random, stratified, systematic, and cluster. Random is by far the most commonly employed method in toxicology. It stresses the fulfillment of the assumption of avoiding bias. When the entire pool of possibilities is mixed or randomized (procedures for randomization are presented in a later chapter), then the members of the group are selected in the order that is drawn from the pool.

Stratified sampling is performed by first dividing the entire pool into subsets or strata and then doing randomized sampling from each stratum. This method is employed when the total pool contains subsets which are distinctly different but in which each subset contains similar members. An example is a large batch of a powdered pesticide in which it is desired to determine the nature of the particle size distribution. Larger pieces or particles are on the top, while progressively smaller particles have settled lower in the container, and at the very bottom, the material has been packed and compressed into aggregates. To determine a timely representative answer, proportionally sized subsets from each layer or stratum should be selected, mixed, and randomly sampled. This method is used more commonly in diet studies.

In systematic sampling, a sample is taken at set intervals (such as every fifth container of reagent or taking a sample of water from a fixed sample point in a flowing stream every hour). This is most commonly employed in quality assurance or (in the clinical chemistry lab) in quality control.

In cluster sampling, the pool is already divided into numerous separate groups (such as bottles of tablets), and we select small sets of groups (such as several bottles of tablets) and then select a few members from each set. What one gets then is a cluster of measures. Again, this is a method most commonly used in quality control or in environmental studies when the effort and expense of physically collecting a small group of units are significant.

In classical toxicology studies, sampling arises in a practical sense in a limited number of situations. The most common of these are as follows:

1. Selecting a subset of animals or test systems from a study to make some measurement (which either destroys or stresses the measured system or is expensive) at an interval during a study. This may include such cases as doing interim necropsies in a chronic study or collecting and analyzing blood samples from some animals during a subchronic study.

2. Analyzing inhalation chamber atmospheres to characterize aerosol distributions with a new generation system.
3. Analyzing diet in which test material has been incorporated.
4. Performing quality control on an analytical chemistry operation by having duplicate analyses performed on some materials.
5. Selecting data to audit for quality assurance purposes.

32.2.3 Dose Levels

This is a very important and controversial area. In screening studies aimed at hazard identification, it is normal, in order to avoid requiring huge numbers of animals, to test at dose levels higher than those to which man will be exposed, but not so high that marked toxicity occurs. A range of doses are usually tested to guard against the possibility of a misjudgment of an appropriate high dose and that the metabolic pathways at the high doses differ markedly from those at lower doses and, perhaps, to ensure no large effects occur at dose levels in the range to be used by man. In studies aimed more at-risk estimation, more and lower doses may be tested to obtain fuller information on the shape of the dose-response curve.

32.2.4 Number of Animals

This is obviously an important determinant of the precision of the findings. The calculation of the appropriate number depends on (i) the critical difference, that is, the size of the effect it is desired to detect; (ii) the false-positive rate, that is, the probability of an effect being detected when none exists (equivalent to the “ α level” or “type I error”); (iii) the false negative rate, that is, the probability of no effect being detected when one of exactly the critical size exists (equivalent to the “ β level” or “type II error”); and (iv) some measure of the variability in the material.

Tables relating numbers of animals required to obtain values of critical size, α and β are given in Kraemer and Thiemann (1987) and Gad (2005) and software is also available for this purpose. As a rule of thumb, to reduce the critical difference by a factor n for a given α and β , the number of animals required will have to increase by a factor n^2 .

32.2.5 Duration of the Study

It is obviously important not to terminate the study too early for fatal conditions, which are normally strongly age related. Less obviously, going on for too long in a study can be a mistake, partly because the last few weeks or months may produce relatively few extra data at a disproportionate cost and

partly because diseases of extreme old age may obscure the detection of tumors and other conditions of more interest. For nonfatal conditions, the ideal is to sacrifice the animals when the average prevalence is around 50%.

32.2.6 Stratification

To detect a treatment difference with accuracy, it is important that the groups being compared are as homogeneous as possible with respect to other known causes of the response. In particular, suppose that there is another known important cause of the response for which the animals vary, so that the animals are a mixture of hyper- and hyporesponders from this cause. If the treated group has a higher proportion of hyperresponders, it will tend to have a higher response even if treatment has no effect. Even if the proportion of hyperresponders is the same as in the controls, it will be more difficult to detect an effect of treatment because of the increased between-animal variability.

Given that this other factor is known, it will be sensible to take it into account in both the design and analysis of the study. In the design, it can be used as a “blocking factor” so that animals at each level are allocated equally (or in the correct proportion) to control and treated groups. In the analysis, the factor should be treated as a stratifying variable, with separate treatment–control comparisons made at each level, and the comparisons combined for an overall test of difference. This is discussed later, where we refer to the factorial design as one example of the more complex designs that can be used to investigate the separate effect of multiple treatments.

32.2.7 Randomization

Random allocation of animals to treatment groups is a prerequisite of good experimental design. If not carried out, one can never be sure whether treatment–control differences are due to treatment or to “confounding” by other relevant factors. The ability to randomize easily is a major advantage animal experiments have over epidemiology.

While randomization eliminates bias (as least in expectation), simple randomization of all animals may not be the optimal technique for producing a sensitive test. If there is another major source of variation (e.g., sex or batch of animals), it will be better to carry out stratified randomization (i.e., carry out separate randomizations within each level of the stratifying variable).

The need for randomization applies not only to the allocation of the animals to the treatment but also to anything that can materially affect the recorded response. The same random number that is used to apply animals to treatment group can be used to determine cage position, order of weighing, order of bleeding for clinical chemistry, order of sacrifice at terminations, and so on.

32.2.8 Adequacy of Control Group

While historical control data can, on occasion, be useful, a properly designed study demands that a relevant concurrent control group be included with which results for the test group can be compared. The principle that like should be compared with like, apart from treatment, demands that control animals should be randomized from the same source as treatment animals. Careful consideration should also be given to the appropriateness of the control group. Thus, in an experiment involving treatment of a compound in a solvent, it would often be inappropriate to include only an untreated control group, as any differences observed could only be attributed to the treatment–solvent combination. To determine the specific effects of the compound, a comparison group given the solvent only, by the same route of administration, would be required.

It is not always generally realized that the position of the animal in the room in which it is kept may affect the animal’s response. An example is the strong relationship between incidence of retinal atrophy in albino rats and closeness to the lighting source. Systematic differences in cage position should be avoided, preferably via randomization.

We have now become accustomed to developing exhaustively detailed protocols for an experiment or study prior to its conduct. A priori selection of statistical methodology (as opposed to the *post hoc* approach) is as significant a portion of the process of protocol development and experimental design as any other and can measurably enhance the value of the experiment or study. Prior selection of statistical methodologies is essential for proper design of other portions of a protocol such as the number of animals per group or the sampling intervals for body weight. Implied in such a selection is the notion that the toxicologist has both an in-depth knowledge of the area of investigation and an understanding of the general principles of experimental design, for the analysis of any set of data is dictated to a large extent by the manner in which the data are obtained.

A second concept and its understanding are essential to the design of experiments in toxicology, that of censoring. Censoring is the exclusion of measurements from certain experimental units, or indeed of the experimental units themselves, from consideration in data analysis or inclusion in the experiment at all. Censoring may occur either prior to initiation of an experiment (where, in modern toxicology, this is almost always a planned procedure), during the course of an experiment (when they are almost universally unplanned, such as resulting from the death of animals on test), or after the conclusion of an experiment (when usually data are excluded because of being identified as some form of outlier).

In practice, a priori censoring in toxicology studies occurs in the assignment of experimental units (such as animals) to

test groups. The most familiar example is in the common practice of assignment of test animals to acute, subacute, subchronic, and chronic studies, where the results of otherwise random assignments are evaluated for body weights of the assigned members. If the mean weights are found not to be comparable by some preestablished criterion (such as a 90% probability of difference by ANOVA), then members are reassigned (censored) to achieve comparability in terms of starting body weights. Such a procedure of animal assignment to groups is known as a *censored randomization*.

The first precise or calculable aspect of experimental design encountered is determining sufficient test and control group sizes to allow one to have an adequate level of confidence in the results of a study (i.e., in the ability of the study design with the statistical tests used to detect a true difference—or effect—when it is present). The statistical test contributes a level of power to such detection. Remember that the power of a statistical test is the probability that a test results in rejection of a hypothesis, H_0 , say, when some other hypothesis, H , say, is valid. This is termed the power of the test “with respect to the (alternative) hypothesis H .”

If there is a set of possible alternative hypotheses, the power, regarded as a function of H , is termed the *power function* of the test. When the alternatives are indexed by a single parameter θ , simple graphic presentation is possible. If the parameter is a vector θ , one can visualize a *power surface*.

If the power function is denoted by $\beta(\theta)$ and H_0 specifies $\theta = \theta_0$, then the value of $\beta(\Pi)$ —the probability of rejecting H_0 when it is in fact valid—is the significance level. A test’s power is greatest when the probability of a type II error is the least. Specified powers can be calculated for tests in any specific or general situation.

Some general rules to keep in mind are the following:

- The more stringent the significance level, the greater the necessary sample size. More subjects are needed for a 1% level test than for a 5% level test.
- Two-tailed tests require larger sample sizes than one-tailed tests. Assessing two directions at the same time requires a greater investment.
- The smaller the critical effect size, the larger the necessary sample size. Subtle effects require greater efforts.
- Any difference can be significant if the sample size is large enough.
- The larger the power required, the larger the necessary sample size. Greater protection from failure requires greater effort. The smaller the sample size, the smaller the power, that is, the greater the chance of failure.
- The requirements and means of calculating necessary sample size depend on the desired (or practical) comparative sizes of test and control groups.

This number (N) can be calculated, for example, for equal-sized test and control groups, using the formula

$$N = \frac{(t_1 + t_2)^2}{d^2} S$$

where t_1 is the one-tailed t value with $N-1$ degrees of freedom (df) corresponding to the desired level of confidence, t_2 is the one-tailed t value with $N-1$ df corresponding to the probability that the sample size will be adequate to achieve the desired precision, variable “ d ” is the meaningful change in variable, and S is the sample SD, derived typically from historical data and calculated as follows:

$$S = \sqrt{\frac{1}{N-1} \sum (V_1 - V_2)^2}$$

V_1 and V_2 are the highest and lowest historical data points. There are a number of aspects of experimental designs which are specific to the practice of toxicology. Before we look at a suggestion for step-by-step development of experimental designs, these aspects should first be considered as follows:

1. Frequently, the data gathered from specific measurements of animal characteristics are such that there is wide variability in the data. Often, such wide variability is not present in a control or low-dose group, but in an intermediate dosage group, variance inflation may occur. That is, there may be a large SD associated with the measurements from this intermediate group. In the face of such a set of data, the conclusion that there is no biological effect based on a finding of no statistically significant effect might well be erroneous.
2. In designing experiments, one should keep in mind that potential effect of involuntary censoring on sample size. In other words, though a study might start with five dogs per group, this provides no margin should any die before the study is ended, and blood samples are collected and analyzed. Just enough experimental units per group frequently leave too few at the end to allow meaningful statistical analysis, and allowances should be made accordingly in establishing group sizes.
3. It is certainly possible to pool the data from several identical toxicological studies. One approach to this is meta-analysis, considered in detail later in this chapter. For example, after first having performed an acute inhalation study where only three treatment group animals survived to the point at which a critical measure (such as analysis of blood samples) was performed, we would not have enough data to perform a meaningful statistical analysis. We could then repeat the protocol with new control and treatment group animals from the same source. At the end, after assuring

ourselves that the two sets of data are comparable, we could combine (or pool) the data from survivors of the second study with those from the first. The costs of this approach, however, would then be both a greater degree of effort expended (than if we had performed a single study with larger groups) and increased variability in the pooled samples (decreasing the power of our statistical methods).

4. Another frequently overlooked design option in toxicology is the use of an unbalanced design—that is, of different group sizes for different levels of treatment. There is no requirement that each group in a study (control, low dose, intermediate dose, and high dose) have an equal number of experimental units assigned to it. Indeed, there are frequently good reasons to assign more experimental units to one group than to others, and, as we shall see later in this book, all the major statistical methodologies have provisions to adjust for such inequalities, within certain limits. The two most common uses of the unbalanced design have larger groups assigned to either the highest dose, to compensate for losses due to possible deaths during the study, or to the lowest dose to give more sensitivity in detecting effects at levels close to an effect threshold—or more confidence to the assertion that no effect exists.
5. We are frequently confronted with the situation where an undesired variable is influencing our experimental results in a nonrandom fashion. Such a variable is called a confounding variable—its presence, as discussed earlier, makes the clear attribution and analysis of effects at best difficult and at worst impossible. Sometimes such confounding variables are the result of conscious design or management decisions, such as the use of different instruments, personnel, facilities, or procedures for different test groups within the same study. Occasionally, however, such confounding variables are the result of unintentional factors or actions, in which it is called a lurking variable. Examples of such variables are almost always the result of standard operating procedures being violated, like water not being connected to a rack of animals over a weekend, a set of racks not being cleaned as frequently as others, or a contaminated batch of feed being used.
6. Finally, some thought must be given to the clear definition of what is meant by experimental unit and concurrent control.

The experimental unit in toxicology encompasses a wide variety of possibilities. It may be cells, plates of microorganisms, individual animals, litters of animals, and so on. The importance of clearly defining the experimental unit is that the number of such units per group is the “*N*” which is used in statistical calculations or analyses and critically affects such calculations.

The experimental unit is the unit which receives treatments and yields a response which is measured and becomes a datum.

A true concurrent control is one that is identical in every manner with the treatment groups except for the treatment being evaluated. This means that all manipulations, including gavaging with equivalent volumes of vehicle or exposing to equivalent rates of air exchanges in an inhalation chamber, should be duplicated in control groups just as they occur in treatment groups.

The goal of the four principles of experimental design is statistical efficiency and the economizing of resources. The single most important initial step in achieving such an outcome is to clearly define the objective of the study—get a clear statement of what questions are being asked.

For the reader who would like to further explore experimental design, there are a number of more detailed texts available which include more extensive treatments of the statistical aspects of experimental design (Federer, 1955; Myers, 1972; Cochran and Cox, 1975; Diamond, 1981; Hicks, 1982; Kraemer and Thiemann, 1987).

There are four basic experimental design types used in toxicology. These are the randomized block, Latin square, factorial design, and nested design. Other designs that are used are really combinations of these basic designs and are very rarely employed in toxicology. Before examining these four basic types, however, we must first examine the basic concept of blocking.

Blocking is, simply put, the arrangement or sorting of the members of a population (such as all of an available group of test animals) into groups based on certain characteristics which may (but are not sure to) alter an experimental outcome. Such characteristics which may cause a treatment to give a differential effect include genetic background, age, sex, overall activity levels, and so on. The process of blocking then acts (or attempts to act), so that each experimental group (or block) is assigned its fair share of the members of each of these subgroups.

We should now recall that randomization is aimed at spreading out the effect of undetectable or unsuspected characteristics in a population of animals or some portion of this population. The merging of the two concepts of randomization and blocking leads to the first basic experimental design, the randomized block. This type of design requires that each treatment group have at least one member of each recognized group (such as age), the exact members of each block being assigned in an unbiased (or random) fashion.

The second type of experimental design assumes that we can characterize treatments (whether intended or otherwise) as belonging clearly to separate sets. In the simplest case, these categories are arranged into two sets which may be thought of as rows (for, say, source litter of test animal, with the first litter as row 1, the next as row 2, etc.) and the secondary set of categories as columns (for, say, our ages of test animals, with 6–8 weeks as column 1, 8–10 weeks as column 2, etc.). Experimental units are then assigned so that each major

treatment (control, low dose, intermediate dose, etc.) appears once and only once in each row and each column. If we denote our test groups as A (control), B (low), C (intermediate), and D (high), such an assignment would appear as in the table in the succeeding text:

Source Litter	Age			
	6–8 Weeks	8–10 Weeks	10–12 Weeks	12–14 Weeks
1	A	B	C	D
2	B	C	D	A
3	C	D	A	B
4	D	A	B	C

The third type of experimental design is the factorial design, in which there are two or more clearly understood treatments, such as exposure level to test chemical, animal age, or temperature. The classical approach to this situation (and to that described under the Latin square) is to hold all but one of the treatments constant and at any one time to vary just that one factor. Instead, in the factorial design, all levels of a given factor are combined with all levels of every other factor in the experiment. When a change in one factor produces a different change in the response variable at one level of a factor than at other levels of this factor, there is an interaction between these two factors which can then be analyzed as an interaction effect.

The last of the major varieties of experimental design are the nested designs, where the levels of one factor are nested within (or are subsamples of) another factor. That is, each subfactor is evaluated only within the limits of its single larger factor.

32.3 DATA RECORDING

Two distinct sources of systematic bias may occur in data recording. One is that awareness of treatment may, consciously or subconsciously, affect the values recorded by the measurer. This can be avoided by organizing data recording so that observations are made blind. The second is that there is a systematic shift in the standard of measurement with time, coupled with a tendency for different groups to be measured at different time points. This is particularly important when a pathologist grades a lesion for severity and when the control and high-dose animals are read before the intermediate-dose animals. In some situations, it may be necessary to reread all the slides blind and in random order to be sure that diagnostic drift is avoided (Gad and Taulbee, 1996).

Valid analysis cannot be conducted unless one can distinguish animals which were examined and did not have the relevant response and animals which were not examined. It can also be important clearly to identify why data are missing. Table 32.4 identifies some basic rules for effective design of data collection forms.

TABLE 32.4 Rules for Form Design and Preparation

1. Forms should be used when some form of repetitive data must be collected. They may be either paper or electronic.
2. If only a few (two or three) pieces of data are to be collected, they should be entered into a notebook and not onto a form. This assumes that the few pieces are not a daily event, with the aggregate total of weeks/months/years ending up as lots of data to be pooled for analysis.
3. Forms should be self-contained, but should not try to repeat the content of the SOPs or method descriptions.
4. Column headings on forms should always specify the units of measurement and other details of entries to be made. The form should be arranged so that sequential entries proceed down a page, not across. Each column should be clearly labeled with a heading that identifies what is to be entered in the column. Any fixed part of entries (such as °C) should be in the column header.
5. Columns should be arranged from left to right so that there is a logical sequential order to the contents of an entry as it is made. An example would be date/time/animal number/bodyweight/name of the recorder. The last item for each entry should be the name or unique initials of the individual who made the data entry.
6. Standard conditions that apply to all the data elements to be recorded on a form or the columns of the form should be listed as footnotes at the bottom of the form.
7. Entries of data on the form should not use more digits than are appropriate for the precision of the data being recorded.
8. Each form should be clearly titled to indicate its purpose and use. If multiple types of forms are being used, each should have a unique title or number.
9. Before designing the form, carefully consider the purpose for which it is intended. What data will be collected, how often, with what instrument, and by whom? Each of these considerations should be reflected in some manner on the form. Before designing the form, carefully consider the purpose for which it is intended. What data will be collected, how often, with what instrument, and by whom? Each of these considerations should be reflected in some manner on the form. Before designing the form, carefully consider the purpose for which it is intended. What data will be collected, how often, with what instrument, and by whom? Each of these considerations should be reflected in some manner on the form.
10. Those things which are common/standard for all entries on the form should be stated as such once. These could include such things as instrument used, scale of measurement (°C, F, or K), or the location where the recording is made.

32.4 GENERALIZED METHODOLOGY SELECTION

One approach for the selection of appropriate techniques to employ in a particular situation is to use a decision tree method. Figure 32.1 is a decision tree that leads to the choice of one of three other trees to assist in technique selection, with each of the subsequent trees addressing one of the three functions of statistics that were defined earlier in this chapter. Figure 32.2 is for the selection of hypothesis-testing procedures, Figure 32.3 for modeling procedures, and Figure 32.4 for reduction of dimensionality procedures. For the vast majority of situations, these trees will guide the user into the choice of the proper technique. The tests and terms in these trees will be explained subsequently.

32.5 STATISTICAL ANALYSIS: GENERAL CONSIDERATIONS

32.5.1 Variables to Be Analyzed

Although some pathologists still regard their discipline as providing qualitative rather than quantitative data, it is abundantly clear that pathology, when applied to routine screening of animal toxicity and carcinogenicity studies, has to be quantitative to at least some degree so that statistical inferences and statements can be made about possible treatment effects. Inevitably, there will be some descriptive text which will not be appropriate for statistical analysis. However, the main objective of the pathologist should be to provide

information on the presence or absence (with severity grade or size where appropriate) of a list of conditions, consistently recorded from animal to animal and classified by well-defined criteria, which can be validly used in a statistical assessment.

Given that statistical analysis is worth doing and data are available that would be analyzed, should one then analyze all the end points recorded? Some arguments have been put forward against analyzing all the end-point studies, none of which really hold water.

One argument is that some end points are not of interest. Perhaps the study is essentially a carcinogenicity study, so that nonneoplastic end points are not considered to be “background pathology” and almost per se unrelated to treatment. However, if the pathologist has gone to the trouble of recording the data, then surely, in general, they ought to be analyzed. The costs of the statistical analysis are much less than those of doing the study and the pathology. While one might justify failure to analyze nonneoplastic data where tumor analysis has already shown that the compound is clearly carcinogenic and no longer of market potential, the general rule ought to be to analyze everything that has been specifically investigated.

Another argument put forward against doing multiple analyses is that it may yield many chance significant *p* values that have to be considered and evaluated for biological significance in the context of the entire set of available data. The whole context of dose response, as summarized in Table 32.5, must be kept in mind. A detailed look at the data can only aid interpretation, provided that one is not hide-bound by the false argument that statistical significance necessarily equates with

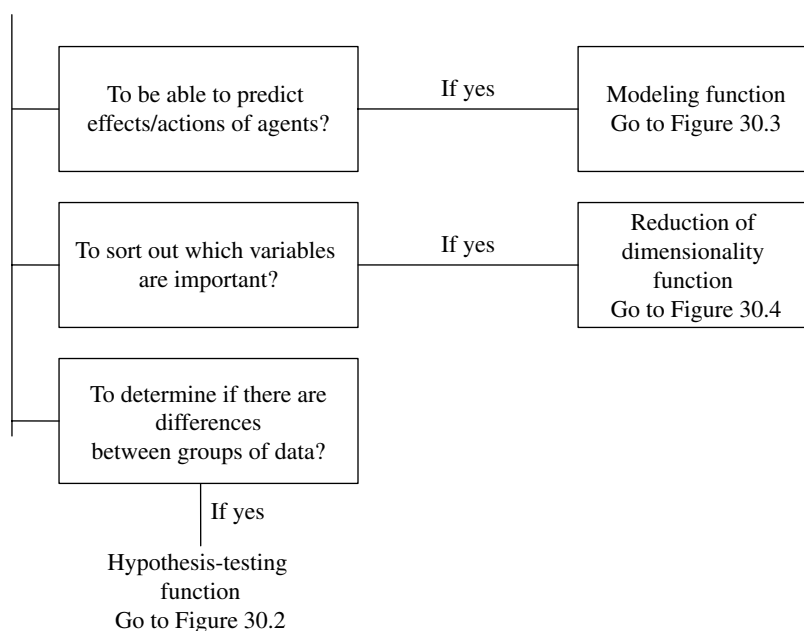

FIGURE 32.1 Overall decision tree for selecting statistical procedures.

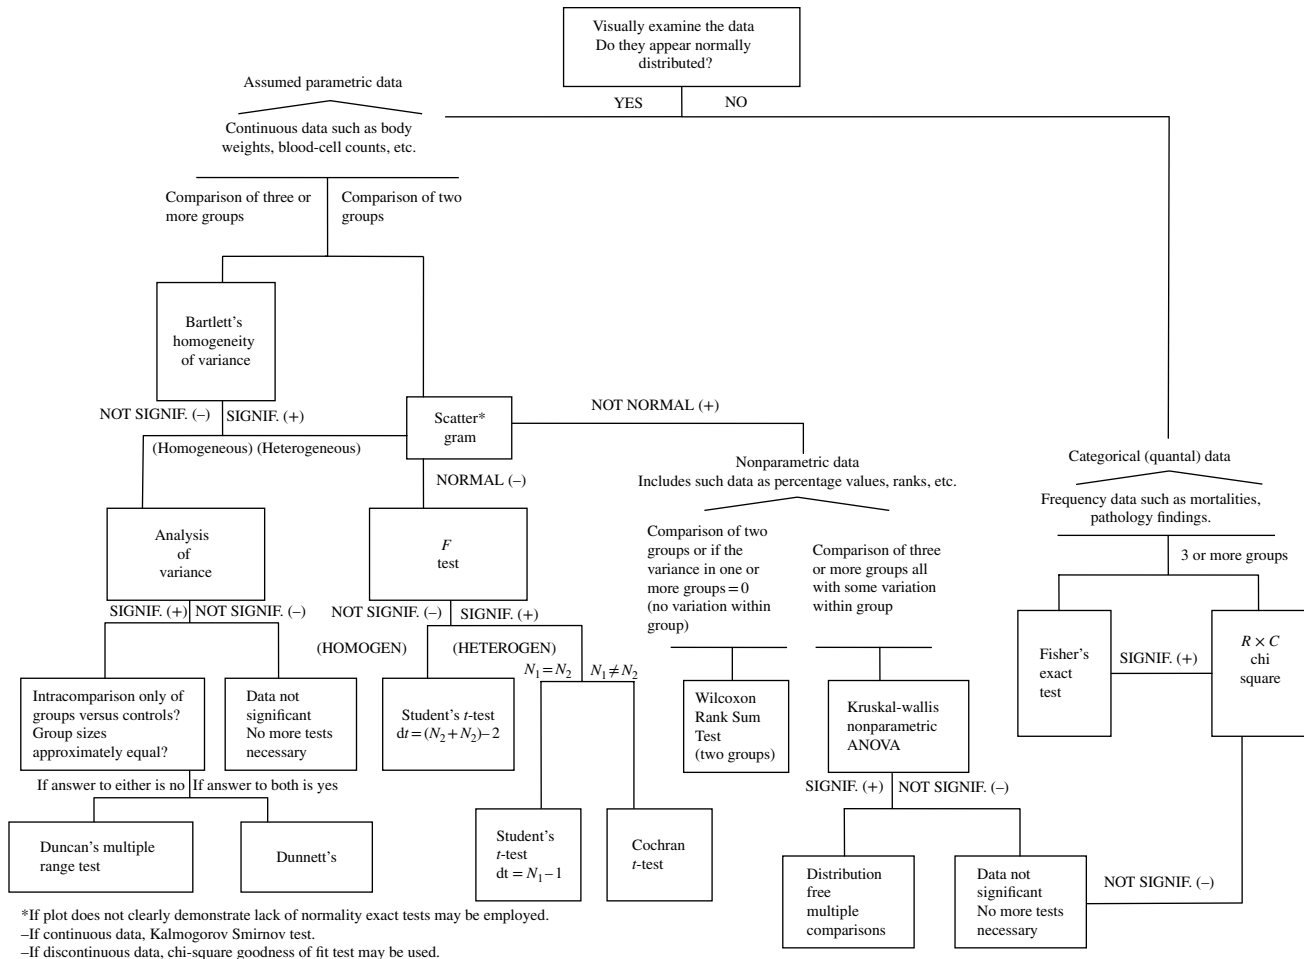

FIGURE 32.2 Decision tree for selecting hypothesis-testing procedures.

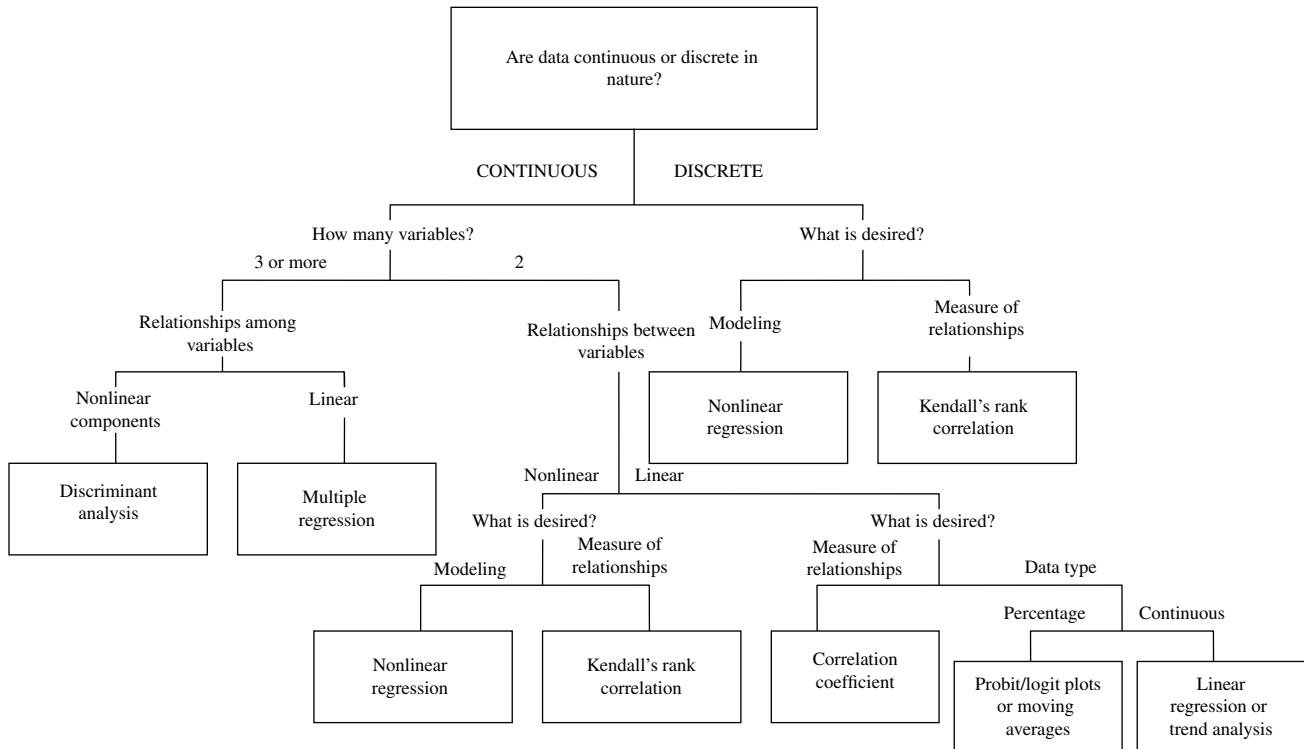

FIGURE 32.3 Decision tree for selecting modeling procedures.

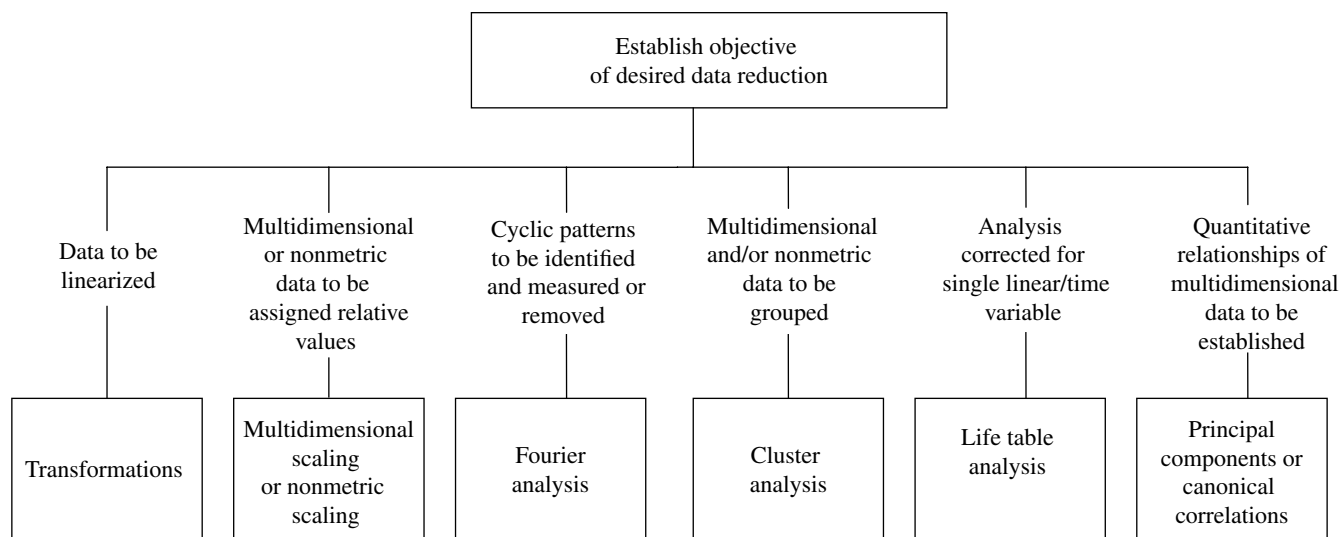

FIGURE 32.4 Decision tree for selection of reduction of dimensionality procedures.

TABLE 32.5 The Three Dimensions of Dose Response

As dose increases:

- Incidence of responders in an exposed population increases
- Severity of response in effected individuals increases
- Time to occurrence of response or of progressive stage of response decreases

biological importance and definitely indicates a true effect of treatment.

Finally, some end points occur only very rarely. One must then be clear what “very rarely” is. For a typical study with a control and three dose groups of equal size, one would get a significant trend statistics if all three cases occurred at the top-dose level or in the control group (two-tailed $p \approx 0.03$), so a total of three cases will normally be enough for statistical analysis. End points occurring once or twice only are not worth analyzing formally, although, if only seen in the top-dose group, they may be worth noting in the report. This is especially true if they are lesions that are rarely reported.

32.5.2 Combination of Observations (Such as Pathological Conditions)

There are four main situations where one might consider combining pathological conditions in a statistical analysis.

The first is when essentially the same pathological condition has been recorded under two or more different names or even under the same name in different places. Here failure to combine these conditions in the analysis may severely limit the chances of detecting a true treatment effect. It should be noted, however, that grouping together conditions which are actually different may also result in the masking of

a true treatment effect, particularly if the treatment has a very specific effect.

The second is when separately recorded pathological conditions form successive steps on the pathway of the same process. The most important example of this is for the incidence of related types of malignant tumor, benign tumor, and focal hyperplasia. It will normally be appropriate to carry out analyses of (i) incidence of malignant tumor, (ii) incidence of benign or malignant tumor, and, where appropriate, (iii) incidence of focal hyperplasia and benign or malignant tumor. It will not normally be appropriate to carry out analyses of benign tumor incidence only or of the incidence of hyperplasia only.

The third situation for combining is when the same pathological condition appears in different organs as a result of the same underlying process. Examples of this are the multicentric tumors (such as myeloid leukemia, reticulum cell sarcoma, and lymphosarcoma) or certain nonneoplastic conditions (such as arteritis/periarteritis and amyloid degeneration). Here analysis will normally be carried out only of incidence at any site, although in some situations site-specific analyses might be worth carrying out.

The final situation where an analysis of combined pathological conditions is normal is for analyses of overall incidence of malignant tumor at any site, of benign or malignant tumor at any site, or of multiple tumor incidence. While analyses of tumor incidence at specific sites are normally more meaningful, since treatments often affect only a few specific sites, these additional analyses are usually required to guard against the possibility that treatment had some weak but general tumor-enhancing effect not otherwise evident.

In some situations, one might also envisage analyses of other combinations of specific tumors, such as tumors at related sites (e.g., endocrine organs if the compound had a hormonal effect) or of similar histological type.

32.5.3 Taking Severity into Account

The same line or argument that suggests that if the pathologist records data, they should be analyzed also suggests that if the pathologist chooses to grade a condition for severity, the grade should be taken into account in the analysis. There are two ways to carry out analysis when the grade has to be taken into account. In one, analyses are carried out not only of whether or not the animal has a condition but also of whether or not the condition is at least grade 2, at least grade 3, and so on. In the other approach, nonparametric (rank) methods are used. The latter approach is more powerful, as it uses all the information in one analysis, although the output may not be so easily understood by those without some statistical training.

Note that the analyses based on grade can be carried out only if grading has been consistently applied throughout. If a condition has been scored only as present/absent for some animals, but has been graded for others, it is not possible to carry out graded analyses unless the pathologist is willing to go back and grade the specific animals showing the condition.

32.5.4 Using Simple Methods Which Avoid Complex Assumptions

Different methods for statistical analysis can vary considerably in their complexity and in the number of assumptions they make. Although the use of statistical models has its place, more so for effect estimation than for hypothesis testing, and more so in studies of complex design than in those of simple design, there are advantages in using, wherever possible, statistical methods that are simple and robust and make as few assumptions as possible. There are three reasons for this. First, such methods are more generally understandable to the toxicologist. Second, there are hardly ever extensive enough data in practice to validate any given formal model fully. Third, even if a particular model were known to be appropriate, the loss of efficiency in using appropriate simpler methods is often only very small.

The methods we advocate for routine use for the analysis of tumor incidence tend, therefore, not to be based on the use of formal parametric statistical models. For example, when studying the relationship of treatment to incidence of a pathological condition and wishing to adjust for other factors (in particular, age at death) that might otherwise bias the comparison, methods involving “stratification” are recommended, rather than a multiple regression approach or time-to-tumor models. ANOVA methods can be useful in the case of continuously distributed data for estimating treatment effects. However, they involve underlying assumptions (normally distributed variables and variability equal in each group). If these assumptions are violated, nonparametric methods based on the rank of observations, rather than their actual value, may be preferable for hypothesis testing.

32.5.5 Using All the Data

Often information is available about the relationship between a treatment and a condition of interest for groups of animals differing systematically in respect to some other factor. Obvious examples are males and females, differing times of sacrifice, and differing secondary treatments. While it will be necessary, in general, to look at the relationship within levels of this other factor, it will also be advisable to try to come to some assessment of the relationship over all levels of the other factor, and where a combined inference is not sensible, but in far more situations, this is not the case, and using all the data in one analysis allows a more powerful test of the relationship under study. Some scientists consider that conclusions for males and females should always be drawn separately, but there are strong statistical arguments for a joint analysis.

32.5.6 Combining, Pooling, and Stratification

Suppose in a hypothetical study of a toxic agent which induces tumors that do not shorten the lives of tumor-bearing animals, the data regarding the number of animals with tumor out of the number examined are as follows:

	Control	Exposed	Combined
Early deaths	1/20 (5%)	18/90 (20%)	19/110 (17%)
Late deaths	24/80 (30%)	7/10 (70%)	31/90 (34%)
Total	25/100 (25%)	25/100 (25%)	50/200 (25%)

It can be seen that if the time of death is ignored and the *pooled* data are studied, the incidence of tumors is the same in each group, resulting in the *false* conclusion that treatment had no effect. Looking within each time of death, however, an increased incidence in the exposed group can be seen. An appropriate statistical method would *combine* a measure of difference between the groups based on the early deaths and a measure of difference based on the late deaths and conclude *correctly* that incidence, after adjustment for time of death, is greater in the exposed groups.

In this example, time of death is the stratifying variable, with two strata—early deaths and late deaths. The essence of the methodology is to make comparisons only within strata (so that one is always comparing like with like except in respect to treatment) and then to combine the differences over strata. Stratification can be used to adjust for any variable or indeed combinations of variables.

Some studies are of factorial design, in which combinations of treatments are tested. The simplest such design is one in which four equal-sized groups of animals receive (i) no treatment, (ii) treatment A only, (iii) treatment B only, and (iv) treatments A and B. If one is prepared to assume that any effects of the two treatments are independent, one can use stratification to enable more powerful tests to be conducted of

the possible individual treatment effects. Thus, to test for effects of treatment A, for example, one conducts comparisons in two strata, the first consisting of groups 1 and 2 not given treatment B and the second consisting of groups 3 and 4 given treatment B. A combination of results from the two strata is based on twice as many animals and is therefore markedly more likely to detect possible effects of treatment A than a simple comparison of groups 1 and 2. There is also the possibility of identifying interactions, such as synergism and antagonism, between the two treatments.

In some routine long-term screening studies, the study design involved five groups of (usually) 50 animals of each sex, 3 of which are treated with successive doses of a compound and 2 of which are untreated controls. Assuming that there is no systematic difference between the control groups (e.g., the second control group in a different room or from a different batch of animals), it will be normal to carry out the main analyses with the control groups treated as a single group of 100 animals. It will usually be a sensible preliminary precaution to carry out additional analyses comparing incidences in the two control groups.

32.5.7 Trend Analysis, Low-Dose Extrapolation, and NOEL Estimation

While comparisons of individual treated groups with the control group are important, a more powerful test of a possible effect of treatment will be to carry out a test for a dose-related trend. This is because most true effects of treatment tend to result in a response which increases (or decreases) with increasing dose and because trend tests take into account all the data in a single analysis. In interpreting the results of trend tests, it should be noted that a significant trend does not necessarily imply an increased risk at lower doses nor, conversely, does a lack of increase at lower doses necessarily indicate evidence of a threshold (i.e., a dose below which no increase occurs).

Note that the testing for trend is seen as a more sensitive way of picking up a possible treatment effect than simple pairwise comparisons of treated and control groups. Attempting to estimate the magnitude of effects at low doses, typically below the lowest positive dose tested in the study, is a much more complex procedure and is heavily dependent on the assumed functional form of the dose-response relationship.

Deterministic trend models are based on the assumption that the trend of a time series can be approximated closely by simple mathematical functions of time over the entire span of the series. The most common representation of a deterministic trend is by means of polynomials or of transcendental functions. The time series from which the trend is to be identified is assumed to be generated by a nonstationary process where the nonstationarity results from a deterministic trend. A classical model is the regression or error model

(Anderson, 1971), where the observed series is treated as the sum of a systematic part or trend and a random part or irregular. This model can be written as

$$Z_t = Y_t + U_t'$$

where U_t is a purely random process, that is, $U_t \sim$ i.i.d. $(0, \sigma_u^2)$ (independent and identically distributed with expected value 0 and variance σ_u^2).

Trend tests are generally described as “ k -sample tests of the null hypothesis of identical distribution against an alternative of linear order,” that is, if sample i has distribution function F_i , $i = 1, \dots, k$, then the null hypothesis

$$H_0: F_1 = F_2 = \dots = F_k$$

is tested against the alternative

$$H_1: F_1 \geq F_2 \geq \dots = F_k$$

(or its reverse); at least one of the inequalities is strict. These tests can be thought of as special cases of tests of regression or correlation in which association is sought between the observations and its ordered sample index. They are also related to ANOVA except that the tests are tailored to be powerful against the subset of alternatives H_1 , instead of the more general set $\{F_i \neq F_j, \text{ some } i \neq j\}$.

Different tests arise from requiring power against specific elements or subsets of this rather extensive set of alternatives.

The most popular trend test in toxicology is currently that presented by Tarone in 1975 because it is used by the National Cancer Institute (NCI) in the analysis of carcinogenicity data. A simple, but efficient alternative is the Cox and Stuart (1955) test which is a modification of the sign test. For each point at which we have a measure (such as the incidence of animals observed with tumors), we form a pair of observations—one from each of the groups we wish to compare. In a traditional NCI bioassay, this would mean pairing control with low dose and low dose with high dose (to explore a dose-related trend) or each time period observation in a dose group (except the first) with its predecessor (to evaluate time-related trend). When the second observation in a pair exceeds the earlier observation, we record a plus sign for that pair. When the first observation is greater than the second, we record a minus sign for that pair. A preponderance of plus signs suggests a downward trend, while an excess of minus signs suggests an upward trend. A formal test at a preselected confidence level can then be performed.

More formally put, after having defined what trend we want to test for, we first match pairs as $(X_1, X_{1+c}), (X_2, X_{2+c}), \dots, (X_{n-c}, X_n)$, where $c = n'/2$ when n' is even and $c = (n' + 1)/2$ when n' is odd (where n' is the number of observations in a set).

The hypothesis is then tested by comparing the resulting number of excess positive or negative signs against a sign test table such as those found in Beyer (1976).

EXAMPLE 32.1

In a chronic feeding study in rats, we tested the hypothesis that, in the second year of the study, there was a dose-responsive increase in tumor incidence associated with the test compound. We utilize, in the succeeding text, a Cox–Stuart test for trend to address this question. All groups start the second year with an equal number of animals.

Month of Study	Control		Low Doses			High Doses		
	Total X, Animals with Tumors	Change (X_{A-B})	Total Y, Animals with Tumors	Change (Y_{A-B})	Compared to Control ($Y-X$)	Total Z, Animals with Tumors	Change (Z_{a-b})	Compared to Control ($Z-X$)
12 (A)	1	NA	0	NA	NA	5	NA	NA
13 (B)	1	0	0	0	0	7	2	(+2)
14 (C)	3	2	1	1	(-1)	11	4	(+2)
15 (D)	3	0	1	0	0	11	0	0
16 (E)	4	1	1	0	(-1)	13	2	(+1)
17 (F)	5	1	3	2	(+1)	14	1	0
18 (G)	5	0	3	0	0	15	1	(+1)
19 (H)	5	0	5	2	(+2)	18	3	(+3)
20 (I)	6	1	6	1	0	19	1	0
21 (J)	8	2	7	1	(-1)	22	3	(+1)
22 (K)	12	4	9	2	(-2)	26	4	0
23 (L)	14	2	12	3	(+1)	28	2	0
24 (M)	18	4	17	5	(+1)	31	3	(-1)
			Sum of signs		(+4)			(+6)
					(-4)			(-1)
			$Y-X = 0$					
			No trend					$Z-X = +5$

We can, of course, combine a number of observations to allow ourselves to actively test for a set of trends, such as the existence of a trend of increasing difference between two groups of animals over a period of time. This is demonstrated in Example 32.1.

ASSUMPTIONS AND LIMITATIONS

1. Trend tests seek to evaluate whether there is a monotonic tendency in response to a change in treatment. That is, the dose–response direction is absolute—as dose goes up, the incidence of tumors increases. Thus, the test loses power rapidly in response to the occurrences of “reversals”—for example, a low-dose group with a decreased tumor incidence. There are methods (Dykstra and Robertson, 1983) which “smooth the bumps” of reversals in long data series. In toxicology, however, most data series are short (i.e., there are only a few dose levels).

Tarone’s trend test is most powerful at detecting dose-related trends when tumor onset hazard functions are proportional to each other. For more power against other dose-related group differences, weighted versions of the statistic are also available (Breslow, 1984; Crowley and Breslow, 1984).

In 1985, the US *Federal Register* recommended that the analysis of tumor incidence data be carried out with a Cochran–Armitage (Cochran, 1954; Armitage, 1955) trend test. The test statistic of the Cochran–Armitage test is defined as this term:

$$T_{CA} = \frac{N}{(N-r)r} \frac{\sum_{i=0}^k (R_i - (n_i/N)r) d_i}{\sqrt{\sum_{i=0}^k (n_i/N) d_i^2 - \left(\sum_{i=0}^k (n_i/N) d_i \right)^2}}$$

with dose scores d_i . Armitage’s test statistic is the square of this term (T_{CA}^2). The actual “test” is of a contingency table form. R = row number, in increments from i to N . As one-sided

tests are carried out for an increase in tumor rates, the square is not considered. Instead, the aforementioned test statistic which is presented by Portier and Hoel (1984) is used. This test statistic is asymptotically standard normal distributed. The Cochran–Armitage test is asymptotically efficient for all monotone alternatives (Tarone, 1975), but this result only holds asymptotically, and tumors are rare events, so the binominal proportions are small. In this situation, approximations may become unreliable.

Therefore, exact tests which can be performed using two different approaches: conditional and unconditional are considered. In the first case, the total number of tumors r is regarded as fixed. As a result, the null distribution of the test statistic is independent of the common probability p . The exact conditional null distribution is a multivariate hypergeometric distribution.

The unconditional model treats the sum of all tumors as a random variable. Then the exact unconditional null distribution is a multivariate binomial distribution. The distribution depends on the unknown probability.

Such low-dose extrapolation is typically only conducted for tumors believed to be caused by a genotoxic effect which some, but by no means all, scientists believe has no threshold. For other types of tumors and for many nonneoplastic end points, a threshold cannot be estimated directly from data at a limited number of dose levels; a no-observable-effect level (NOEL) can be estimated by finding the highest dose level at which there is no significant increase in effects.

A useful technique for determining if there is an effect of treatment on any toxicological parameter is the NOSTASOT method (Tukey et al., 1985; Antonello et al., 1993). This test is based on the principle that a possible toxicological effect of interest occurs with a normal dose response, that is, there is an increasing effect with increasing dosage. The data to be analyzed should be examined first to confirm that this principle is not violated. In this method, regression analysis is used to determine if there is an increased or decreased response in a parameter with increasing dosage. This method can be visualized as a plot of response versus dosage in which the analysis determines if the slope of the plotted line deviates significantly from zero.

This method can be used for essentially all parameters. Three analyses are performed—each with different spacing between dosage levels. The spacing in the first analysis is based on the arithmetic values of the dosage levels. The spacing in the second, referred to as the ordinal scaling, has equal spacing between dosage levels, that is, the control through high-dosage levels are assigned values of 0, 1, 2, and 3. In the third analysis, the log of the dosage level is used. Since the log of zero is impractical, the control group is assigned a value based on the spacing between the low- and middle-dosage levels according to a formula that assigns a log-scale value to the control such that the ratio of the difference between the control and low-dose groups and the difference between the

low- and middle-dose groups is equal both in absolute values and in log-scale values. This places the control group at a reasonable distance from the low-dosage group. The lowest p value among the three analyses—arithmetic, ordinal, and logarithmic—is taken as the p value of the overall analysis based on the assumption that, if there is a dosage-related effect, the method of analysis yielding the lowest value is the best model for that dosage response. A correction for the multiplicity of analyses can be applied. If none of the three analyses are significant at the 0.05 level, the analysis is complete, and the high-dosage level is referred to as the “no statistical significance of trend dose” or the NOSTASOT dose. If there is a significant trend through the high-dosage level, the data from the high-dosage level are deleted and the trend test repeated. This process is repeated until a NOSTASOT dose is determined. Effects at dosage levels above the NOSTASOT dose are then considered to be statistically significant.

There are two major benefits of the NOSTASOT method. One is that spurious statistically significant results only at the low- and/or middle-dosage levels are eliminated, resulting in a reduction in false positives. A second benefit is that in some cases, there may be real effects at multiple dosage levels that at any single-dosage level are not statistically significant but will nevertheless result in a significant trend, thus providing increased sensitivity and reducing false negatives.

32.5.8 Need for Age Adjustment

Where there are marked differences in survival between treated groups, it is widely recognized that there is a need for an age adjustment (i.e., an adjustment for age at death or onset). This is illustrated in the example in the preceding text, where, because of the greater number of deaths occurring early in the treated group, the true effect of treatment disappears if no adjustment is made. Thus, a major purpose of age adjustment is to avoid bias.

It is not so generally recognized, however, that, even where there are no survival differences, age adjustment can increase the power to detect between-group differences. This is illustrated in the example in the succeeding text:

	Control	Exposed
Early deaths	0/20	0/20
Middle deaths	1/10	9/10
Late deaths	20/20	20/20
Total	21/50	29/50

Here treatment results in a somewhat earlier onset of a condition which occurs eventually in all animals. Failure to age-adjust will result in a comparison of 29/50 with 21/50, which is not statistically significant. Age adjustment will essentially ignore the early and late deaths, which contribute no comparative statistical information, and be based on the comparison of $9/10$ with $1/10$, which is statistically significant. Here age

adjustment sharpens the contrast, rather than avoiding bias, by avoiding diluting data capable of detecting treatment effects with data that are of little or no value for this purpose.

32.5.9 Need to Take Context of Observation into Account

It is now widely recognized that age adjustment cannot properly be carried out unless the context of observation is taken into account. There are three relevant contexts, the first two relating to the situation where the condition is only observed at death (e.g., an internal tumor) and the third where it can be observed in life (e.g., a skin tumor).

In the first context, the condition is assumed to have caused the death of the animal, that is, to be *fatal*. Here the incidence rate for a time interval and a group is calculated by

$$\frac{\text{Number of animals dying in the interval because of the lesion}}{\text{Number of animals alive at the start of the interval}}$$

In the second context, the animal is assumed to have died of another cause, that is, the condition is *incidental*. Here the rate is calculated by

$$\frac{\text{Number of animals dying in the interval with the lesion}}{\text{Total number of animals dying in the interval}}$$

In the third context, where the condition is *visible*, the rate is calculated by

$$\frac{\text{Number of animals getting the condition in the interval}}{\text{Number of animals without the condition at the start of the interval}}$$

A problem with the method of Peto et al. (1980), which takes context of observation into account, is that some pathologists are unwilling or feel unable to decide whether, in any given case, a condition is fatal or incidental. A number of points should be made here.

First, where there are marked survival differences, it may not be possible to conclude reliably whether a treatment is beneficial or harmful unless such a decision is made. This is well illustrated by the example of Peto et al. (1980), where assuming all pituitary tumors were fatal results in the (false) conclusion that *N*-nitrosodimethylamine (NDMA) was carcinogenic, while assuming they were all incidental resulted in the (false) conclusion that NDMA was protective. Using, correctly, the pathologist's best opinion as to which were, and which were not, likely to be fatal resulted in an analysis which (correctly) concluded NDMA had no effect. If the pathologist, in this case, had been unwilling to make a judgment as to fatality, believing it to be unreliable, no conclusion could have been reached. This state of affairs would, however, be a fact of life and *not* a position reached because an inappropriate statistical method was being used.

Although it will normally be a good routine for the pathologist to ascribe "factors contributory to death" for each animal that was not part of a scheduled sacrifice, it is in fact not strictly necessary to determine the context of observation for all conditions at the outset. An alternative strategy is to analyze under differing assumptions: (i) no cases fatal, (ii) all cases occurring in decedents fatal, and (iii) all cases of same defined severity occurring in decedents fatal, with, under each assumption, other cases incidental.

If the conclusion turns out the same under each assumption, or if the pathologist can say, on general grounds, that one assumption is likely to be a close approximation to the truth, it may not be necessary to know the context of observation for the condition in question for each individual animal. Using the alternative strategy might result in a saving of the pathologist's time by only having to make a judgment for a limited number of conditions where the conclusion seems to hinge on correct knowledge of the context of observation.

Finally, it should be noted that, although many nonneoplastic conditions observed at death are never causes of death, it is, in principle, as necessary to know the context of observation for nonneoplastic conditions as it is for tumors.

32.5.10 Experimental and Observational Units

In many situations, the animal is both the "experimental unit" and the "observational unit," but this is not always so. For determining treatment effects by the methods of the next section, it is important that each experimental unit provides only one item of data for analysis, as the methods all assume that individual data items are statistically independent. In many feeding studies, where the cage is assigned to a treatment, it is the cage, rather than the animal, that is the experimental unit. In histopathology, observations for a tissue are often based on multiple sections per animal, so that the section is the observational unit. Multiple observations per experimental unit should be combined in some suitable way into an overall average for that unit before analysis.

32.5.11 Missing Data

In many types of analysis, animals with missing data are simply removed from the analysis. There are, however, some situations where this can be an inappropriate thing to do. One situation is when carrying out an analysis of a condition that is assumed to have caused the death of the animal. Although an animal dying at week 83 for which the section was unavailable for microscopic examination cannot contribute to the group comparison at week 83, one knows that it did not die because of any condition in previous weeks, so it should contribute to the denominator of the calculations in all previous weeks.

Another situation is when histopathological examination of a tissue is not carried out unless an abnormality is seen post-mortem. In such an experiment, one might have the following data for that tissue:

- *Control group*: 50 animals, 2 abnormal postmortem, 2 examined microscopically, and 2 with tumor of specific type
- *Treated group*: 50 animals, 15 abnormal postmortem, 15 examined microscopically, and 14 with tumor of specific type

Ignoring animals with no microscopic sections, one would compare $2/2 = 100\%$ with $14/15 = 93\%$ and conclude treatment nonsignificantly decreased incidence. This is likely to be a false conclusion, and it would be better here to compare the percentages of animals which had a postmortem abnormality which turned out to be a tumor, that is, $2/50 = 4\%$ with $14/50 = 28\%$. Unless some aspect of treatment made tumors much easier to detect postmortem, one could then conclude that treatment did have an effect on tumor incidence.

Particular care has to be taken in studies where the procedures for histopathological examination vary by group. In a number of studies conducted in recent years, the protocol demands full microscopic examination of a given tissue list in decedents in all groups and in terminally killed controls in high-dose animals. In other animals, terminally killed low- and mid-dose animals, microscopic examination of a tissue is only conducted if the tissue is found to be abnormal postmortem. Such a protocol is designed to save money but leads to difficulty in comparing the treatment groups validly. Suppose, for example, responses in terminally killed animals are $8/20$ in the controls and $3/3$ (with 17 unexamined) in the low-dose and $5/6$ (with 14 unexamined) in the mid-dose animals. Is one supposed to conclude that treatment at the low and mid doses increased response, based on a comparison of the proportions examined microscopically (40%, 100%, and 83%), or that it decreased response, based on the proportion of animals in the group (40%, 15%, and 25%)? It could well be that treatment had no effect, but some small tumors were missed postmortem. In this situation, a valid comparison can only be achieved by ignoring the low- and mid-dose groups when carrying out the comparison for the age stratum “terminal kill.” This, of course, seems wasteful of data, but these are data that cannot be usefully used owing to the inappropriate protocol.

32.5.12 Use of Historical Control Data

In some situations, particularly where incidences are low, the results from a single study may suggest an effect of treatment on tumor incidence but be unable to demonstrate it conclusively. The possibility of comparing results in the treated groups with those of control groups from other

studies is then often raised. Thus, a nonsignificant incidence of 2 cases out of 50 in a treated group may seem much more significant if no cases have been seen in, say, 1000 animals representing controls from 20 similar studies. Conversely, a significant incidence of 5 cases out of 50 in a treated group as compared with 0 out of 50 in the study controls may seem far less convincing if many other control groups had incidences around 5 out of 50.

While not understating the importance of looking at historical control data, it must be emphasized that there are a number of reasons why variation between studies may be greater than variation within study. Differences in diet, in duration of the study, in intercurrent mortality, and in who the study pathologist is may all contribute. Statistical techniques that ignore this and carry out simple statistical tests of treatment incidence against a pooled control incidence may well give results that are seriously in error and are likely to overstate statistical significance considerably.

32.5.13 Methods for Data Examination and Preparation

The data from toxicology studies should always be examined before any formal analysis. Such examinations should be directed to determining if the data are suitable for analysis and if so what form the analysis should take (see Figure 32.2). If the data as collected are not suitable for analysis, or if they are only suitable for low-powered analytic techniques, one may wish to use one of the many forms of data transformation to change the data characteristics so that they are more amenable to analysis.

The previous two objectives, data examination and preparation, are the primary focus of this chapter. For data examination, two major techniques are presented—the scattergram and Bartlett’s test. Likewise, for data preparation (with the issues of rounding and outliers having been addressed previously) two techniques are presented; randomization (including a test for randomness in a sample of data) and transformation. Exploratory data analysis (EDA) is presented and briefly reviewed later. This is a broad collection of techniques and approaches to “probe” data—that is, to both examine and to perform some initial, flexible analysis of the data.

32.5.14 Scattergram

Two of the major points to be made throughout this volume are (i) the use of the appropriate statistical tests, and (ii) the effects of small sample sizes (as is often the case in toxicology) on our selection of statistical techniques. Frequently, simple examination of the nature and distribution of data collected from a study can also suggest patterns and results which were unanticipated and for which the use of additional or alternative statistical methodology is warranted. It was these three points which caused the author to consider a

section on scattergrams and their use essential for toxicologists.

Bartlett's test may be used to determine if the values in groups of data are homogeneous. If they are, this (along with the knowledge that they are from a continuous distribution) demonstrates that parametric methods are applicable.

But if the values in the (continuous data) groups fail Bartlett's test (i.e., are heterogeneous), we cannot be secure in our belief that parametric methods are appropriate until we gain some confidence that the values are normally distributed. With large groups of data, we can compute parameters of the population (kurtosis and skewness, in particular) and from these parameters determine if the population is normal (with a certain level of confidence). If our concern is especially marked, we can use a chi-square goodness-of-fit test for normality. But when each group of data consists of 25 or fewer values, these measures or tests (kurtosis, skewness, and chi-square goodness-of-fit) are not accurate indicators of normality. Instead, in these cases, we should prepare a scattergram of the data and then evaluate the scattergram to estimate if the data are normally distributed. This procedure consists of developing a histogram of the data and then examining the histogram to get a visual appreciation of the location and distribution of the data.

The abscissa (or horizontal scale) should be in the same scale as the values and should be divided so that the entire range of observed values is covered by the scale of the

abscissa. Across such a scale, we then simply enter symbols for each of our values. Example 32.2 shows such a plot.

Figure 32.5 is a traditional and rather limited form of scatterplot, but such plots can reveal significant information about the amount and types of association between the two variables, the existence and nature of outliers, the clustering of data, and a number of other two-dimensional factors (Anscombe, 1973; Chambers et al., 1983; Gad, 1985).

Current technology allows us to add significantly more graphic information to scatterplots by means of graphic symbols (letters, faces, different shapes such as squares, colors, etc.) for the plotted data points. One relatively simple example of this approach is shown in Figure 32.5, where the simple case of dose (in a dermal study), dermal irritation, and white blood cell (WBC) count is presented. This graph quite clearly suggests that as dose (variable *x*) is increased, dermal irritation (variable *y*) also increases, and as irritation becomes more severe, WBC count (variable *z*) an indicator of immune system involvement, suggesting infection or persistent inflammation, also increases. There is no direct association of variables *x* and *z*, however (Cleveland and McGill, 1984; Cleveland, 1985; Tufte, 1990).

Group 1 can be seen to approximate a normal distribution (bell-shaped curve); we can proceed to perform the appropriate parametric tests with such data. But group 2 clearly does not appear to be normally distributed. In this case, the appropriate nonparametric technique must be used.

FIGURE 32.5 Exploratory data analysis (EDA).

EXAMPLE 32.2

Suppose we have the two data sets in the succeeding text:

Group 1: 4.5, 5.4, 5.9, 6.0, 6.4, 6.5, 6.9, 7.0, 7.1, 7.0, 7.4, 7.5, 7.5, 7.5, 7.6, 8.0, 8.1, 8.4, 8.5, 8.6, 9.0, 9.4, 9.5, and 10.4

Group 2: 4.0, 4.5, 5.0, 5.1, 5.4, 5.5, 5.6, 6.5, 6.5, 7.0, 7.4, 7.5, 7.5, 8.0, 8.1, 8.5, 8.5, 9.0, 9.1, 9.5, 9.5, 10.1, 10.0, and 10.4

Both of these groups contain 24 values and cover the same range. From these, we can prepare the following scattergrams:

Group 1

Group 2

X is individual datum point; χ (chi) is calculated value.

32.5.15 Bartlett’s Test for Homogeneity of Variance

Bartlett’s test (Sokal and Rohlf, 1994) is used to compare the variances (values reflecting the degree of variability in data sets) among three or more groups of data, where the data in the groups are continuous sets (such as body weights, organ weights, red blood cell [RBC] counts, or diet consumption measurements). It is expected that such data will be suitable for parametric methods (normality of data is assumed) and Bartlett’s is frequently used as a test for the assumption of equivalent variances.

Bartlett’s is based on the calculation of the corrected χ² (chi-square) value by the formula

$$\chi_{\text{corr}}^2 = 2.3026 \frac{\sum df \left(\log_{10} \left\{ \frac{\sum [df(S^2)]}{\sum df} \right\} \right) - \sum [df (\log_{10} S^2)]}{1 + \left\{ \frac{1}{3(K-1)} \right\} \left[\sum (1/df) - (1/\sum df) \right]}$$

where

- S² = variance = [n ΣX² - (Σ X)²/n]/(n - 1)
- X = individual datum within each group
- n = number of data within each group
- K = number of groups being compared
- df = df for each group = (N - 1).

The corrected χ² value yielded by the earlier calculations is compared to the values listed in the chi-square table according to the number of df (Snedecor and Chocran, 2014).

If the calculated value is smaller than the table value at the selected p level (traditionally 0.05), the groups are accepted to

ASSUMPTIONS AND LIMITATIONS

1. Bartlett’s test does not test for normality but rather homogeneity of variance (also called equality of variances or homoscedasticity).
2. Homoscedasticity is an important assumption for Student’s t-test, ANOVA, and analysis of covariance (ANCOVA).
3. The F-test (covered in the Section 32.5.16) is actually a test for the two-sample (i.e., control and one test group) case of homoscedasticity. Bartlett’s test is designed for three or more samples.
4. Bartlett’s test is very sensitive to departures from normality. As a result, a finding of a significant chi-square value in Bartlett’s test may indicate nonnormality rather than heteroscedasticity. Such a finding can be brought about by outliers, and the sensitivity to such erroneous findings is extreme with small sample sizes.

be homogeneous, and the use of ANOVA is assumed proper. If the calculated χ^2 is greater than the table value, the groups are heterogeneous and other tests (as indicated in Figure 32.2, the decision tree) are necessary.

32.5.16 Statistical Goodness-of-Fit Tests

A goodness-of-fit test is a statistical procedure for comparing individual measurements to a specified type of statistical distribution. For example, a normal distribution is completely specified by its arithmetic mean and variance (the square of the SD). The null hypothesis, that the data represent a sample from a single normal distribution, can be tested by a statistical goodness-of-fit test. Various goodness-of-fit tests have been devised to determine if the data deviate significantly from a specified distribution. If a significant departure occurs, it indicates only that the specified distribution can be rejected with some assurance. This does not necessarily mean that the true distribution contains two or more subpopulations. The true distribution may be a single distribution, based upon a different mathematical relationship, for example, lognormality. In the latter case, logarithms of the measurement would not be expected to exhibit by a goodness-of-fit test a statistically significant departure from a lognormal distribution.

Everitt and Hand (1981) recommended the use of a sample of 200 or more to conduct a valid analysis of mixtures of populations. Even the maximum likelihood method, the best available method, should be used with extreme caution, or not at all, when separation between the means of the subpopulations is less than 3 SD and sample sizes are less than 300. None of the available methods conclusively establish bimodality, which may, however, occur when separation between the two means (modes) exceeds 2 SD. Conversely, inflections in probits or separations in histograms *less than 2 SD* apart may arise from genetic differences in test subjects.

Mendell et al. (1993) compared eight tests of normality to detect a mixture consisting of two normally distributed components with different means but equal variances. Fisher's skewness statistic was preferable when one component comprised less than 15% of the total distribution. When the two components comprised more nearly equal proportions (35–65%) of the total distribution, the Engelman and Hartigan (1969) test was preferable. For other mixing proportions, the maximum likelihood ratio test was best. Thus, the maximum likelihood ratio test appears to perform very well, with only small loss from optimality, even when it is not the best procedure.

The method of *maximum likelihood* provides estimators which are usually quite satisfactory. They have the desirable properties of being consistent, asymptotically normal, and asymptotically efficient for large samples under quite general conditions. They are often biased, but the bias is frequently removable by a simple adjustment. Other methods of obtain-

ing estimators are also available, but the maximum likelihood method is the most frequently used.

Maximum likelihood estimators also have another desirable property: *invariance*. Let us denote the maximum likelihood estimator of the parameter θ by $\hat{\sigma}$. Then, if $f(\theta)$ is a single-valued function of θ , the maximum likelihood estimator of $f(\theta)$ is $f(\hat{\sigma})$. Thus, for example, $\hat{\sigma} = (\hat{\sigma}^2)^{1/2}$.

The principle of maximum likelihood tells us that we should use as our estimate that value which maximizes the likelihood of the observed event.

These maximum likelihood methods can be used to obtain *point estimates* of a parameter, but we must remember that a point estimator is a random variable distributed in some way around the true value of the parameter. The true parameter value may be higher or lower than our estimate. It is often useful therefore to obtain an interval within which we are reasonably confident the true value will lie, and the generally accepted method is to construct what are known as *confidence limits*.

The following procedure will yield upper and lower 95% confidence limits with the property that when we say that these limits include the true value of the parameter, 95% of all such statements will be true and 5% will be incorrect:

1. Choose a (test) statistic involving the unknown parameter and no other unknown parameter.
2. Place the appropriate sample values in the statistic.
3. Obtain an equation for the unknown parameter by equating the test statistic to the upper 2½% point of the relevant distribution.
4. The solution of the equation gives one limit.
5. Repeat the process with the lower 2½% point to obtain the other limit.

One can also construct 95% CI using unequal tails (e.g., using the upper 2% point and the lower 3% point). We usually want our CI to be as short as possible, however, and with a symmetrical distribution such as the normal or *t*, this is achieved using equal tails. The same procedure very nearly minimizes the CI with other nonsymmetrical distributions (e.g., chi-square) and has the advantage of avoiding rather tedious computations.

When the appropriate statistic involves the square of the unknown parameter, both limits are obtained by equating the statistic to the upper 5% point of the relevant distribution. The use of two tails in this situation would result in a pair of nonintersecting intervals. When two or more parameters are involved, it is possible to construct a region within which we are reasonably confident the true parameter values will lie. Such regions are referred to as confidence regions. The implied interval for p_1 does not form a 95% CI, however. Nor is it true that an 85.7375% confidence region for $p_1, p_2,$ and

p_3 can be obtained by considering the intersection of the three separate 95% CI, because the statistics used to obtain the individual CI are not independent. This problem is obvious with a multiparameter distribution such as the multinomial, but it even occurs with the normal distribution because the statistic which we use to obtain a CI for the mean and the statistic which we use to obtain a CI for the variance are not independent. The problem is not likely to be of great concern unless a large number of parameters are involved.

32.5.17 Randomization

Randomization is the act of assigning a number of items (e.g., plates of bacteria or test animals) to groups in such a manner that there is an equal chance for any one item to end up in any one group. This is a control against any possible bias in assignment of subjects to test groups. A variation on this is censored randomization, which ensures that the groups are equivalent in some aspect after the assignment process is complete. The most common example of a censored randomization is one in which it is ensured that the body weights of test animals in each group are not significantly different from those in the other groups. This is done by analyzing group weights both for homogeneity of variance and by ANOVA after animal assignment and then rerandomizing if there is a significant difference at some nominal level, such as $p \leq 0.10$. The process is repeated until there is no significant difference.

There are several methods for actually performing the randomization process. The three most commonly used are card assignment, use of a random number table, and use of a computerized algorithm.

For the card-based method, individual identification numbers for items (e.g., plates or animals) are placed on separate index cards. These cards are then shuffled, placed one at a time in succession into piles corresponding to the required test groups. The results are a random group assignment.

The random number table method requires only that one that has unique numbers assigned to test subjects and access to a random number table. One simply sets up a table with a column for each group to which subjects are to be assigned. We start from the head of any one column of numbers in the random table (each time the table is used, a new starting point should be utilized). If our test subjects number less than 100, we utilize only the last two digits in each random number in the table. If they number more than 99 but less than 1000, we use only the last three digits. To generate group assignments, we read down a column, one number at a time. As we come across digits which correspond to a subject number, we assign that subject to a group (enter its identifying number in a column) proceeding to assign subjects to groups from left to right filling one row at a time. After a number is assigned to an animal, any duplication of its unique number is ignored.

We use as many successive columns of random numbers as we may need to complete the process.

The third (and now most common) method is to use a random number generator that is built into a calculator or computer program. Procedures for generating these are generally documented in user manuals.

32.5.18 Transformations

If our initial inspection of a data set reveals it to have an unusual or undesired set of characteristics (or to lack a desired set of characteristics), we have a choice of three courses of action. We may proceed to select a method or test appropriate to this new set of conditions, or abandon the entire exercise, or transform the variable(s) under consideration in such a manner that the resulting transformed variates (e.g., X' and Y' , as opposed to the original variates X and Y) meet the assumptions or have the characteristics that are desired.

The key to all this is that the scale of measurement of most (if not all) variables is arbitrary. Although we are most familiar with a linear scale of measurement, there is nothing which makes this the "correct" scale on its own, as opposed to a logarithmic scale (familiar logarithmic measurements are that of pH values or earthquake intensity [Richter scale]). Transforming a set of data (converting X to X') is really as simple as changing a scale of measurement. There are at least four good reasons to transform data:

1. To normalize the data, making them suitable for analysis by our most common parametric techniques such as ANOVA. A simple test of whether a selected transformation will yield a distribution of data which satisfy the underlying assumptions for ANOVA is to plot the cumulative distribution of samples on probability paper (i.e., a commercially available paper which has the probability function scale as one axis). One can then alter the scale of the second axis (i.e., the axis other than the one which is on a probability scale) from linear to any other (logarithmic, reciprocal, square root, etc.,) and see if a previously curved line indicating a skewed distribution becomes linear to indicate normality. The slope of the transformed line gives us an estimate of the SD, and if the slopes of the lines of several samples or groups of data are similar, we accordingly know that the variance of the different groups is homogenous.
2. To linearize the relationship between a paired set of data, such as dose and response. This is the most common use in toxicology for transformations and is demonstrated in the section under probit/logit plots.
3. To adjust data for the influence of another variable. This is an alternative in some situations to the more complicated process of ANCOVA. A ready example of this usage is the calculation of organ weight to body

weight ratios in *in vivo* toxicity studies, with the resulting ratios serving as the raw data for an ANOVA performed to identify possible target organs. This use is discussed in detail later in this chapter.

- Finally, to make the relationships between variables clearer by removing or adjusting for interactions with third, fourth, and so on. Uncontrolled variables influence the pair of variables of interest. This case is discussed in detail under time series analysis.

Common transformations are presented in Table 32.6.

32.5.19 Exploratory Data Analysis

Over the past 20 years, an entirely new approach has been developed to get the most information out of the increasingly larger and more complex data sets that scientists are faced with. This approach involves the use of a very diverse set of fairly simple techniques which comprise EDA. As expounded by Tukey (1977), there are four major ingredients to EDA:

Displays: These visually reveal the behavior of the data and suggest a framework for analysis. The scatterplot (presented earlier) is an example of this approach.

Residuals: These are what remain of a set of data after a fitted model (such as a linear regression) or some similar level of analysis has been removed.

Reexpressions: These involved questions of what scale would serve to best simplify and improve the analysis of the data. Simple transformations, such as those presented earlier in this chapter, are used to simplify data behavior (e.g., linearizing or normalizing) and clarify analysis.

Resistance: This is a matter of decreasing the sensitivity of analysis and summary of data to misbehavior, so that the occurrence of a few outliers, for example, will not complicate or invalidate the methods used to ana-

lyze the data. For example, in summarizing the location of a set of data, the median (but not the arithmetic mean) is highly resistant.

These four ingredients are utilized in a process falling into two broad phases: an exploratory phase and a confirmatory phase. The exploratory phase isolates patterns in and features of the data and reveals them, allowing an inspection of the data before there is any firm choice of actual hypothesis testing or modeling methods have been made.

Confirmatory analysis allows evaluation of the reproducibility of the patterns or effects. Its role not only is close to that of classical hypothesis testing but also often includes steps such as (i) incorporating information from an analysis of another, closely related set of data and (ii) validating a result by assembling and analyzing additional data. These techniques are in general beyond the scope of this text. However, Velleman and Hoaglin (1981) and Hoaglin and Mosteller (2000) present a clear overview of the more important methods, along with codes for their execution on a microcomputer (they have also now been incorporated into Minitab). A short examination of a single case of the use of these methods, however, is in order.

Toxicology has long recognized that no population—animal or human—is completely uniform in its response to any particular toxicant. Rather, a population is composed of a (presumably normal) distribution of individuals—some resistant to intoxication (hyporesponders), the bulk that responds close to a central value (such as an LD₅₀), and some that are very sensitive to intoxication (hyperresponders). This population distribution can, in fact, result in additional statistical techniques. The sensitivity of techniques such as ANOVA is reduced markedly by the occurrence of outliers (extreme high or low values—including hyper- and hyporesponders) which, in fact, serve to markedly inflate the variance (SD) associated with a sample. Such variance inflation is particularly common in small groups that are exposed or dosed at just over or under a threshold level, causing a small

TABLE 32.6 Common Data Transformations^a

Transformation	Means of Calculation ^b	Example of Use
Arithmetic	$x' = x/y$ or $x' = x + c$	Organ weight/body weight
Reciprocals	$x' = 1/x$	Linearizing data, particularly rate phenomena
Arcsine (also called angular)	$x' = \arcsine \sqrt{x}$	Normalizing dominant lethal and mutation rate data
Logarithmic	$x' = \log x$	pH values
Probability (probit)	$x' = p(x)$	Percentage responding
Square roots	$x' = \sqrt{x}$	Surface area of animal from body weights
Box-Cox	$x' = (x^v - 1)/v$: for $v \neq 0$ $x' = \ln x$: for $v = 0$	A family of transforms For use when one has no prior knowledge of the appropriate transformation to use
Rank transformations	Depends on nature of samples	As a bridge between parametric and nonparametric statistics (Conover and Inman, 1981)

^a Plotting a double reciprocal (i.e., 1/x vs. 1/y) will linearize almost any data set. So will plotting the log transforms of a set of variables.

^b x and y are original variables and x' and y' transformed values. "c" stands for a constant.

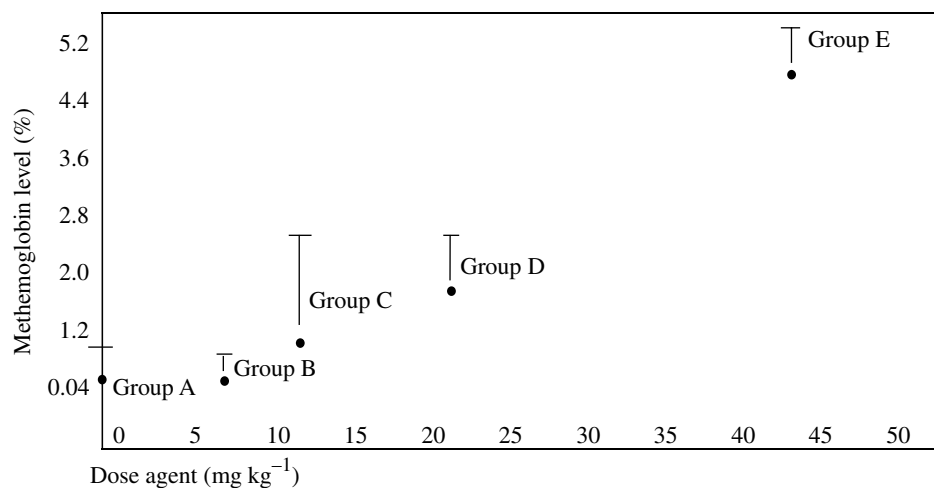

FIGURE 32.6 Variance inflation: points are means minus error bars plus one SD.

number of individuals in the sample (who are more sensitive than the other members) to respond markedly. Such a situation is displayed in Figure 32.6 which plots the mean and SD of methemoglobin levels in a series of groups of animals exposed to successively higher levels of a hemolytic agent.

Though the mean level of methemoglobin in group C is more than double that of the control group (A), no hypothesis test will show this difference to be significant because it has such a large SD associated with it. Yet this “inflated” variance exists because a single individual has such a marked response. The occurrence of the inflation is certainly an indicator that the data need to be examined closely. Indeed, all tabular data in toxicology should be visually inspected for both trend and variance inflation.

A concept related (but not identical) to resistance and EDA is that of robustness. Robustness generally implies insensitivity to departures from assumptions surrounding an underlying model, such as normality.

In summarizing the location of data, the median, though highly resistant, is not extremely robust. But the mean is both nonresistant and nonrobust.

32.6 HYPOTHESIS TESTING OF CATEGORICAL AND RANKED DATA

Categorical (or contingency table) presentations of data can contain any single type of data, but generally the contents are collected and arranged so that they can be classified as belonging to treatment and control groups, with the members of each of these groups then classified as belonging to one of two or more response categories (such as tumor/no tumor or normal/hyperplastic/neoplastic). For these cases, two forms of analysis are presented—Fisher’s exact test (for the 2×2 contingency table) and the $R \times C$ chi-square test (for large tables). It should be noted, however, that there are ver-

sions of both of these tests which permit the analysis of any size of contingency table.

The analysis of rank data—what is generally called non-parametric statistical analysis—is an exact parallel of the more traditional (and familiar) parametric methods. There are methods for the single comparison case (just as Student’s t -test is used) and for the multiple comparison case (just as ANOVA is used) with appropriate *post hoc* tests for exact identification of the significance with a set of groups. Four tests are presented for evaluating statistical significance in rank data—the Wilcoxon rank-sum test, distribution-free multiple comparisons, Mann–Whitney U test, and the Kruskal–Wallis nonparametric ANOVA. For each of these tests, tables of distribution values for the evaluations of results can be found in any of a number of reference volumes (Gad, 2005).

It should be clearly understood that for data which do not fulfill the necessary assumptions for parametric analysis, these nonparametric methods are either as powerful or in fact more powerful than the equivalent parametric test.

32.6.1 Fisher’s Exact Test

Fisher’s exact test should be used to compare two sets of discontinuous, quantal (all or none) data. Small sets of such data can be checked by contingency data tables, such as those of Finney et al., (1963). Larger sets, however, require computation. These include frequency data such as incidences of mortality or certain histopathological findings, and so on. Thus, the data can be expressed as ratios. These data do not fit on a continuous scale of measurement but usually involve a number of responses classified as either negative or positive—that is, contingency table situation (Sokal and Rohlf, 2011).

The analysis is started by setting up a 2×2 contingency table to summarize the number of “positive” and “negative” responses as well as the totals of these, as follows:

	“Positive”	“Negative”	Total
Group I	<i>A</i>	<i>B</i>	<i>A+B</i>
Group II	<i>C</i>	<i>D</i>	<i>C+D</i>
Totals	<i>A+C</i>	<i>B+D</i>	<i>A+B+C+D = N_{total}</i>

Using the earlier set of symbols, the formula for *P* appears as follows:¹

$$P = \frac{(A+B)!(C+D)!(A+C)!(B+D)!}{N!A!B!C!D!}$$

The exact test produces a probability (*P*) which is the sum of the previous calculation repeated for each possible arrangement of the numbers in the earlier cells (i.e., *A*, *B*, *C*, and *D*) showing an association equal to or stronger than that between the two variables.

The *P* resulting from these computations will be the exact one- or two-tailed probability depending on which of these two approaches is being employed. This value tells us if the groups differ significantly (with a probability <0.05) and the degree of significance.

ASSUMPTIONS AND LIMITATIONS

1. Tables are available which provide individual exact probabilities for small sample size contingency tables (see Zar, 1974, pp. 518–542).
2. Fisher’s exact test must be used in preference to the chi-square test when there are small cell numbers.
3. The probability resulting from a two-tailed test is exactly double that of a one-tailed test from the same data.
4. Ghent has developed and proposed a good (though, if performed by hand, laborious) method extending the calculation of exact probabilities to 2×3, 3×3, and *R* × *C* contingency tables (Ghent, 1972).
5. Fisher’s probabilities are not necessarily symmetrical. Although some analysts will double the one-tailed *p* value to obtain the two-tailed result, this method is usually overly conservative.

32.6.2 2×2 Chi-Square

Though Fisher’s exact test is preferable for analysis of most 2×2 contingency tables in toxicology, the chi-square test is still widely used and is preferable in a few unusual situations (particularly if cell sizes are large yet only limited computational support is available).

¹ *A*! is *A* factorial. For 4! as an example this would be (4) (3) (2) (1) = 24.

The formula is simply

$$\chi^2 = \frac{(O_1 - E_1)^2}{E_1} + \frac{(O_2 - E_2)^2}{E_2}$$

$$= \sum \frac{(O_i - E_i)^2}{E_i}$$

where *O* are observed numbers (or counts) and *E* are expected numbers. The common practice in toxicology is for the observed figures to be test or treatment group counts. The expected figure is calculated as

$$E = \frac{(\text{column total})(\text{row total})}{\text{grand total}}$$

for each box or cell in a contingency table.

Our df are (R-1)(C-1) = (2-1)(2-1) = 1. Looking at a chi-square table (provided in Gad, 2005) for 1 df, we see that this is greater than the test statistic at 0.05 (3.84) but less than that at 0.01 (6.64) so that 0.05 > *p* > 0.01.

ASSUMPTIONS AND LIMITATIONS

Assumptions

1. Data are univariate and categorical.
2. Data are from a multinomial population.
3. Data are collected by random, independent sampling.
4. Groups being compared are of approximately same size, particularly for small group sizes.

When to Use:

1. The data are of a categorical (or frequency) nature.
2. The data fit the earlier assumptions.
3. Goodness-to-fit to a known form of distribution is being tested.
4. Cell sizes are large.

When Not to Use

1. The data are continuous rather than categorical.
2. Sample sizes are small and very unequal.
3. Sample sizes are too small (e.g., when total *N* is less than 50 or if any expected value is less than 5).
4. Any 2×2 comparison is being performed (use Fisher’s exact test instead).

32.6.3 R×C Chi-Square

The *R*×*C* chi-square test can be used to analyze discontinuous (frequency) data as in Fisher’s exact or 2×2 chi-square tests. However, in the *R*×*C* test (*R* = row; *C* = column) we

wish to compare three or more sets of data. An example would be comparison of the incidence of tumors among mice on three or more oral dosage levels. We can consider the data as “positive” (tumors) or “negative” (no tumors). The expected frequency for any box = (row total)(column total)/(N_{total}).

As in Fisher’s exact test, the initial step is setting up a table (this time an $R \times C$ contingency table). This table would appear as follows:

	“Positive”	“Negative”	Total
Group I	A_1	B_1	$A_1 + B_1 = N_1$
Group II	A_2	B_2	$A_2 + B_2 = N_2$
	↓	↓	
Group R	A_R	B_R	$A_R + B_R = N_R$
Totals	N_A	N_B	N_{total}

Using these symbols, the formula for chi-square (χ^2) is

$$\chi^2 = \frac{N_{tot}^2}{N_A N_B N_K} \left(\frac{A_1^2}{N_1} + \frac{A_2^2}{N_2} + \dots + \frac{A_K^2}{N_K} - \frac{A_A^2}{N_{tot}} \right)$$

The resulting χ^2 value is compared to table values (as in Snedecor and Cochran (2014) pp. 470–471) according to the number of df, which is equal to $(R - 1)(C - 1)$. If χ^2 is smaller than the table value at the 0.05 probability level, the groups are not significantly different. If the calculated χ^2 is larger, there is some difference among the groups, and $2 \times R$ chi-square or Fisher’s exact tests will have to be compared to determine which group(s) differs from which other group(s).

ASSUMPTIONS AND LIMITATIONS

1. The test is based on data being organized in a table (such as below) with *cells* (in the following table, A, B, C, and D are “cells”)

		Columns (C)		
		Control	Treated	Total
Rows (R)	No Effect	A	B	A + B
	Effect	C	D	C + D
Total		A + C	B + D	A + B + C + D

2. None of the expected frequency values should be less than 5.0.
3. The chi-square test is always one tailed.
4. Without the use of some form of correction, the test becomes less accurate as the differences between group sizes increase.

5. The results from each additional column (group) are approximately additive. Due to this characteristic, the chi-square test can be readily used for evaluating any $R \times C$ combination.
6. The results of the chi-square calculation must be a positive number.
7. The test is weak with either small sample sizes or when the expected frequency in any cell is less than 5 (this latter limitation can be overcome by pooling, or combining, cells).
8. Test results are independent of order of cells, unlike Kolmogorov–Smirnov.
9. The test can be used to test the probability of validity of any distribution.

32.6.4 Wilcoxon Rank-Sum Test

The Wilcoxon rank-sum test is commonly used for the comparison of two groups of nonparametric (interval or not normally distributed) data, such as those which are not measured exactly but rather as falling within certain limits (e.g., how many animals died during each hour of an acute study). The test is also used when there is no variability (variance = 0) within one or more of the groups we wish to compare (Sokal and Rohlf, 2011).

The data in both groups being compared are initially arranged and listed in order of increasing value. Then each number in the two groups must receive a rank value. Beginning with the smallest number in either group (which is given a rank of 1.0), each number is assigned a rank. If there are duplicate numbers (called “ties”), then each value of equal size will receive the median rank for the entire identically sized group. Thus if the lowest number appears twice, both figures receive a rank of 1.5. This, in turn, means that the ranks of 1.0 and 2.0 have been used and that the next highest number has a rank of 3.0. If the lowest number appears three times, then each is ranked as 2.0 and the next number has a rank of 4.0. Thus, each tied number gets a “median” rank. This process continues until all of the numbers are ranked. Each of the two columns of ranks (one for each group) is totaled giving the “sum of ranks” for each group being compared. As a check, we can calculate the value

$$\frac{(N)(N+1)}{2}$$

where N is the total number of data in both groups. The result should be equal to the sum of the sum of ranks for both groups.

The sum of rank values are compared to table values (Beyer, 1976, pp. 409–413) to determine the degree of significant differences, if any. These tables include two limits

(an upper and a lower) that are dependent upon the probability level. If the number of data is the same in both groups ($N_1 \neq N_2$), then the lesser sum of ranks (smaller N) is compared to the table limits to find the degree of significance. Normally the comparison of the two groups ends here and the degree of significant difference can be reported.

32.6.5 Distribution-Free Multiple Comparison

The distribution-free multiple comparison test should be used to compare three or more groups of nonparametric data. These groups are then analyzed two at a time for any significant differences (Hollander and Wolfe, 2013, pp. 124–129). The test can be used for data similar to those compared by the rank-sum test. We often employ this test for reproduction and mutagenicity studies (such as comparing survival rates of offspring of rats fed with various amounts of test materials in the diet).

Two values must be calculated for each pair of groups: the difference in mean ranks and the probability level value against which the difference will be compared. To determine the difference in mean ranks, we must first arrange the data within each of the groups in order of increasing values. Then we must assign rank values, beginning with the smallest overall figure. Note that this ranking is similar to that in the Wilcoxon test except that it applies to more than two groups.

The ranks are then added for each of the groups. As a check, the sum of these should equal

$$\frac{N_{\text{tot}}(N_{\text{tot}} + 1)}{2}$$

where N_{tot} is the total number of figures from all groups. Next, we can find the mean rank (R) for each group by dividing the sum of ranks by the numbers in the data (N) in the group. These mean ranks are then taken in those pairs which we want to compare (usually each test group vs. the control) and the differences are found ($|R_1 - R_2|$). This value is expressed as an absolute figure, that is, it is always a positive number.

The second value for each pair of groups (the p value) is calculated from the expression

$$z \left[\frac{a}{K} (K - 1) \right] \sqrt{\frac{N_{\text{tot}}(N_{\text{tot}} + 1)}{12}} \sqrt{\frac{1}{N_1} \frac{1}{N_2}}$$

where a is the level of significance for the comparison (usually 0.05, 0.01, 0.001, etc.), K is the total number of groups, and Z is a figure obtained from a normal probability table and determining the corresponding “Z-score.”

The result of the p value calculation for each pair of groups is compared to the corresponding mean difference $|R_1 - R_2|$. If $|R_1 - R_2|$ is smaller, there is no significant difference between

the groups. If it is larger, the groups are different and $|R_1 - R_2|$ must be compared to the calculated p values for $a = 0.01$ and 0.001 to find the degree of significance.

ASSUMPTIONS AND LIMITATIONS

1. As with the Wilcoxon rank-sum test, too many tied ranks inflate the false positive.
2. Generally, this test should be used as a *post hoc* comparison after Kruskal–Wallis.

32.6.6 Mann–Whitney U Test

This is a nonparametric test in which the data in each group are first ordered from lowest to highest values, and then the entire set (both control and treated values) is ranked, with the average rank being assigned to tied values. The ranks are then summed for each group and U is determined according to

$$U_t = n_c n_t + \frac{n_t(n_t + 1)}{2} - R_t$$

$$U_c = n_c n_t + \frac{n_c(n_c + 1)}{2} - R_c$$

where n_c, n_t = sample size for control and treated groups and R_c, R_t = sum of ranks for the control and treated groups.

For the level of significance for a comparison of the two groups, the larger value of U_c or U_t is used. This is compared to critical values as found in tables (Siegel, 1956).

The Mann–Whitney U test is employed for the count data, but which test should be employed for the percentage variables should be decided on the same grounds as described later under reproduction studies.

ASSUMPTIONS AND LIMITATIONS

1. It does not matter whether the observations are ranked from smallest to largest or vice versa.
2. This test should not be used for paired observations.
3. The test statistics from a Mann–Whitney test are linearly related to those of Wilcoxon. The two tests will always yield the same result. The Mann–Whitney is presented here for historical completeness, as it has been much favored in reproductive and developmental toxicology studies; however, it should be noted that the authors do not include it in the decision tree for method selection (Figure 32.2).

32.6.7 Kruskal–Wallis Nonparametric ANOVA

The Kruskal–Wallis nonparametric one-way ANOVA should be the initial analysis performed when we have three or more groups of data which are by nature nonparametric (either not a normally distributed population, or of a discontinuous nature, or all the groups being analyzed are not from the same population) but not a categorical (or quantal) nature. Commonly these will be either rank-type evaluation data (such as behavioral toxicity observation scores) or reproduction study data. The analysis is initiated (Pollard, 1977, pp. 170–173) by ranking all the observations from the combined groups to be analyzed. Ties are given the average rank of the tied values (i.e., if two values would tie for 12th rank—and therefore would be ranked 12th and 13th—both would be assigned the average rank of 12.5).

The sum of ranks of each group (r_1, r_2, \dots, r_k) is computed by adding all the rank values for each group. The test value H is then compute as

$$H = \frac{12}{n(n+1)} \sum \left(\frac{r_1^2}{n_1} + \frac{r_2^2}{n_2} + \dots + \frac{r_k^2}{n_k} \right) - 3(n+1)$$

where n_1, n_2, \dots, n_k are the number of observations in each group. The test statistic is then compared with a table of H values. If the calculated value of H is greater than the table value for the appropriate number of observations in each group, there is significant difference between the groups, but further testing (using the distribution-free multiple comparison method) is necessary to determine where the difference lies.

ASSUMPTIONS AND LIMITATIONS

1. The test statistic H is used for both small and large samples.
2. When we find a significant difference, we do not know which groups are different. It is not correct to then perform a Mann–Whitney U test on all possible combinations; rather, a multiple comparison method must be used, such as the distribution-free multiple comparisons.
3. Data must be independent for the test to be valid.
4. Too many tied ranks will decrease the power of this test and also lead to increased false-positive levels.
5. When $k = 2$, the Kruskal–Wallis chi-square value has 1 df. This test is identical to the normal approximation used for the Wilcoxon rank-sum test. As noted in previous sections, a chi-square with 1 df can be represented by the square of a standardized normal random variable. In the case of $k = 2$, the h -statistic is the square of the Wilcoxon rank-sum Z -test (without the continuity correction).
6. The effect of adjusting for tied ranks is to slightly increase the value of the test statistic, h ; therefore, omission of this adjustment results in a more conservative test.

32.6.8 Log-Rank Test

The log-rank test is a statistical methodology for comparing the distribution of time until the occurrence of the event in independent groups. In toxicology, the most common event of interest is death or occurrence of a tumor, but it could just as well be liver failure, neurotoxicity, or any other event which occurs only once in an individual. The elapsed time from initial treatment or observation until the *event* is the *event time*, often referred to as “survival time,” even when the *event* is not “death.”

The log-rank test provides a method for comparing “risk-adjusted” event rates, useful when test subjects in a study are subject to varying degrees of opportunity to experience the event. Such situations arise frequently in toxicology studies due to the finite duration of the study, early termination of the animal, or interruption of treatment before the event occurs.

Examples where use of the log-rank test might be appropriate include comparing survival times in carcinogenicity bioassay animals which are given a new treatment with those in the control group or comparing times to liver failure for several dose levels of a new nonsteroidal anti-inflammatory drug (NSAID), where the animals are treated for 10 weeks or until cured, whichever comes first.

If every animal were followed until the event occurrence, the event times could be compared between two groups using the Wilcoxon rank-sum test. However, some animals may die or complete the study before the event occurs. In such cases, the actual time to the event is unknown since the event does not occur while under study observation. The event times for these animals are based on the last known time of study observation and are called “censored” observations since they represent the lower bound of the true, unknown event times. The Wilcoxon rank-sum test can be highly biased in the presence of the censored data.

The null hypothesis tested by the log-rank test is that of equal event time distributions among groups. Equality of the distributions of event times implies similar event rates among groups not only for the clinical trial as a whole but also for any arbitrary time point during the trial. Rejection of the null hypothesis indicates that the event rates differ among groups at one or more time points during the study.

The idea behind the log-rank test for comparison of two life tables is simple; if there were no difference between the groups, the total deaths occurring at any time should split between the two groups at that time. So if the numbers at risk in the first and second groups in (say) the sixth month were 70 and 30, respectively, and 10 deaths occurred in that month, we would expect

$$10 \times \frac{70}{70 + 30} = 7$$

of these deaths to have occurred in the first group and

$$10 \times \frac{30}{70 + 30} = 3$$

of these deaths to have occurred in the second group.

A similar calculation can be made at each time of death (in either group). By adding together for the first group the results of all such calculations, we obtain a single number, called the extent of exposure (E_1), which represents the “expected” number of deaths in that group if the two groups had the distribution of survival time. An extent of exposure (E_2) can be obtained for the second group in the same way. Let O_1 and O_2 denote the actual total number of deaths in the two groups. A useful arithmetic check is that the total number of deaths $O_1 + O_2$ must equal the sum $E_1 + E_2$ of the extents of exposure.

The discrepancy between the O s and E s can be measured by the quantity

$$x^2 = \frac{((|O_1 - E_1|) - (1/2))^2}{E_1} + \frac{((|O_2 - E_2|) - (1/2))^2}{E_2}$$

For rather obscure reasons, x^2 is known as the log-rank statistic. An approximate significance test of the null hypothesis of identical distributions of survival time in the two groups is obtained by referring x^2 to a chi-square distribution on 1 df.

The log-rank test as presented by Peto et al. (1977) uses the product-limit life-table calculations rather than the actuarial estimators shown in the preceding text. The distinction is unlikely to be of practical importance unless the grouping intervals are very coarse.

Peto and Pike (1973) suggest that the approximation in treating the null distribution of χ^2 as a chi-square is conservative, so that it will tend to understate the degree of statistical significance. In the formula for χ^2 , we have used the continuity correction of subtracting 1/2 from $|O_1 - E_1|$ and $|O_2 - E_2|$ before squaring. This is recommended by Peto et al. (1977) when, as in nonrandomized studies, the permutational argument does not apply. Peto et al. (1977) give further details of the log-rank test and its extension to comparisons of more than two treatment groups and to tests that control for categorical confounding factors.

ASSUMPTIONS AND LIMITATIONS

1. The end point of concern is or is defined so that it is “right censored”—once it happens, it does not reoccur. Examples are death or a minimum or maximum value of an enzyme or a physiologic function (such as respiration rate).
2. The method makes no assumptions on distribution.

3. Many variations of the log-rank test for comparing survival distributions exist. The most common variant has the form:

$$X^2 = \frac{(O_1 - E_1)^2}{E_1} + \frac{(O_2 - E_2)^2}{E_2}$$

where O_i and E_i are computed for each group, as in the formulas given previously. This statistic also has an approximate chi-square distribution with 1 df under H_0 .

A continuity correction can also be used to reduce the numerators by 1/2 before squaring. Use of such a correction leads to even further conservatism and may be omitted when sample sizes are moderate or large.

4. The Wilcoxon rank-sum test could be used to analyze the event times in the absence of censoring. A “generalized Wilcoxon” test, sometimes called the Gehan test, based on an approximate chi-square distribution has been developed for use in the presence of censored observations.
5. Both the log-rank and the generalized Wilcoxon tests are nonparametric tests and require no assumptions regarding the distribution of event times. When the event rate is greater early in the trial than toward the end, the generalized Wilcoxon test is the more appropriate test since it gives greater weight to the earlier differences.
6. Survival and failure times often follow the exponential distribution. If such a model can be assumed, a more powerful alternative to the log-rank test is the likelihood ratio test.
7. This parametric test assumes that event probabilities are constant over time. That is, the chance that a patient becomes event-positive at time t given that he or she is event-negative up to time t does not depend on t . A plot of the negative log of the event time distribution showing a linear trend through the origin is consistent with exponential event times.
8. Life tables can be constructed to provide estimates of the event time distributions. Estimates commonly used are known as the Kaplan–Meier estimates.

32.7 HYPOTHESIS TESTING: UNIVARIATE PARAMETRIC TESTS

Univariate case² data from normally distributed populations generally have a higher information value associated with them, but the traditional hypothesis testing techniques (which include all the methods described in this chapter) are

²That is, where each datum is defined by one treatment and one effect variable.

generally neither resistant nor robust. All the data analyzed by these methods are also, effectively, continuous—that is, at least for practical purposes, the data may be represented by any number, and each such data number has a measurable relationship to other data numbers. Note that Diem and Lentner (1975) and Pollard (1977) are excellent sources of statistical value tables.

32.7.1 Student’s *t*-Test (Unpaired *t*-Test)

Pairs of groups of continuous, randomly distributed data are compared via this test. We can use this test to compare three or more groups of data, but they must be intercompared by examination of two groups taken at a time and are preferentially compared by ANOVA. Usually, this means comparison of a test group versus a control group, although two test groups may be compared as well. To determine which of the three types of *t*-tests described in this chapter should be employed, the *F*-test is usually performed first. This will tell us if the variances of the data are approximately equal, which is a requirement for the use of the parametric methods. If the *F*-test indicates homogeneous variances and the numbers of data within the groups (*N*) are equal, then Student’s *t*-test is the appropriate procedure (Sokal and Rohlf, 1994). If the *F* is significant (the data are heterogeneous) and the two groups have equal numbers of data, the modified Student’s *t*-test is applicable (Cochran and Cox, 1975).

The value of *t* for Student *t*-test is calculated using the formula:

$$t = \frac{\overline{X_1} - \overline{X_2}}{\sqrt{\frac{\Sigma D_1^2 + \Sigma D_2^2}{N_1 + N_2}}} \sqrt{\frac{N_1 N_2}{N_1 + N_2} (N_1 + N_2 - 2)}$$

where the value of $\Sigma D^2 = [N\Sigma X^2 - (\Sigma X)^2]/N$

The value of *t* obtained from the earlier calculations is compared to the values in a *t*-distribution table according to the appropriate number of df. If the *F* value is not significant (i.e., variances are homogeneous), the df = $N_1 + N_2 - 2$. If the *F* was significant and $N_1 = N_2$, then the df = $N - 1$. Although this case indicates a nonrandom distribution, the modified *t*-test is still valid. If the calculated value is larger than the table value at $p = 0.05$, it may then be compared to the appropriate other table values in order of decreasing probability to determine the degree of significance between the two groups.

ASSUMPTIONS AND LIMITATIONS

1. The test assumes that the data are univariate, continuous, and normally distributed.
2. Data are collected by random sampling.
3. The test should be used when the assumptions in 1 and 2 are met, and there are only two groups to be compared.

4. Do not use when the data are ranked, when the data are not approximately normally distributed, or when there are more than two groups to be compared. Do not use for paired observations.
5. This is the most commonly misused test method, except in those few cases where one is truly only comparing two groups of data and the group sizes are roughly equivalent. It is not valid for multiple comparisons (because of resulting additive errors) or where group sizes are very unequal.
6. Test is robust for moderate departures from normality and, when N_1 and N_2 are approximately equal, robust for moderate departures from homogeneity of variances.
7. The main difference between the *Z*-test and the *t*-test is that the *Z*-statistic is based on a known SD, σ , while the *t*-statistic uses the sample SD, *s*, as an estimate of σ . With the assumption of normally distributed data, the variance σ^2 is more closely estimated by the sample variance s^2 as *n* gets large. It can be shown that the *t*-test is equivalent to the *Z*-test for infinite df. In practice, a “large” sample is usually considered $n \geq 30$.

32.7.2 Cochran *t*-Test

The Cochran test should be used to compare two groups of continuous data when the variances (as indicated by the *F*-test) are heterogeneous and the numbers of data within the groups are not equal ($N_1 \neq N_2$). This is the situation, for example, when the data, though expected to be randomly distributed, were found not to be randomly distributed (Cochran and Cox, 1975, pp. 100–102).

Two *t* values are calculated for this test, the “observed” *t* (t_{obs}) and the “expected” *t* (t'). The observed *t* is obtained by

$$t_{\text{obs}} = \frac{\overline{X_1} - \overline{X_2}}{\sqrt{W_1 + W_2}}$$

where

$$W = \text{SEM}^2 \text{ (SEM squared)} \\ = S^2 / N$$

where *S* (variance) can be calculated from

$$S = \frac{[N\Sigma X^2 - (\Sigma X)^2] / N}{N - 1}$$

The value for t' is obtained from

$$t' = \frac{t'_1 W_1 + t'_2 W_2}{W_1 + W_2}$$

where t'_1 and t'_2 are values for the two groups taken from the t -distribution table corresponding to $N - 1$ df (for each group) at the 0.05 probability level (or such level as one may select).

The calculated t_{obs} is compared to the calculated t' value (or values, if t' values were prepared for more than one probability level). If t_{obs} is smaller than a t' , the groups are not considered to be significantly different at that probability level.

ASSUMPTIONS AND LIMITATIONS

1. The test assumes that the data are univariate, continuous, and normally distributed and that group sizes are unequal.
2. The test is robust for moderate departures from normality and very robust for departures from equality of variances.

32.7.3 F-Test

This is a test of the homogeneity of variances between two groups of data (Sokal and Rohlf, 1994). It is used in two separate cases. The first is when Bartlett's indicates heterogeneity of variances among three or more groups (i.e., it is used to determine which pairs of groups are heterogeneous). Second, the F -test is the initial step in comparing two groups of continuous data which we would expect to be parametric (two groups not usually being compared using ANOVA), the results indicating whether the data are from the same population and whether subsequent parametric comparisons would be valid.

The F is calculated by dividing the larger variance (S_1^2) by the smaller one (S_2^2). S^2 is calculated as follows:

$$S^2 = \frac{[N\sum X^2 - (\sum X)^2] / N}{N - 1}$$

where N is the number of data in the group and X represents the individual values within the group. Frequently, S^2 values may be obtained from ANOVA calculations.

The calculated F value is compared to the appropriate number in an F -value table for the appropriate df ($N - 1$) in the numerator (along the top of the table) and in the denominator (along the side of the table). If the calculated value is smaller, it is not significant, and the variances are considered homogeneous (and Student's t -test would be appropriate for further comparison). If the calculated F value is greater, F is significant, and the variances are heterogeneous (and the next test would be modified Student's t -test if $N_1 = N_2$ or the Cochran t -test if $N_1 \neq N_2$; see Figure 32.2 to review the decision tree).

ASSUMPTIONS AND LIMITATIONS

1. This test could be considered as a two-group equivalent of Bartlett's test.
2. If the test statistic is close to 1.0, the results are (of course) not significant.
3. The test assumes normality and independence of data.

32.7.4 Analysis of Variance (ANOVA)

ANOVA is used for a comparison of three or more groups of continuous data when the variances are homogeneous and the data are independent and normally distributed.

A series of calculations are required for ANOVA, starting with the values within each group being added ($\sum X$) and then these sums being added ($\sum \sum X$). Each figure within the groups is squared, and these squares are then summed ($\sum X^2$) and these sums added ($\sum \sum X^2$). Next the "correction factor" (CF) can be calculated from the following formula:

$$CF = \frac{\left(\sum_1^k \sum_1^N X \right)^2}{N_1 + N_2 + \dots + N_k}$$

where N is the number of values in each group, and K is the number of groups. The total sum of squares (SS) is then determined as follows:

$$SS_{\text{total}} = \sum_1^K \sum_1^N X^2 - CF$$

In turn, the SS between groups (bg) is found from

$$SS_{\text{bg}} = \frac{(\sum X_1)^2}{N_1} + \frac{(\sum X_2)^2}{N_2} + \dots + \frac{(\sum X_k)^2}{N_k} - CF$$

The SS within groups (wg) is then the difference between the last two figures, or

$$SS_{\text{wg}} = SS_{\text{total}} - SS_{\text{bg}}$$

Now, there are three types of df to determine. The first, total df, is the total number of data within all groups under analysis minus one ($N_1 + N_2 + \dots + N_k - 1$). The second figure (the df between groups) is the number of groups minus one ($K - 1$). The last figure (the df within groups or "error df") is the difference between the first two figures ($df_{\text{total}} - df_{\text{bg}}$).

The next set of calculations requires determination of the two mean squares (MS_{bg} and MS_{wg}). These are the respective SS values divided by the corresponding df figures ($MS = SS/df$). The final calculation is that of the F ratio. For this, the MS

between groups is divided by the MS within groups ($F = MS_{bg} / MS_{wg}$).

A table of the results of these calculations would appear as follows:

	df	SS	MS	F
bg	3	0.04075	0.01358	4.94
wg	12	0.03305	0.00275	
Total	15	0.07380		

For interpretation, the F -ratio value obtained in the ANOVA is compared to a table of F values. If $F \leq 1.0$, the results are not significant and comparison with the table values is not necessary. The df for the greater mean square (MS_{bg}) is indicated along the top of the table. Then read down the side of the table to the line corresponding to the df for the lesser mean square (MS_{wg}). The figure shown at the desired significance level (traditionally 0.05) is compared to the calculated F value. If the calculated number is smaller, there are no significant differences among the groups being compared. If the calculated value is larger, there is some difference but further (*post hoc*) testing will be required before we know which groups differ significantly.

ASSUMPTIONS AND LIMITATIONS

1. What is presented here is the workhorse of toxicology—the one-way ANOVA. Many other forms exist for more complicated experimental designs.
2. The test is robust for moderate departures from normality if the sample sizes are large enough. Unfortunately, this is rarely the case in toxicology.
3. ANOVA is robust for moderate departures from equality of variances (as determined by Bartlett’s test) if the sample sizes are approximately equal.
4. It is not appropriate to use a t -test (or a two groups at a time version of ANOVA) to identify where significant differences are within the design group. A multiple comparison *post hoc* method must be used.

32.7.5 Post Hoc Tests

There is a wide variety of *post hoc* tests available to analyze data after finding significant result in an ANOVA. Each of these tests has advantages and disadvantages, proponents, and critics. Four of the tests are commonly used in toxicology and will be presented or previewed here. These are Dunnett’s t -test and Williams’ t -test. Two other tests which are available in many statistical packages are Turkey’s

method and the Student–Newman–Keuls method (Zar, 1974, pp. 151–161).

If ANOVA reveals no significance, it is not appropriate to proceed to perform a *post hoc* test in hope of finding differences. To do so would only be another form of multiple comparisons, increasing the type I error rate beyond the desired level.

32.7.6 Duncan’s Multiple Range Test

Duncan’s (1955) is used to compare groups of continuous and randomly distributed data (such as body weights and organ weights). The test normally involves three or more groups taken one pair at a time. It should only follow observation of a significant F value in the ANOVA and can serve to determine which group (or groups) differs significantly from which other group (or groups). There are two alternative methods of calculation.

The selection of the proper one is based on whether the number of data (N) is equal or unequal in the groups.

32.7.7 Groups with Equal Number of Data ($N_1 = N_2$)

Two sets of calculations must be carried out: first, the determination of the difference between the means of pairs of groups and, second, the preparation of a probability rate against which each difference in means is compared (as shown in the first of the two examples in this section).

The means (averages) are determined (or taken from the ANOVA calculation) and ranked in either decreasing or increasing order. If two means are the same, they take up two equal positions (thus, for four means we could have ranks of 1, 2, 2, and 4 rather than 1, 2, 3, and 4). The groups are then taken in pairs and the differences between the means ($\bar{X}_1 - \bar{X}_2$), expressed as positive numbers, are calculated. Usually, each pair consists of a test group and the control group; through multiple tests, groups may be intracompared if so desired. The relative rank of the two groups being compared must be considered. If a test group is ranked “2” and the control group is ranked “1,” then we say that there are two places between them, while if the test group were ranked “3,” then there would be three places between it and the control.

To establish the probability table, the SEM must be calculated as presented earlier or as follows:

$$\sqrt{\frac{\text{Error mean square}}{N}} = \sqrt{\frac{\text{Mean square within group}}{N}}$$

where N is the number of animals or replications per dose level. The mean square within groups (MS_{wg}) can be calculated from the information given in the ANOVA procedure (refer to the earlier section on ANOVA). The SEM is then

multiplied by a series of table values (Harter, 1960; Beyer, 1976) to set up a probability table. The table values used for the calculations are chosen according to the probability levels (note that the tables have sections for 0.05, 0.01, and 0.001 levels) and the number of means apart from the groups being compared and the number of “error” df. The “error” df is the number of df within the groups. This last figure is determined from the ANOVA calculation and can be taken from ANOVA output. For some values of df, the table values are not given and should thus be interpolated.

32.7.8 Groups with Unequal Number of Data ($N_1 \neq N_2$)

This procedure is very similar to that discussed in the preceding text. As before, the means are ranked and the differences between the means are determined ($X_1 - X_2$). Next, weighing values (“ a_{ij} ” values) are calculated for the pairs of groups being compared in accordance with

$$a_{ij} = \sqrt{\frac{2N_i N_j}{(N_i + N_j)}} = \frac{2N_1 N_2}{(N_1 + N_2)}$$

This weighting value for each pair of groups is multiplied by $(\bar{X}_1 - \bar{X}_2)$ for each value to arrive at a “ t ” value. It is the “ t ” that will later be compared to a probability table.

The probability table is set up as before except that, instead of multiplying the appropriate table values by SEM, SEM^2 is used. This is equal to $\sqrt{MS_{wg}}$.

For the desired comparison of two groups at a time, the $(\bar{X}_1 - \bar{X}_2)$ value (if $N_1 = N_2$) is compared to the appropriate probability table. Each comparison must be made according to the number of places between the means. If the table value is larger at the 0.05 level, the two groups are not considered to be statistically different. If the table value is smaller, the groups are different, and the comparison is repeated at lower levels of significance. Thus, the degree of significance may be determined. We might have significant differences at 0.05 but not at 0.01, in which case, the probability would be represented at $0.05 > p > 0.01$.

ASSUMPTIONS AND LIMITATIONS

1. Duncan’s assures a set alpha level or type I error rate for all tests when means are separated by no more than ordered step increases. Preserving this alpha level means that the test is less sensitive than some others, such as the Student–Newman–Keuls. The test is inherently conservative and not resistant or robust

32.7.9 Scheffe’s Multiple Comparisons

Scheffe’s is another *post hoc* comparison method for groups of continuous and randomly distributed data. It also normally involved three or more groups (Scheffe, 1959; Harris, 2013). It is widely considered a more powerful significance test than Duncan’s.

Each *post hoc* comparison is tested by comparing an obtained test value (F_{contr}) with the appropriate critical F value at the selected level of significance (the table F value multiplied by $K-1$ for an F with $K-1$ and $N-K$ df²). F_{contr} is computed as follows:

- a. Compute the mean for each sample (group).
- b. Denote the residual mean square by MS_{wg} .
- c. Compute the test statistic as

$$F_{contr} = \frac{(C_1 \bar{X}_1 + C_2 \bar{X}_2 + \dots + C_k \bar{X}_k)^2}{(K-1)MS_{wg}(C_1^2/n_1 + \dots + C_k^2/n_k)}$$

where C_k is the comparison number such that the sum of $C_1, C_2, \dots, C_k = 0$.

ASSUMPTIONS AND LIMITATIONS

1. The Scheffe procedure is robust to moderate violations of the normality and homogeneity of variance assumptions.
2. It is not formulated on the basis of groups with equal numbers (as one of Duncan’s procedures is), and if $N_1 \neq N_2$ there is no separate weighing procedure.
3. It tests all linear contrasts among the population means (the other three methods confine themselves to pairwise comparison, except they use a Bonferroni-type correlation procedure).
4. The Scheffe procedure is powerful because of its robustness, yet it is very conservative. Type I error (the false-positive rate) is held constant at the selected test level for each comparison.

32.7.10 Dunnett’s t -Test

Dunnett’s t -test (Dunnett, 1955, 1964) has as its starting point the assumption that what is desired is a comparison of each of several means with one other mean and only one other mean, in other words, that one wishes to compare each and every treatment group with the control group, but not compare treatment groups with each other. The problem here is that, in toxicology, one is frequently interested in comparing treatment groups with other treatment groups. However, if one does want only to compare treatment groups versus a control group, Dunnett’s is a useful approach. In a study with

K groups (one of them being the control), we will wish to make $K - 1$ comparisons. In such a situation, we want to have a P level for the entire set of $K - 1$ decisions (not for each individual decision). Dunnett's distribution is predicated on this assumption. The parameters for utilizing a Dunnett's table, such as those found in his original article, are K (as in the preceding text) and the number of df for mean square with groups (MS_{wg}). The test value is calculated as

$$t = \frac{|T_j - T_i|}{\sqrt{2MS_{wg}/n}}$$

where n is the number of observations in each of the groups. The mean square within group (MS_{wg}) is as we have defined it previously; T_j is the control group mean, and T_i is the mean of, in order, each successive test group observation. Note that one uses the absolute value of the positive number resulting from subtracting T_i from T_j . This is to ensure a positive number for our final t .

ASSUMPTIONS AND LIMITATIONS

1. Dunnett's seeks to ensure that the type I error rate will be fixed at the desired level by incorporating CF into the design of the test value table.
2. Treated group sizes must be approximately equal.

32.7.11 Williams' t -Test

Williams' t -test (Williams, 1971, 1972) is popular, although its use is quite limited in toxicology. It is designed to detect the highest level (in a set of dose/exposure levels) at which there is no significant effect. It assumes that the response of interest (such as change in body weights) occurs at higher levels, but not at lower levels, and that the responses are monotonically ordered so that $X_0 \leq X_1 \dots \leq X_k$. This is, however, frequently not the case. The Williams' technique handles the occurrence of such discontinuities in a response series by replacing the offending value and the value immediately preceding it with weighted average values. The test also is adversely affected by any mortality at high-dose levels. Such mortalities "impose a severe penalty, reducing the power of detecting an effect not only at level K but also at all lower doses" (Williams, 1972, p. 529). Accordingly, it is not generally applicable in toxicology studies.

32.7.12 Analysis of Covariance

ANCOVA is a method for comparing sets of data which consist of two variables (treatment and effect, with our effect variable being called the "variate"), when a third var-

iable (called the "covariate") exists which can be measured but not controlled and which has a definite effect on the variable of interest. In other words, it provides an indirect type of statistical control, allowing us to increase the precision of a study and to remove a potential source of bias. One common example of this is in the analysis of organ weights in toxicity studies. Our true interest here is the effect of our dose or exposure level on the specific organ weights, but most organ weights also increase (in the young, growing animals most commonly used in such studies) in proportion to increases in animal body weight. As we are not interested here in the effect of this covariate (body weight), we measure it to allow for adjustment. We must be careful before using ANCOVA, however, to ensure that the underlying nature of the correspondence between the variate and covariate is such that we can rely on it as a tool for adjustments (Anderson et al., 1980; Kotz and Johnson, 1982).

Calculation is performed in two steps. The first is a type of linear regression between the variate Y and the covariate X .

This regression, performed as described under the linear regression section, gives us the model

$$Y = a_1 + BX + e$$

which in turn allows us to define adjusted means (\bar{Y} and X) such that $\bar{Y}_{1a} = \bar{Y}_1 - (\bar{X}_1 - X)$.

If we consider the case where K treatments are being compared such that $K = 1, 2, \dots, K$, and we let X_{ik} and Y_{ik} represent the predictor and predicted values for each individual i in group k , we can let X_k and Y_k be the means. Then, we define the between-group (for treatment) SS and cross products as

$$T_{xx} = \sum_{k=1}^K n_k (\bar{X}_k - \bar{X})^2$$

$$T_{yy} = \sum_{k=1}^K n_k (\bar{Y}_k - \bar{Y})^2$$

$$T_{xy} = \sum_{k=1}^K n_k (\bar{X}_k - \bar{X}) (\bar{Y}_k - \bar{Y})$$

In a like manner, within-group sums of squares and cross products are calculated as

$$\Sigma_{xx} = \sum_{k=1}^k \sum_i (X_{ik} - X_k)^2$$

$$\Sigma_{yy} = \sum_{k=1}^k \sum_i (Y_{ik} - Y_k)^2$$

$$\Sigma_{xy} = \sum_{k=1}^k \sum_i (X_{ik} - X_k)(Y_{ik} - Y_k)$$

where i indicates the sum from all the individuals within each group; f = total number of subjects minus number of groups

$$S_{xx} = T_{xx} + \sum_{xx}$$

$$S_{yy} = T_{yy} + \sum_{xx}$$

$$S_{xy} = T_{xy} + \sum_{xy}$$

With these in hand, we can then calculate the residual mean squares of treatments (St^2) and error (Se^2)

$$St^2 = \frac{T_{yy} - (S_{xy}^2 / S_{xx}) + (\sum_{xy}^2 / \sum_{xx})}{lc - 1}$$

$$Se^2 = \frac{[\sum_{yy} - (\sum_{xy}^2 / \sum_{xx})]}{f - 1}$$

These can be used to calculate an F -statistic to test the null hypothesis that all treatment effects are equal:

$$F = \frac{St^2}{Se^2}$$

The estimated regression coefficient of Y or X is

$$B = \frac{\sum_{xy}}{\sum_{xx}}$$

The estimated standard error (Se) for the adjusted difference between two groups is given by

$$Sd = Se \frac{1}{n_j} + \frac{1}{n_j} + \frac{(X_i - X_j)^2}{\sum_{xx}}$$

where n_0 and n_1 are the sample sizes of the two groups. A test of the null hypothesis that the adjusted differences between the groups are zero is provided by

$$t = \frac{Y_1 - Y_0 - B(X_1 - X_0)}{Sd}$$

The test value for the t is then looked up in the t -distribution table with $f-1$ df.

Computation is markedly simplified if all the groups are of equal size.

32.7.13 Modeling

The mathematical modeling of biological systems, restricted even to the field of toxicology, is an extremely large and vig-

ASSUMPTIONS AND LIMITATIONS

1. The underlying assumptions for ANCOVA are fairly rigid and restrictive. The assumptions include the following:
 - a. The slopes of the regression lines of a Y and X are equal from group to group. This can be examined visually or formally (i.e., by a test). If this condition is not met, ANCOVA cannot be used.
 - b. The relationship between X and Y is linear.
 - c. The covariate X is measured without error. Power of the test declines as error increases.
 - d. There are no unmeasured confounding variables.
 - e. The errors inherent in each variable are independent of each other. Lack of independence effectively (but to an immeasurable degree) reduces sample size.
 - f. The variances of the errors in groups are equivalent between groups.
 - g. The measured data that form the groups are normally distributed. ANCOVA is generally robust to departures from normality.
2. Of the seven assumptions provided earlier, the most serious are the first four.

orously growing area. Broadly speaking, modeling is the principal conceptual tool by which toxicology seeks to develop as a mechanistic science. In an iterative process, models are developed or proposed, tested by experiment, reformulated, and so on, in a continuous cycle. Such a cycle could also be described as two related types of modeling—explanatory (where the concept is formed) and correlative (where data are organized, and relationships derived). An excellent introduction to the broader field of modeling of biological systems can be found in Gold (1977) or Gad (2005).

In toxicology, modeling is of prime interest in seeking to relate a treatment variable with an effect variable and, from the resulting model, predict effects at exact points where no experiment has been done (but in the range where we have performed experiments, such as “determining” LD_{50}), to estimate how good our prediction is and, occasionally, simply to determine if a pattern of effects is related to a pattern of treatment.

For use in prediction, the techniques of linear regression, probit/logit analysis (a special case of linear regression), moving averages (an efficient approximation method), and nonlinear regression (for doses where data cannot be made to fit a linear pattern) are presented. For evaluating the predictive value of these models, both the correlation coefficient (for

parametric data) and Kendall’s rank correlation (for nonparametric data) are given, and finally, the concept of trend analysis is introduced, and a method presented.

When we are trying to establish a pattern between several data points (whether this pattern is in the form of a line or a curve), what we are doing is interpolating. It is possible for any given set of points to produce an infinite set of lines or curves which pass near (for lines) or through (for curves) the data points. In most cases, we cannot actually know the “real” pattern; so we apply a basic principle of science—Occam’s razor. We use the simplest explanation (or, in this case, model) which fits the facts (or data). A line is, of course, the simplest pattern to deal with and describe, so fitting the best line (linear regression) is the most common form of model in toxicology.

32.7.14 Linear Regression

Foremost among the methods for interpolating within a known data relationship is regression—the fitting of a line or curve to a set of known data points on a graph and the interpolation (“estimation”) of this line or curve in areas where we have no data points. The simplest of these regression models is that of linear regression (valid when increasing the value of one variable changes the value of the related variable in a linear fashion, either positively or negatively). This is the case we will explore here, using the method of least squares.

Given that we have two sets of variables, x (say, mg/kg of test material administered) and y (say, percentage of animals so dosed that die), what is required is solving for a and b in the equation $Y_i = a + bx_i$ (where the uppercase Y_i is the fitted value of y_i at x_i , and we wish to minimize $(y_i - Y_i)^2$). So we solve the equations

$$b = \frac{\sum x_i y_i - n \bar{x} \bar{y}}{\sum x_i^2 - n \bar{x}^2} \text{ and } a = \bar{y} - b \bar{x}$$

where a is the y intercept, b is the slope of the time, and n is the number of data points.

Note that in actuality, dose–response relationships are often not linear, and instead we must use either a transform (to linearize the data) or a nonlinear regression method (Gallant, 1975).

Note also that we can use the correlation test statistic (to be described in the correlation coefficient section) to determine if the regression is significant and, therefore, valid at a defined level of certainty. A more specific test for significance would be the linear regression ANOVA (Pollard, 1977). To do so we start by developing the appropriate ANOVA table.

Finally, we might wish to determine the CI for our regression line—that is, given a regression line with calculated values for Y_i given x_i , within what limits may we be certain (with, say, a 95% probability) what the real value of Y_i is?

If we denote the residual mean square in the ANOVA by s^2 , the 95% confidence limits for a (denoted by A , the notation for the true—as opposed to the estimated—value for this parameter) are calculated as

$$t_{n-2} = \frac{a - A}{\sqrt{\left[s^2 \left(\sum x_i^2 \right) / n \sum x_i^2 - n^2 \bar{x}^2 \right]}}$$

$$\frac{9.2 - A}{\sqrt{\left[8.8(51) / \left[4(51) - (16)(10.562) \right] \right]}} = \frac{9.2 - A}{\sqrt{448/35.008}}$$

$$= \frac{9.2 - A}{3.58} = -4.303$$

$$9.2 - A = -15.405$$

$$A = 9.2 - 15.405$$

ASSUMPTIONS AND LIMITATIONS

1. All the regression methods are for interpolation, not extrapolation; that is, they are valid only in the range that we have data—the experimental region—not beyond.
2. The method assumes that the data are independent and normally distributed, and it is sensitive to outliers. The x -axis (or horizontal) component plays an extremely important part in developing the least square fit. All points have equal weight in determining the height of a regression line, but extreme x -axis values unduly influence the slope of the line.
3. A good fit between a line and a set of data (i.e., a strong correlation between treatment and response variables) does not imply any causal relationship.
4. It is assumed that the treatment variable can be measured without error, that each data point is independent, that variances are equivalent, and that a linear relationship does not exist between the variables.
5. The many excellent texts on regression, which is a powerful technique, include Draper and Smith (1998) and Montgomery and Smith (1983), which are not overly rigorous mathematically.

32.7.15 Probit/Log Transforms and Regression

As we noted in Section 32.7.14, dose–response problems (among the most common interpolation problems encountered in toxicology) rarely are straightforward enough to make a valid linear regression directly from the raw data. The most common valid interpolation methods are based upon probability (“probit”) and logarithmic (“log”) value

scales, with percentage responses (death, tumor incidence, etc.) being expressed on the probit scale, while doses (Y_i) are expressed on the log scale. There are two strategies for such an approach. The first is based on transforming the data to these scales and then doing a weighted linear regression on the transformed data (if one does not have access to a computer or a high-powered programmable calculator, the only practical strategy is not to assign weights). The second requires the use of algorithms (approximate calculation techniques) for the probit value and regression process and is extremely burdensome to perform manually.

Our approach to the first strategy requires that we construct a table with the pairs of values of x_i and y_i listed in order of increasing values of Y_i (percentage response). Beside each of these columns, a set of blank columns should be left so that the transformed values may be listed. We then simply add the columns described in the linear regression procedure. Log and probit values may be taken from any of a number of sets of tables (such as provided in Appendix A), and the rest of the table is then developed from these transformed x_i' and y_i' values (denoted as x_i' and y_i'). A standard linear regression is then performed.

The second strategy we discussed has been broached by a number of authors (Bliss, 1935; Litchfield and Wilcoxon, 1949; Prentice, 1976; Finney, 1977). All of these methods, however, are computationally cumbersome. It is possible to approximate the necessary iterative process using the algorithms developed by Abramowitz and Stegun (1964), but even this merely reduces the complexity to a point where the procedure may be readily programmed on a small computer or programmable calculator.

ASSUMPTIONS AND LIMITATIONS

1. The probit distribution is derived from a common error function, with the midpoint (50% point) moved to a score of 5.00.
2. The underlying frequency distribution becomes asymptotic as it approaches the extremes of the range. That is, in the range of 16–84%, the corresponding probit values change gradually—the curve is relatively linear. But beyond this range, they change ever more rapidly as they approach either 0% or 100%. In fact, there are no values for either of these numbers.
3. A normally distributed population is assumed, and the results are sensitive to outliers.

32.7.16 Nonlinear Regression

More often than not in toxicology, we find that our data demonstrate a relationship between two variables (such as age and body weight) which is not linear. That is, a change in one

variable (say, age) does not produce a directly proportional change in the other (e.g., body weight). But some form of relationship between the variables is apparent. If understanding such a relationship and being able to predict unknown points are of value, we have a pair of options available to us. The first, which was discussed and reviewed earlier, is to use one or more transformations to linearize our data and then to make use of linear regression. This approach, though most commonly used, has a number of drawbacks. Not all data can be suitably transformed; sometimes the transformations necessary to linearize the data require a cumbersome series of calculations, and the resulting linear regression is not always sufficient to account for the differences among sample values—there are significant deviations around the linear regression line (i.e., a line may still not give us a good fit to the data or do an adequate job of representing the relationship between the data). In such cases, we have available a second option—the fitting of data to some nonlinear function such as some form of the curve. This is, in general form, nonlinear regression and may involve fitting data to an infinite number of possible functions. But most often, we are interested in fitting curves to a polynomial function of the general form:

$$Y = a + bx + cx^2 + dx^2 + \dots$$

where x is the independent variable. As the number of powers of x increases, the curve becomes increasingly complex and will be able to fit a given set of data increasingly well.

Generally in toxicology, however, if we plot the log of a response (such as body weight) versus a linear scale of our dose or stimulus, we get one of four types of nonlinear curves. These are (Snedecor and Cochran, 2014):

1. Exponential growth, where $\log Y = A(B^x)$, such as the growth curve for the log phase of a bacterial culture
2. Exponential decay, where $\log Y = A(B^{-x})$, such as a radioactive decay curve
3. Asymptotic regression, where $\log Y = A - B(p^x)$, such as a first-order reaction curve
4. Logistic growth curve, where $\log Y = A/(1 + Bp^x)$, such as a population growth curve

In all these cases, A and B are constant, while p is a log transform. These curves are illustrated in Figure 32.7.

All four types of curves are fit by iterative processes—that is, best guess numbers are initially chosen for each of the constants and, after a fit is attempted, the constants are modified to improve the fit. This process is repeated until an acceptable fit has been generated. ANOVA or ANCOVA can be used to objectively evaluate the acceptability of it. Needless to say, the use of a computer generally accelerates such a curve-fitting process.

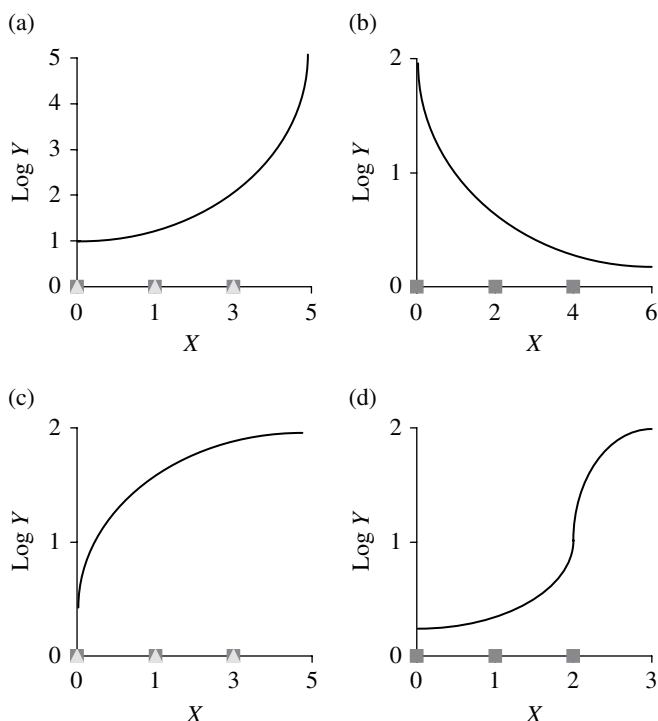

FIGURE 32.7 Common curvilinear curves: (a) exponential growth law, $\log Y = A(B^x)$; (b) exponential decay law, $\log Y = A(B^{-x})$; (c) asymptotic regression, $\log Y = A - B(\Psi^x)$; and (d) logistic growth law, $\log Y = A/(1 + B\Psi^x)$.

ASSUMPTIONS AND LIMITATIONS

1. The principle of using least squares may still be applicable in fitting the best curve, if the assumptions of normality, independence, and reasonably error-free measurement of response are valid.
2. Growth curves are best modeled using a non-linear method.

32.7.17 Correlation Coefficient

The correlation procedure is used to determine the degree of linear correlation (direct relationship) between two groups of continuous (and normally distributed) variables; it will indicate whether there is any statistical relationship between the variables in the two groups. For example, we may wish to determine if the liver weights of dogs on a feeding study are correlated with their body weights. Thus, we will record the body and liver weights at the time of sacrifice and then calculate the correlation coefficient between these pairs of values to determine if there is some relationship.

A formula for calculating the linear correlation coefficient (r_{xy}) is as follows:

$$r_{xy} = \frac{N\Sigma XY - (\Sigma X)(\Sigma Y)}{\sqrt{N\Sigma X^2 - (\Sigma X)^2} \sqrt{N\Sigma Y^2 - (\Sigma Y)^2}}$$

where X is each value for one variable (such as the dog body weights in the previous example), Y is the matching value for the second variable (the liver weights), and N is the number of pairs of X and Y . Once we have obtained r_{xy} , it is possible to calculate t_r , which can be used for more precise examination of the degree of significant linear relationship between the two groups. This value is calculated as follows:

$$t_r = \frac{r_{zy} \sqrt{N-2}}{\sqrt{1-r_{zy}^2}}$$

This calculation is also equivalent to $r = \text{sample covariance}/(S_x S_y)$, as was seen earlier under ANCOVA.

The value obtained for r_{xy} can be compared to table values (Snedecor and Cochran, 2014) for the number of pairs of data involved minus two. If the r_{xy} is smaller (at the selected test probability level, such as 0.05), the correlation is not significantly different from zero (no correlation). If r_{xy} is larger than the table value, there is a positive statistical relationship between the groups. Comparisons are then made at lower levels of probability to determine the degree of relationship (note that if r_{xy} is equal to either 1.0 or -1.0, there is complete correlation between the groups). If r_{xy} is a negative number and the absolute is greater than the table value, there is an inverse relationship between the groups, that is, a change in one group is associated with a change in the opposite direction in the second group of variables.

Since the comparison of r_{xy} with the table values may be considered a somewhat weak test, it is perhaps more meaningful to compare the t_r value with values in a t -distribution table for $N-2$ df, as is done for Student's t -test. This will give a more exact determination of the degree of statistical correlation between the two groups.

Note that this method examines only possible linear relationships between sets of continuous, normally distributed data.

ASSUMPTIONS AND LIMITATIONS

1. A strong correlation does not imply that a treatment causes an effect.
2. The distances of data points from the regression line are the portions of the data not “explained” by the model. These are called residuals. Poor correlation coefficients imply high residuals, which may be due to many small contributions (variations of data from the regression line) or a few large ones. Extreme values (outliers) greatly reduce correlation.
3. X and Y are assumed to be independent.
4. Feinstein (1979) has provided a fine discussion of the difference between correlation (or association of variables) and causation.

32.7.18 Kendall's Coefficient of Rank Correlation

Kendall's rank correlation, represented by τ (tau), should be used to evaluate the degree of association between two sets of data when the nature of the data is such that the relationship may not be linear. Most commonly, this is when the data are not continuous and/or normally distributed. An example of such a case is when we are trying to determine if there is a relationship between the length of hydra and their survival time in a test medium in hours. Both of our variables here are discontinuous, yet we suspect a relationship exists. Another common use is in comparing the subjective scoring done by two different observers.

Tau is calculated at $\tau = N/n(n-1)$, where n is the sample size, and N is the count of ranks, calculated as $N = 4 \binom{n}{2} - n(n-1)$, with the computing of " C_i " being demonstrated in the example.

If a second variable Y_2 is exactly correlated with the first variable Y_1 , then the variates Y_2 should be in the same order as the Y_1 variates. However, if the correlation is less than exact, the order of the variates Y_2 will not correspond entirely to that of Y_1 . The quantity N measures how well the second variable corresponds to the order of the first. It has a maximum value of $n(n-1)$ and a minimum value of $-n(n-1)$.

A table of data is set up with each of the two variables being ranked separately. Tied ranks are assigned as demonstrated earlier under the Kruskal–Wallis test. From this point, disregard the original variates and deal only with the ranks. Place the ranks of one of the two variables in rank order (from lowest to highest), paired with the rank values assigned for the other variable. If one (but not the other) variable has tied ranks, order the pairs by the variables without ties (Sokal and Rohlf, 1994).

The resulting value of tau will range from -1 to $+1$, as does the familiar parametric correlation coefficient, r .

ASSUMPTION AND LIMITATION

1. A very robust estimator which does not assume normality, linearity, or minimal error of measurement.

32.7.19 Trend Analysis

Trend analysis is a collection of techniques that have been "discovered" by toxicology since the mid-1970s (Tarone, 1975). The actual methodology dates back to the mid-1950s (Cox and Stuart, 1955).

Trend analysis methods are a variation on the theme of regression testing. In the broadest sense, the methods are used to determine whether a sequence of observations taken over an ordered range of a variable (most commonly time) exhibit some form of pattern of change (either an increase or upward

trend) associated with another variable of interest (in toxicology, some form or measure of dosage and exposure).

Trend corresponds to sustained and systematic variations over a long period of time. It is associated with the structural causes of the phenomenon in question, for example, population growth, technological progress, new ways of organization, or capital accumulation.

The identification of trend has always posed a serious statistical problem. The problem is not one of mathematical or analytical complexity but of conceptual complexity. This problem exists because the trend and the remaining components of a time series are latent (nonobservables) variables, and, therefore, assumptions must be made on their behavioral pattern. The trend is generally thought of as a smooth and slow movement over a long term. The concept of "long" in this connection is relative and what is identified as trend for a given series span might well be part of a long cycle once the series is considerably augmented. Often, a long cycle is treated as a trend because the length of the observed time series is shorter than one complete face of this type of cycle.

The ways in which data are collected in toxicology studies frequently serve to complicate trend analysis, as the length of time for the phenomena underlying a trend to express themselves is frequently artificially censored.

To avoid the complexity of the problem posed by a statistically vague definition, statisticians have resorted to two simple solutions: one consists of estimating trend and cyclic fluctuations together, calling this combined movement *trend-cycle*; the other consists of defining the trend in terms of the series length, denoting it as the longest nonperiodic movement.

Within the large class of models identified for trend, we can distinguish two main categories, deterministic trends and stochastic trends.

32.8 METHODS FOR THE REDUCTION OF DIMENSIONALITY

Techniques for the reduction of dimensionality are those that simplify the understanding of data, either visually or numerically, while causing only minimal reductions in the amount of information present. These techniques operate primarily by pooling or combining groups of variables into single variables but may also entail the identification and elimination of low-information-content (or irrelevant) variables.

Descriptive statistics (calculations of means, SD, etc.,) are the simplest and most familiar form of reduction of dimensionality. At this juncture, we first need to address classification, which provides the general conceptual tools for identifying and quantifying similarities and differences between groups of things which have more than a single linear scale of measurement in common (e.g., which both have been determined to have and lack a number of enzyme activities). Then we will consider two collections of methodologies which

combine graphic and computational methods, multidimensional/nonmetric scaling, and cluster analysis. Multidimensional scaling (MDS) is a set of techniques for quantitatively analyzing similarities, dissimilarities, and distances between data in a display-like manner. Nonmetric scaling is an analogous set of methods for displaying and relating data when measurements are nonquantitative (the data are described by attributes or ranks). Cluster analysis is a collection of graphic and numerical methodologies for classifying things based on the relationships between the values of the variables that they share.

The final pair of methods for reduction of dimensionality which will be tackled in this chapter are Fourier analysis and the life-table analysis. Fourier analysis seeks to identify cyclic patterns in data and can analyze the patterns or the residuals after the patterns are taken out. Life-table analysis techniques are directed to identifying and quantitating the time course of risks (such as death or the occurrence of tumors).

32.8.1 Classification

Classification is both a basic concept and a collection of techniques which are necessary prerequisites for further analysis of data when the members of a set of data are (or can be) each described by several variables. At least some degree of classification (which is broadly defined as the dividing of the members of a group into smaller groups in accordance with a set of decision rules) is necessary prior to any data collection. Whether formally or informally, an investigator has to decide which things are similar enough to be counted as the same and develop rules for governing collection procedures. Such rules can be as simple as “measure and record body weights only of live animals on study” or as complex as those demonstrated by the expanded weighting classification procedure demonstrated in the succeeding text. Such a classification also demonstrates that the selection of which variables to measure will determine the final classification of data.

Expanded Weighting Procedure

I.	Does the animal belong to the desired species?	Yes/no
II.	Is the animal a member of study group?	Yes/no
III.	Is the animal alive?	Yes/no
IV.	Which group does the animal belong to?	
	A. Control	
	B. Low dose	
	C. Intermediate dose	
	D. High dose	
V.	What sex is the animal?	Male/female
VI.	Is the measured weight in acceptable range?	Yes/no

Classifications of data have two purposes (Gordon, 1981; Hartigan, 1983): data simplification (also called a descriptive function) and prediction. Simplification is necessary because

there is a limit to both the volume and complexity of data that the human mind can comprehend and deal with conceptually. Classification allows us to attach a label (or name) to each group of data, to summarize the data (i.e., assign individual elements of data to groups and to characterize the population of the group), and to define the relationships between groups (i.e., develop a taxonomy).

Prediction, meanwhile, is the use of summaries of data and knowledge of the relationships between groups to develop hypotheses as to what will happen when further data are collected (as when more animals or people are exposed to an agent under defined conditions) and as to the mechanisms which cause such relationships to develop. Indeed, classification is the prime device for the discovery of mechanisms in all of science. A classic example of this was Darwin’s realization that there were reasons (the mechanisms of evolution) behind the differences and similarities in species which had caused Linnaeus to earlier develop his initial modern classification scheme (or taxonomy) for animals.

To develop a classification, one first sets bounds wide enough to encompass the entire range of data to be considered but not unnecessarily wide. This is typically done by selecting some global variables (variables every piece of data have in common) and limiting the range of each so that it just encompasses all the cases on hand. Then one selects a set of local variables (characteristics which only some of the cases have, say, the occurrence of certain tumor types, enzyme activity levels, or dietary preferences and which thus serve to differentiate between groups). Data are then collected, and a system for measuring differences and similarities is developed. Such measurements are based on some form of measurement of distance between two cases (x and y) in terms of each single variable scale. If the variable is a continuous one, then the simplest measure of distance between two pieces of data is the Euclidean distance, ($d(x, y)$), defined as follows:

$$d(x, y) = \sqrt{(x_i - y_i)^2}$$

For categorical or discontinuous data, the simplest distance measure is the matching distance, defined as follows:

$$d(x, y) = \text{number of time } x_i \neq y_i$$

After we have developed a table of such distance measurements for each of the local variables, some weighting factor is assigned to each variable. A weighting factor seeks to give greater importance to those variables which are believed to have more relevance or predictive value. The weighted variables are then used to assign each piece of data to a group. The actual act of developing numerically based classifications and assigning data members to them is the realm of cluster analysis and will be discussed later in this chapter. Classification of biological data based on qualitative factors has been well

discussed (Glass, 1975; Schaper et al., 1985) and does an excellent job of introducing the entire field and mathematical concepts.

Relevant examples of the use of classification techniques range from the simple to the complex. Schaper et al. (1985) developed and used a very simple classification of response methodology to identify those airborne chemicals which alter the normal respiratory response induced by CO₂. At the other end of the spectrum, Kowalski and Bender (1972) developed a more mathematically based system to classify chemical data (a methodology they termed pattern recognition).

32.8.2 Statistical Graphics

The use of graphics in one form or another in statistics is the single most effective and robust statistical tool and, at the same time, one of the most poorly understood and improperly used (Cleveland, 1994).

Graphs are used for one of four major purposes. Each of the four is a variation on the central theme of making complex data easier to understand and use. These four major functions are exploration, analysis, communication and display of data,

and graphic aids. Exploration (which may be simply summarizing data or trying to expose relationships between variables) is determining the characteristics of data sets and deciding on one or more appropriate forms of further analysis, such as the scatterplot. Analysis is the use of graphs to formally evaluate some aspect of the data, such as whether there are outliers present or if an underlying assumption of a population distribution is fulfilled. As long ago as 1960 (Anderson, 1960), some 18 graphic methods for analyzing multivariate data relationships were developed and proposed. Table 32.7 presents a summary of major graphic techniques that are available.

Communication and display of data is the most commonly used function of statistical graphics in toxicology, whether used for internal reports, presentations at meetings, or formal publications in the literature. In communicating data, graphs should not be used to duplicate data that are presented in tables, but rather to show important trends and/or relationships in the data. Though such communication is most commonly of a quantitative compilation of actual data, it can also be used to summarize and present the results of statistical analysis. The fourth and final function of graphics is one that is largely

TABLE 32.7 Forms of Statistical Graphics (by Function)

Data Summary	Two Variables	Three or More Variables
<i>Exploration</i>		
Box and whisker plot	Autocorrelation plot	Biplot
Histogram ^a	Cross-correlation plot	Cluster trees ^a
Dot array diagram	Scatterplot ^a	Labeled scatterplot ^a
Frequency polygon	Sequence plot	Glyphs and metroglyphs
Ogive		Fourier plots
Stem-and-leaf diagram		Similarity and preference maps
		MDS displays
		Weather vane plot
Distribution Assessment	Model Evaluation and Assumption Verification	Decision-Making
<i>Analysis</i>		
Probability plot	Average versus SD	Control chart
Q-Q plot	Component-plus-residual plot	Custom chart
P-P plot	Partial residual plot	Half-normal plot
Hanging histogram	Residual plots	Ridge trace
Rootagram		Youden plot
Poissonness plot		
Quantitative Graphics	Summary of Statistical Analyses	Graphic Aids
	<i>Communication and display of data</i>	
Line chart	Means plot	Confidence limits
Pictogram	Sliding reference distribution	Graph paper
Pie chart	Notched box plot	Power curves
Contour plot	Factor space/response	Nomographs
Stereogram	Interaction plot	Sample size curves
Color map	Contour plot	Trilinear coordinates
Histogram	Predicted response plot	
	Confidence region plot	

^aReviewed in the text of this chapter.

becoming outdated as microcomputers become more widely available. Graphic aids to calculation include nomograms (the classic example in toxicology of a nomogram is that presented by Litchfield and Wilcoxon (1949) for determining median effective doses) and extrapolating and interpolating data graphically based on plotted data.

There are many forms of statistical graphics (a partial list, classified by function, is presented in Table 32.6), and a number of these (such as scatterplots and histograms) can be used for each of a number of possible functions. Most of these plots are based on a Cartesian system (i.e., they use a set of rectangular coordinates), and our review of construction and use will focus on these forms of graphs.

Construction of a rectangular graph of any form starts with the selection of the appropriate form of graph followed by the laying out of the coordinates (or axes). Even graphs which are going to encompass multivariate data (i.e., more than two variables) generally have as their starting point two major coordinates. The vertical axis, or ordinate (also called the *Y*-axis), is used to present an independent variable. Each of these axes is scaled in the units of measure which will most clearly present the trends of interest in the data. The range covered by the scale of each axis is selected to cover the entire region for which data are presented. The actual demarking of the measurement scale along an axis should allow for easy and accurate assessment of the coordinates of any data point yet should not be cluttered.

Actual data points should be presented by symbols which present the appropriate indicators of location, and if they represent a summary of data from a normal data population, it would be appropriate to present a symbol for the mean and some indication of the variability (or error) associated with that population, commonly by using “error bars” which present the SD (or standard error) from the mean. If, however, the data are not normal or continuous, it would be more appropriate to indicate location by the median and present the range or semiquartile distance for variability estimates. The symbols which are used to present data points can also be used to present a significant amount of additional information. At the simplest level, a set of clearly distinct symbols (circles, triangles, squares, etc.) are very commonly used to provide a third dimension of data (most commonly treatment group). But by clever use of symbols, all sorts of additional information can be presented. Using a method such as Chernoff’s faces (Chernoff, 1973), in which faces are used as symbols of the data points (and various aspects of the faces present additional data, such as the presence or absence of eyes denoting the presence or absence of a secondary pathological condition), it is possible to present a large number of different variables on a single graph.

The three other forms of graphs that are commonly used are histograms, pie charts, and contour plots.

Histograms are graphs of simple frequency distribution. Commonly, the abscissa is the variable of interest (such as life

span or litter size) and is generally shown as classes or intervals of measurements (such as age ranges of 0–10, 10–20 weeks, etc.). The ordinate, meanwhile, is the incidence or frequency of observations. The result is a set of vertical bars, each of which represents the incidence of a particular set of observations. Measures of error or variability about each incidence are reflected by some form of error bar on top of or in the frequency bars, as shown in Figure 32.8. The size of class intervals may be unequal (in effect, one can combine or pool several small class intervals), but it is proper in such cases to vary the width of the bars to indicate differences in interval size.

Pie charts are the only common form of quantitative graphic technique which is not rectangular. Rather, the figure is presented as a circle out of which several “slices” are delimited. The only major use of the pie chart is in presenting a breakdown of the components of a group. Typically, the entire set of data under consideration (such as total body weight) constitutes the pie, while each slice represents a percentage of the whole (such as the percentages represented by each of several organs). The total number of slices in a pie should be small for the presentation to be effective. Variability or error can be readily presented by having a subslice of each sector shaded and labeled accordingly.

Finally, there is the contour plot, which is used to depict the relationships in a three-variable, continuous data system. That is, a contour plot visually portrays each contour as a locus of the values of two variables associated with a constant value of the third variable. An example would be a relief map that gives both latitude and longitude of constant altitude using contour lines.

The most common misuse of graphs is to either conceal or exaggerate the extent of the difference by using inappropriately scaled or ranged axis. Tufte (1983) has termed a statistic for evaluating the appropriateness of scale size, the lie factor, calculated as the ratio of the shown effect size to the range of potential change or effect. An acceptable range for the lie factor is from 0.95 to 1.05. Less means the size of an effect is being understated, more that the effect is being exaggerated.

There are a number of excellent references available for those who would like to pursue statistical graphics more. Anscombe (1973) presents an excellent short overview, while others (Schmid, 1983; Tufte, 1983; Young, 1985; Tufte, 1990, 1997) provide a wealth of information.

32.8.3 Multidimensional and Nonmetric Scaling

MDS is a collection of analysis methods for data sets which have three or more variables making up each data point. MDS displays the relationships of three or more-dimensional extensions of the methods of statistical graphics.

MDS presents the structure of a set of objects from data that approximate the distances between pairs of the objects. The data, called similarities, dissimilarities, distances, or proximities, must be in such a form that the degree of similarities and differences between the pairs of the objects (each of

FIGURE 32.8 Acquisitions of postnatal development landmarks in rats.

which represents a real-life data point) can be measured and handled as a distance (remember the discussion of measures of distances under classifications). Similarity is a matter of degree—small differences between objects cause them to be similar (a high degree of similarity), while large differences cause them to be considered dissimilar (a small degree of similarity).

In addition to the traditional human conceptual or subjective judgments or similarity, data can be an “objective” similarity measure (the difference in weight between a pair of animals)

or an index calculated from multivariate data (the proportion of agreement in the results of a number of carcinogenicity studies). However, the data must always represent the degree of similarity of pairs of objects.

Each object or data point is represented by a point in a multidimensional space. These plots or projected points are arranged in this space so that the distances between pairs of points have the strongest possible relation to the degree of similarity among the pairs of objects. That is, two similar objects are represented by two points that are close together,

and two dissimilar objects are represented by a pair of points that are far apart. The space is usually a two- or three-dimensional Euclidean space but may be non-Euclidean and may have more dimensions.

MDS is a general term which includes a number of different types of techniques. However, all seek to allow geometric analysis of multivariate data. The forms of MDS can be classified (Young, 1985) according to the nature of the similarities in the data. It can be qualitative (nonmetric) or quantitative (metric MDS). The types can also be classified by the number of variables involved and by the nature of the model used, for example, classical MDS (there is only one data matrix, and no weighting factors are used on the data), replicated MDS (more than one matrix and no weighting), and weighted MDS (more than one matrix and at least some of the data being weighted).

MDS can be used in toxicology to analyze the similarities and differences between effects produced by different agents, in an attempt to use an understanding of the mechanism underlying the actions of one agent to determine the mechanisms of the other agents. Actual algorithms and a good intermediate-level presentation of MDS can be found in Davison (1983).

Nonmetric scaling is a set of graphic techniques closely related to MDS and definitely useful for the reduction of dimensionality. Its major objective is to arrange a set of objects (each object, for our purposes, consisting of a number of related observations) graphically in a few dimensions while retaining the maximum possible fidelity to the original relationships between members (i.e., values which are most different are portrayed as most distant). It is not a linear technique; it does not preserve linear relationships (i.e., A is not shown as twice as far from C as B, even though its “value difference” may be twice as much). The spacing (interpoint distances) are kept such that if the distance of the original scale between members A and B is greater than that between C and D, the distances on the model scale shall likewise be greater between A and B than between C and D. Figure 32.5, presented earlier, uses a form of this technique in adding a third dimension by using letters to present degrees of effect on the skin.

This technique functions by taking observed measures of similarity or dissimilarity between every pair of M objects and then finding a representation of the objects as points in Euclidean space that the interpoint distances in some sense “match” the observed similarities or dissimilarities by means of weighting constants.

32.8.4 Cluster Analysis

Cluster analysis is a quantitative form of classification. It serves to help develop decision rules and then use these rules to assign a heterogeneous collection of objects to a series of sets. This is almost entirely an applied methodology (as opposed to theoretical). The final result of cluster analysis is

one of several forms of graphic displays and a methodology (set of decision-classifying rules) for the assignment of new members into the classifications.

The classification procedures used are based on either density of population or distance between members. These methods can serve to generate a basis for the classification of a large number of dissimilar variables such as behavioral observations and compounds with distinct but related structures and mechanisms (Gad, 1984, 2005) or to separate tumor patterns caused by treatment from those caused by old age (Hammond et al., 1978).

There are five types of clustering techniques (Everitt et al., 2011; Romesburg, 1984):

- a. *Hierarchical techniques*: Classes are subclassified into groups, with the process being repeated at several levels to produce a tree which gives sufficient definition to groups.
- b. *Optimizing techniques*: Clusters are formed by optimization of a clustering criterion. The resulting classes are mutually exclusive; the objects are partitioned clearly into sets.
- c. *Density or mode-seeking techniques*: Clusters are identified and formed by locating regions in a graphic representation which contains concentrations of data points.
- d. *Clumping techniques*: A variation of density-seeking techniques in which assignment to a cluster is weighted on some variables, so that clusters may overlap in graphic projections.
- e. *Others*: Methods which do not clearly fall into classes a–d.

Romesburg (1984) provides an excellent step-by-step guide to cluster analysis.

32.8.5 Fourier or Time Analysis

Fourier analysis (Bloomfield, 1976) is most frequently a univariate method used for either simplifying data (which is the basis for its inclusion in this chapter) or for modeling. It can, however, also be a multivariate technique for data analysis.

In a sense, it is like trend analysis; it looks at the relationship of sets of data from a different perspective. In the case of Fourier analysis, the approach is by resolving the time dimension variable in the data set. At the simplest level, it assumes that many events are periodic in nature, and if we can remove the variation in other variables because of this periodicity (by using Fourier transforms), we can better analyze the remaining variation from other variables. The complications to this are (i) there may be several overlying cyclic time-based periodicities and (ii) we may be interested in the time-cycle events for their own sake.

Fourier analysis allows one to identify, quantitate, and (if we wish) remove the time-based cycles in data (with their amplitudes, phases, and frequencies) by use of the Fourier transform:

$$nJ_i = x_i \exp(-iw_it)$$

where

- n = length
- J = the discrete Fourier transform for that case
- x = actual data
- i = increment in the series
- w = frequency
- t = time

32.8.6 Life Tables

Chronic *in vivo* toxicity studies are generally the most complex and expensive studies conducted by a toxicologist. Answers to a number of questions are sought in such a study—notably if a material results in a significant increase in mortality or in the incidence of tumors in those animals exposed to it. But we are also interested in the time course of these adverse effects (or risks). The classic approach to assessing these age-specific hazard rates is by the use of life tables (also called survivorship tables).

It may readily be seen that during any selected period of time (t_i) we have a number of risks competing to affect an animal. There are risks of (i) “natural death,” (ii) death induced by a direct or indirect action of the test compound, and (iii) death due to such occurrences of interest of tumors (Hammond et al., 1978; Salsburg, 1980), and we are indeed interested in determining if (and when) the last two of these risks become significantly different than the “natural” risks (defined as what is seen to happen in the control group). Life-table methods enable us to make such determinations as the duration of survival (or time until tumors develop) and the probability of survival (or of developing a tumor) during any period of time.

We start by deciding the interval length (t_i) we wish to examine within the study. The information we gain becomes more exact as the interval is shortened. But as interval length is decreased, the number of intervals increases, and calculations become more cumbersome and less indicative of time-related trends because random fluctuations become more apparent. For a 2-year or lifetime rodent study, an interval length or a month is commonly employed. Some life-table methods, such as the Kaplan–Meier, have each new event (such as a death) define the start of a new interval.

Having established the interval length, we can tabulate our data (Cutler and Ederer, 1958). We start by establishing the following columns in each table (a separate table being

established for each group of animals—i.e., by sex and dose level):

- a. The interval of time selected (t_i).
- b. The number of animals in the group that entered that interval of the study alive (l_i).
- c. The number of animals withdrawn from study during the interval (such as those taken for an interim sacrifice or that may have been killed by a technician error) (ω_i).
- d. The number of animals that died during the interval (d_i).
- e. The number of animals at risk during the interval, $l_i = l_i - 1/2 \omega_i$, or the number on study at the start of the interval minus one half of the number withdrawn during the interval.
- f. The proportion of animals that died = $D_i = d_i/l_i$.
- g. The cumulative probability of an animal surviving until the end of that interval of study, $P_i = 1 - D_i$, or one minus the number of animals that died during that interval divided by the number of animals at risk.
- h. The number of animals dying until that interval (M_i).
- i. Animals found to have died during the interval (m_i).
- j. The probability of dying during the interval of the study $c_i = 1 - (M_i + m_i/l_i)$ or the total number of animals dead until that interval plus the animals discovered to have died during that interval divided by the number of animals at risk through the end of that interval.
- k. The cumulative proportion surviving, p_i , equivalent to the cumulative product of the interval probabilities of survival (i.e., $p_i = p_1 \cdot p_2 \cdot p_3 \cdot p_x$).
- l. The cumulative probability of dying, C_i , equal to the cumulative product of the interval probabilities to that point (i.e., $C_i = c_1 \cdot c_2 \cdot c_3 \cdot c_x$).

With such tables established for each group in a study, we may now proceed to test the hypotheses that each of the treated groups has a significantly shorter duration of survival or that each of the treated groups died more quickly (note that plots of total animals dead and total animals surviving will give one an appreciation of the data, but can lead to no statistical conclusions).

There are a multiplicity of methods for testing significance in life tables, with (as is often the case) the power of the tests increasing as does the difficulty of computation (Cox, 1972; Tarone, 1975; Haseman, 1977; Salsburg, 1980).

We begin our method of statistical comparison of survival at any point in the study by determining the standard error of the K interval survival rate as (Garrett, 1947):

$$S_K = P_k \sqrt{\sum_1^k \left(\frac{D_i}{l_i - d_x} \right)}$$

We may also determine the effective sample size (l_1) in accordance with

$$l_1 = \frac{P(1-P)}{S^2}$$

We may now compute the standard error of difference for any two groups (1 and 2) as

$$S_D = \sqrt{S_1^2 + S_2^2}$$

The difference in survival probabilities for the two groups is then calculated as

$$P_D = P_1 - P_2$$

We can then calculate a test statistic as

$$t' = \frac{P_D}{S_D}$$

This is then compared to the z distribution table. If $t' > z$ at the desired probability level, it is significant at that level. With increasing recognition of the effects of time (both as age and length of exposure to unmeasured background risks), life-table analysis has become a mainstay in chronic toxicology. An example is the reassessment of the ED₀₁ study (SOT ED01 Task Force, 1981) which radically changed interpretation of the results and understanding of underlying methods when adjustment for time on study was made.

The increased importance and interest in the analysis of survival data have not been restricted to toxicology, but rather has encompassed all the life sciences. Those with further interest should consult Lee (1980) or Elandt-Johnson and Johnson (1980), both general in their approach to the subject.

32.9 META-ANALYSIS

Meta-analysis (meaning “analysis among”) is being used increasingly in biomedical research to try to obtain a qualitative or quantitative synthesis of the research literature on a particular issue. The technique is usually applied to the synthesis of several separate but comparable studies.

32.9.1 Selection of the Studies to Be Analyzed

The issue of study selection is perhaps the most troublesome issue for those doing meta-analysis. Several questions need to be addressed:

1. Should studies be limited to those which are published? It is well known that negative studies that report little or no benefit from following a particular

course of action are less likely to be published than are positive studies. Therefore, the published literature may be biased toward studies with positive results, and a synthesis of these studies would give a biased estimate of the impact of pursuing some courses of action. Unpublished studies, however, may be of lower quality than the published studies, and poor research methods often produce an underestimate of impact. Moreover, the unpublished studies may be difficult to discover.

2. Should studies be limited to those which appear in peer-reviewed publications? Peer review is considered the primary method for quality control in scientific publishing. Some investigators recommend that only those studies which are published in peer-reviewed publications be considered in meta-analysis. Although this may seem an attractive option, it might produce an even more highly biased selection of studies.
3. Should studies be limited those which meet additional quality control criteria? If investigators impose an additional set of criteria before including a study in meta-analysis, this may further improve the average quality of the studies used, but it introduces still greater concerns about selection bias. Moreover, different investigators might use different criteria for a “valid” study and therefore select a different group of studies for meta-analysis.
4. Should studies be limited to randomized controlled studies? This is a variant of the earlier question concerning quality control. At one time, rigid quality standards were more likely to be met by randomized controlled studies than by observational studies. Increasingly, however, observational methods have been used to evaluate certain kinds of effects, particularly those that are uncommon. A larger issue may well be that of combining data from studies performed in different laboratories and, even more so, using different strains of a single animal species.
5. Should studies be limited to those using identical methods? For practical purposes, this would mean using only separately published studies from the same lab in a limited time frame, for which the methods were the same for all and the similarity of methods was monitored. This criterion is very difficult to achieve.

32.9.2 Pooled (Quantitative) Analysis

Usually, the main purpose of meta-analysis is quantitative. The goal is to develop better overall estimates of the degree of benefit achieved by specific exposure and dosing techniques, based on the combining (pooling) of estimates found in the existing studies of the interventions. This type of

meta-analysis is sometimes called a pooled analysis (Gerbarg and Horwitz, 1988) because the analysts pool the observations of many studies and then calculate parameters such as risk ratios or odds ratios from the pooled data.

Because of the many decisions regarding inclusion or exclusion of studies, different meta-analyses might reach very different conclusions on the same topic. Even after the studies are chosen, there are many other methodological issues in choosing how to combine means and variances (e.g., what weighting methods should be used). Pooled analysis should report both relative risks and risk reductions as well as absolute risks and risk reductions (Sinclair and Bracken, 1994).

32.9.3 Methodological (Qualitative) Analysis

Sometimes the question to be answered is not how much toxicity is induced by the use of a particular exposure, but whether there is any biologically significant toxicity at all. In this case, a qualitative meta-analysis may be done, in which the quality of the research is scored according to a list of objective criteria. The meta-analyst then examines the methodologically superior studies to determine whether or not the question of toxicity is answered consistently by them. This qualitative approach has been called methodological analysis (Gerbarg and Horwitz, 1988) or quality scores analysis (Greenland, 1994). In some cases, the methodologically strongest studies agree with one another and disagree with the weaker studies, which may or may not be consistent with one another.

32.10 BAYESIAN INFERENCE

It is useful to know the sensitivity and specificity of a test. Once a researcher decides to use a certain test, two important questions require answers: If the test results are positive, what is the probability that the researcher has the condition of interest? If the test results are negative, what is the probability that the patient does not have the disease? Bayes' theorem provides a way to answer these questions.

Bayes' theorem, which was first described centuries ago by the English clergyman after whom it is named, is one of the most imposing statistical formulas in the biomedical sciences (Lindley, 1971). Put in symbols more meaningful for researchers such as pathologists, the formula is as follows:

$$P(D | T^+) = \frac{p(T^+ | D^+)p(D^+)}{[p(T^+ | D^+)p(D^+)] + [p(T^+ | D^-)p(D^-)]}$$

where p denotes probability; D^+ means that the animal has the effect in question; D^- means that the animal does not have the effect; T^+ means that a certain diagnostic test for

the effect is positive; T^- means that the test is negative; and the vertical line ($|$) means "conditional upon" what immediately follows.

Most researchers, even those who can deal with sensitivity, specificity, and predictive values, throw in the towel when it comes to Bayes' theorem. This is odd, because a close look at the earlier equation reveals that Bayes' theorem is merely the formula for the positive predictive value (Box and Tiao, 1973).

The numerator of Bayes' theorem merely describes **cell a** (the true-positive results). The probability of being in cell a is equal to the prevalence times the sensitivity, where $p(D^+)$ is the prevalence (the probability of being in the effected column) and where $p(T^+ | D^+)$ is the sensitivity (the probability of being in the top row, given the fact of being in the effected column). The denominator of Bayes' theorem consists of two terms, the first of which once again describes **cell a** (the true-positive results) and the second of which describes **cell b** (the false-positive error rate, or $p(T^+ | D^-)$), is multiplied by the prevalence of noneffected animals, or $p(D^-)$. The true-positive results (a) divided by the true positive plus false-positive results ($a+b$) give $a/(a+b)$, which is the positive predictive value.

In genetics, an even simpler-appearing formula for Bayes' theorem is sometimes used. The numerator is the same, but the denominator is mere $p(T^+)$. This makes sense because the denominator in $a/(a+b)$ is equal to all of those who have positive test results, whether they are true-positive or false positive results.

32.10.1 Bayes' Theorem and Evaluation of Safety Assessment Studies

In a population with a low prevalence of a particular toxicity, most of the positive results in a screening program for that lesion or effect would be falsely positive. Although this does not automatically invalidate a study or an assessment program, it raises some concerns about cost-effectiveness, and these can be explored using Bayes' theorem (Racine et al., 1986).

A program employing an immunochemical stain-based test to screen tissues for a specific effect will be discussed as an example. This test uses small amounts of antibody tissues for a specific effect, and the presence of an immunologically bound stain is considered a positive result. If the sensitivity and specificity of the test and the prevalence of biochemical effect are known, Bayes' theorem can be used to predict what proportion of the tissues with positive test results will have true-positive results (actually be affected).

Example 32.3 shows how the calculations are made. If the test has a sensitivity of 96% and if the true prevalence is 1%, only 13.9% of tissues with a positive test result are predicted actually to be affected.

EXAMPLE 32.3

USE OF BAYES' THEOREM OR A 2×2 TABLE TO DETERMINE THE POSITIVE PREDICTIVE VALUE OF A HYPOTHETICAL TUBERCULIN SCREENING PROGRAM

Part 1 Beginning data

Sensitivity of immunological stain	96% = 0.96
False-negative error rate of the test	4% = 0.04
Specificity of the test	94% = 0.94
False-positive error rate of the test	6% = 0.06
Prevalence of effect in the tissues	1% = 0.01

Part 2 Use of Bayes' theorem

$$\begin{aligned}
 p(D^+ | T^+) &= \frac{p(T^+ | D^+)p(D^+)}{[p(T^+ | D^+)p(D^+)] + [p(T^+ | D^-)p(D^-)]} \\
 &= \frac{(\text{sensitivity})(\text{prevalence})}{[(\text{sensitivity})(\text{prevalence})] + (\text{false - postive error rate})(1 - \text{prevalence})} \\
 &= \frac{(0.96)(0.01)}{[(0.96)(0.01)] + [(0.06)(0.99)]} = \frac{0.0096}{0.0096 + 0.0594} = \frac{0.0096}{0.0690} \\
 &= 0.139 = \mathbf{13.9\%}
 \end{aligned}$$

Part 3 Use of a 2×2 table, with numbers based on the assumption that 10000 tissues are in the study

	True Disease Status					
	Diseased		Nondiseased		Total	
	Number	Percentage	Number	Percentage	Number	Percentage
<i>Test Result</i>						
Positive	96	96	594	6	690	7
Negative	4	4	9306	94	9310	93
Total	100	100	9900	100	10000	100

Positive predictive value = 96/690 = 0.139 = **13.9%**.

Pathologists and toxicologists can quickly develop a table that lists different levels of test sensitivity, test specificity, and effect prevalence and shows how these levels affect the proportion of positive results that are likely to be true-positive results. Although this calculation is fairly straightforward and is extremely useful, it has seldom been used in the early stages of planning for large studies or safety assessment programs.

32.10.2 Bayes' Theorem and Individual Animal Evaluation

Suppose a pathologist is uncertain about an animal's cause of death and obtains a positive test result for a certain

pathology. Even if the pathologist knows the sensitivity and specificity of the test, that does not solve the problem, because to calculate the positive predictive value, it is necessary to know the prevalence of the particular tissue/effect that the test is designed to detect. The prevalence is thought of as the expected prevalence in the population from which the animal comes. The actual prevalence is usually not known, but often a reasonable estimate can be made.

Say, for example, a pathologist evaluates a male primate that was observed to have easy fatigability and has signs of kidney stones but has no other symptoms or signs of parathyroid disease on physical examination. The pathologist considers the probability of hyperparathyroidism and decides that it is now perhaps 2% (reflecting that in 100 such

primates, probably only two of them would have the disease). This probability is called the prior probability, reflecting the fact that it is estimated prior to the performance of laboratory tests and is based on the estimated prevalence of a particular pathology among primates with similar signs and symptoms. Although the pathologist believes that the probability of hyperparathyroidism is low, he or she considers the results of the serum calcium test to "rule" out the diagnosis. Somewhat to his or her surprise, the results of the test were positive, with an elevated level of 12.2 mg dL⁻¹. He or she could order more special tests or stains for parathyroid disease, but some test results might come back positive and some negative.

Under the circumstances, Bayes' theorem could be used to make a second estimate of probability, which is called the posterior probability, reflecting the fact that it is made after the test results are known. Calculation of the posterior probability is based on the sensitivity and specificity of the test that was performed, which in this case was the serum calcium test, and on the prior probability, which in this case was 2%. If the serum calcium test had a 90% sensitivity and a 95% specificity, that means it had a false-positive error rate of 5% (specificity plus the false-positive error rate equals 100%). When this information is used in the Bayes' equation, as shown in Example 32.4, the result is a posterior probability of 27%. This means that the patient is now in a group of primates with

a significant possibility of parathyroid disease. In Example 32.4, note that the result is the same (i.e., 27%) when a 2×2 table is used. This is true because, as discussed in the preceding text, the probability based on the Bayes' theorem is identical to the positive predictive value.

EXAMPLE 32.4

USE OF BAYES' THEOREM OR A 2×2 TABLE TO DETERMINE THE POSTERIOR PROBABILITY AND THE POSITIVE PREDICTIVE VALUE

Part 1 Beginning data

Sensitivity of first test 90% = 0.90
 Specificity of first test 95% = 0.95
 Prior probability of disease 2% = 0.02

Part 2 Use of Bayes' theorem

$$p(D^+|T^+) = \frac{p(T^+|D^+)p(D^+)}{p(T^+|D^+)p(D^+) + [p(T^+|D^-)p(D^-)]}$$

$$= \frac{(0.90)(0.02)}{[(0.90)(0.02) + (0.05)(0.98)]}$$

$$= \frac{0.018}{0.018 + 0.049} = \frac{0.018}{0.067} = 0.269 = 27\%$$

Part 3 Use of a 2×2 table

	True Disease Status					
	Diseased		Nondiseased		Total	
	Number	Percentage	Number	Percentage	Number	Percentage
<i>Test Result</i>						
Positive	18	90	49	5	67	6.7
Negative	2	10	931	95	933	93.3
Total	20	100	980	100	1000	100.0

Positive predictive value = 18/67 = 0.269 = 27%.

In light of the 27% posterior probability, the pathologist decides to order a parathyroid hormone radioimmunoassay, even though this test is expensive. If the radioimmunoassay had a sensitivity of 95% and a specificity of 98% and the results turned out to be positive, the Bayes' theorem could again be used to calculate the probability of parathyroid disease. This time, however, the posterior probability for the first test (27%) would be used as the prior probability for the second test. The result of the calculation, as shown in Example 32.5, is a new probability of 94%. Thus, the primate in all probabilities did have hyperparathyroidism.

EXAMPLE 32.5

USE OF BAYES' THEOREM OR A 2×2 TABLE TO DETERMINE THE SECOND POSTERIOR PROBABILITY AND THE SECOND POSITIVE PREDICTIVE VALUE

Part 1 Beginning data

Sensitivity of the first test 95% = 0.95
 Specificity of the first test 98% = 0.98
 Prior probability of disease 27% = 0.27

Part 2 Use of Bayes' theorem

$$p(D^+|T^+) = \frac{p(T^+|D^+)p(D^+)}{p(T^+|D^+)p(D^+) + [p(T^+|D^-)p(D^-)]}$$

$$= \frac{(0.95)(0.27)}{[(0.95)(0.27) + (0.02)(0.73)]}$$

$$= \frac{0.257}{0.257 + 0.146} = \frac{0.257}{0.272} = 0.9449^a = 94\%$$

Part 3 Use of a 2×2 table

	True Disease Status					
	Diseased		Nondiseased		Total	
	Number	Percentage	Number	Percentage	Number	Percentage
<i>Test Result</i>						
Positive	256	95	15	2	271	27.1
Negative	13	5	716	98	729	72.9
Total	269	100	731	100	1000	100.0

Positive predictive value = 256/271 = 0.9446^a = 94%.

^aThe slight difference in the results for the two approaches is due to rounding errors. It is not important biologically.

Why did the posterior probability increase so much the second time? One reason was that the prior probability was considerably higher in the second calculation than in the first (27% vs. 2%), based on the fact that the first test yielded positive results. Another reason was that the specificity of the second test was quite high (98%), which markedly reduced the false-positive error rate and therefore increased the positive predictive value.

32.11 DATA ANALYSIS APPLICATIONS IN SAFETY ASSESSMENT STUDIES

Having reviewed basic principles and provided a set of methods for statistical handling of data, the remainder of this book will address the practical aspects and difficulties encountered in working safety assessment.

There are now common practices in the analysis of safety data, though they are not necessarily the best. These are discussed in the remainder of this chapter, which seeks to review statistical methods on a use-by-use basis and to provide a foundation for the selection of alternatives in specific situations. Some of the newer available methodologies (meta-analysis and Bayesian approaches) should be kept in mind, however.

32.11.1 Body and Organ Weights

Among the sets of data commonly collected in studies where animals are dosed with (or exposed to) a chemical are body weight and the weights of selected organs. In fact, body weight is frequently the most sensitive indication of an adverse effect. How to best analyze this and in what form to analyze the organ weight data (as absolute weights, weight changes, or percentages of body weight) have been the subject of a number of articles (Jackson, 1962; Weil, 1962; Weil and Gad, 1980).

Both absolute body weights and rates of body weight change (calculated as changes from a baseline measurement value which is traditionally the animal's weight immediately prior to the first dosing with or exposure to test material) are almost universally best analyzed by ANOVA, followed, if called for, by a *post hoc* test. Even if the groups were randomized properly at the beginning of a study (no group being significantly different in mean body weight from any other group and all animals in all groups within two SD of the overall mean body weight), there is an advantage to performing the computationally slightly more cumbersome (compared to absolute body weights) changes in body weight analysis. The advantage is an increase in sensitivity because the adjustment of starting points (the setting of initial weights as a "zero" value) acts to reduce the amount of initial variability. In this case, Bartlett's test is performed first to ensure homogeneity of variance and the appropriate sequence of analysis follows.

With smaller sample sizes, the normality of the data becomes increasingly uncertain and nonparametric methods such as Kruskal–Wallis may be more appropriate (Zar, 1974).

The analysis of relative (to body weight) organ weights is a valuable tool for identifying possible target organs (Bickis, 1990; Lee and Lovell, 2009). How to perform this analysis is still a matter of some disagreement, however. Weil (1962) presented evidence that organ weight data expressed as percentages of body weight should be analyzed separately for each sex. Furthermore, since the conclusions from organ weight data of males differed so often from those of females, data from animals of each sex should be used in this measurement. Others (Boyd and Knight, 1963; Grubbs, 1969; Boyd, 1972; Weil, 1973) have discussed in detail other factors that influence organ weights and must be taken into account.

The two competing approaches to analyzing relative organ weights call for either:

1. Calculating organ weights as a percentage of total body weight (at the time of necropsy) and analyzing the results by ANOVA.
2. Analyzing results by ANCOVA, with body weights as the covariates as discussed previously by the author (Weil and Gad, 1980).

A number of considerations should be kept in mind when these questions are addressed. First, one must keep a firm grasp on the difference between biological significance and statistical significance. In this particular case, we are especially interested in examining organ weights when an organ weight change is not proportional to changes in whole body weights. Second, we are now required to detect smaller and small changes while still retaining a similar sensitivity (i.e., the $p < 0.05$ level).

There are several devices to attain the desired increase in power. One is to use larger and larger sample sizes (number of animals), and the other is to utilize the most powerful test we can. However, the use of even currently employed numbers of animals is being vigorously questioned, and the power of statistical tests must, therefore, now assume an increased importance in our considerations.

The biological rationale behind analyzing both absolute body weight and the organ weight to body weight ratio (this latter as opposed to a covariance analysis of organ weights) is that in the majority of cases, except for the brain, the organs of interest in the body change weight (except in extreme cases of obesity or starvation) in proportion to total body weight. We are particularly interested in detecting cases where this is not so. Analysis of actual data from several hundred studies (unpublished data) has shown no significant difference in rates of weight change of target organs (other than the brain) compared to total body weight for healthy animals in those species commonly used for repeated-dose studies (rats, mice, rabbits, and dogs). Furthermore, it should be noted that ANCOVA is of questionable validity in analyzing body weight and related organ weight changes, since a primary assumption is the independence of treatment—that the relationship of the two variables is the same for all treatments (Ridgemen, 1975). Plainly, in toxicology this is not true.

In cases where the differences between the error mean squares are much greater, the ratio of F ratios will diverge in precision from the result of the efficiency of covariance adjustment. These cases are where either sample sizes are much larger or where the differences between means themselves are much larger. This latter case is one which does not occur in the designs under discussion in any manner that would leave ANCOVA as a valid approach, because group means start out being very similar and cannot diverge

markedly unless there is a treatment effect. As we have discussed earlier, a treatment effect invalidates a prime underpinning assumption of ANCOVA.

32.11.2 Clinical Chemistry

A number of clinical chemistry parameters are commonly measured for all using study animals (Verma, 2016) on the blood and urine collected from animals in chronic, sub-chronic, and, occasionally, acute toxicity studies. In the past (and still, in some places), the accepted practice has been to evaluate these data using univariate parametric methods (primarily *t*-tests and/or ANOVA). However, this can be shown to be not the best approach on a number of grounds.

First, such biochemical parameters are rarely independent of each other. Neither is our interest often focused on just one of the parameters. Rather, there are batteries of the parameters associated with toxic actions at particular target organs. For example, increases in creatinine phosphokinase (CPK), γ -hydroxybutyrate dehydrogenase (γ -HBDH), and lactate dehydrogenase (LDH), occurring together, are strongly indicative of myocardial damage. In such cases, we are not just interested in a significant increase in one of these, but in all three. Detailed coverage of the interpretation of such clinical laboratory tests can be found in other references (Martin et al., 1975; Harris, 1978; Loeb and Quimby, 1999; Gad and Rousseaux, 2013; Gad, 2015, 2021) or elsewhere in this text. The lists of normally recommended tests have changes based on new information (notable the addition of KIM-1 for kidney effects and Troponin-1 for potential heart damage), but most clinical research organization (CRO)s have not incorporated these into their standard battery of tests.

Similarly, the serum electrolytes (sodium, potassium, and calcium) interact with each other; a decrease in one is frequently tied, for instance, to an increase in one of the others. Furthermore, the nature of the data (in the case of some parameters), either because of the biological nature of the parameter or the way in which it is measured, is frequently either not normally distributed (particularly because of being markedly skewed) or not continuous in nature. This can be seen in some of the reference data for experimental animals in Mitruka and Rawnsley (1977) or Weil (1982) in, for example, creatinine, sodium, potassium, chloride, calcium, and blood.

32.11.3 Hematology

Much of what we said about clinical chemistry parameters is also true for the hematologic measurements made in toxicology studies. Which test to perform should be evaluated by use of a decision tree until one becomes confident as to the most appropriate methods. Keep in mind that sets of values and (in some cases) population distribution vary not only between species but also between the commonly used strains

of species and that “control” or “standard” values will “drift” over the course of only a few years.

Again, the majority of these parameters are interrelated and highly dependent on the method used to determine them. RBC count, platelet counts, and mean corpuscular volume (MCV) may be determined using a device such as a Coulter counter to take direct measurements, and the resulting data are usually stable for parametric methods. The hematocrit, however, may actually be a value calculated from the RBC and MCV values and, if so, is dependent on them. If the hematocrit is measured directly, instead of being calculated from the RBC and MCV, it may be compared by parametric methods.

Hemoglobin is directly measured and is an independent and continuous variable. However, and probably because at any one time a number of forms and conformations (oxyhemoglobin, deoxyhemoglobin, methemoglobin, etc.) of hemoglobin are actually present, the distribution seen is not typically a normal one, but rather may be a multimodal one. Here a nonparametric technique such as the Wilcoxon or multiple rank-sum is called for.

Consideration of the WBC and differential counts leads to another problem. The total WBC is, typically, a normal population amenable to parametric analysis, but differential counts are normally determined by counting, manually, one or more sets of 100 cells each. The resulting relative percentages of neutrophils are then reported as either percentages or are multiplied by the total WBC count with the resulting “count” being reported as the “absolute” differential WBC. Such data, particularly in the case of eosinophils (where the distribution does not approach normality), should usually be analyzed by nonparametric methods. It is widely believed that “relative” (%) differential data should not be reported because they are likely to be misleading.

Lastly, it should always be kept in mind that it is rare for a change in any single hematologic parameter to be meaningful. Rather, because these parameters are so interrelated, patterns of changes in parameters should be expected if a real effect is present, and analysis and interpretation of results should focus on such patterns of changes. Classification analysis techniques often provide the basis for a useful approach to such problems.

32.11.4 Histopathological Lesion Incidence

The last 32 years have seen increasing emphasis placed on histopathological examination of tissues collected from animals in subchronic and chronic toxicity studies. While it is not true that only those lesions which occur at a statistically significantly increased rate in treated/exposed animals are of concern (for there are the cases where a lesion may be of such a rare type that the occurrence of only one or a few such in treated animals “raises a flag”), it is true that, in most cases, a statistical evaluation is the prime method to determine

if what we see in treated animals is significantly worse than what has been seen in control animals, and although cancer is not our only concern, this category of lesions is that of greatest interest (Gad and Rousseaux, 2013).

Typically, a comparison of incidences of any one type of lesion between controls and treated animals is made using the multiple 2×2 chi-square test or Fisher's exact test with a modification of the number of animals as the denominators. Too often, experimenters exclude from consideration all those animals (in both groups) which died prior to the first animals being found with a lesion at that site. The special case of carcinogenicity bioassays will be discussed in detail in Chapter 24.

An option which should be kept in mind is that, frequently, a pathologist can not only identify a lesion as present but also grade those present as to severity. This represents a significant increase in the information content of the data which should not be given up by performing an analysis based only on the perceived quantal nature (present/absent) of the data. Quantal data, analyzed by chi-square or Fisher's exact tests, are a subset (the 2×2 case) of categorical or contingency table data. In this case, it also becomes ranked (or "ordinal") data—the categories are naturally ordered (e.g., no effect < mild lesion < moderate lesion < severe lesion). This gives a $2 \times R$ table if there are only one treatment and one control group or an $N \times R$ ("multiway") table if there are three or more groups of animals.

The traditional method of analyzing multiple, cross-classified data has been to collapse the $N \times R$ contingency table over all but two of the variables and to follow this with the computation of some measure of association between these variables. For an N -dimensional table, this results in $N(N-1)/2$ separate analyses. The result is crude, "giving away" information, and even (by inappropriate pooling of data) yielding a faulty understanding of the meaning of data. Though computationally more laborious, a multiway ($N \times R$ table) analysis should be utilized.

32.11.5 Carcinogenesis

In the experimental evaluation of substances for carcinogenesis based on experimental results in a nonhuman species at some relatively high-dose or exposure level, an attempt is made to predict the occurrence and level of tumorigenesis in humans at much lower levels. An entire chapter could be devoted to examining the assumptions involved in this undertaking and review of the aspects of design and interpretation of animal carcinogenicity studies. Such is beyond the scope of this effort. The reader is referred to Gad (2005) for such an examination.

The single most important statistical consideration in the design of carcinogenicity bioassays in the past was based on the point of view that what was being observed and evaluated was a simple quantal response (cancer occurred or it did not) and that a sufficient number of animals are needed to be used to have reasonable expectations of detecting such an effect. Though the single fact of whether or not the simple incidence of neoplastic tumors is increased due to an agent of concern is of interest, a much more complex model must now be considered. The time-to-tumor, patterns of tumor incidence, effects on survival rate, and age at first tumor all must now be included in a model.

The rationale behind this assumption is that though humans may be exposed at very low levels, detecting the resulting small increase (over background) in the incidence of tumors would require the use of an impractically large number of test animals per group. This point was illustrated by Table 32.1, where, for instance, while only 46 animals (per group) are needed to show a 10% increase over a zero background (i.e., a rarely occurring tumor type), 770 000 animals (per group) would be needed to detect a tenth of a percent increase above a 5 % background. As we increase dose, however, the incidence of tumors (the response) will also increase, until it reaches the point where a modest increase (say, 10%) over a reasonably small background level (say,

TABLE 32.8 Average Number of Animals Needed to Detect a Significant Increase in the Incidence of an Event (Tumors, Anomalies, etc.) Over the Background Incidence (Control) at Several Expected Incidence Levels Using Fisher's Exact Probability Test ($p = 0.05$)

Background Incidence (%)	Expected Increase in Incidence (%)					
	0.01	0.1	1	3	5	10
0	46 000 000 ^a	460 000	4 600	511	164	46
0.01	46 000 000	460 000	4 600	511	164	46
0.1	47 000 000	470 000	4 700	520	168	47
1	51 000 000	510 000	5 100	570	204	51
5	77 000 000	770 000	7 700	856	304	77
10	100 000 000	1 000 000	10 000	1 100	400	100
20	148 000 000	1 480 000	14 800	1 644	592	148
25	160 000 000	1 600 000	16 000	1 840	664	166

^aNumber of animals needed in each group—controls as well as treated.

1%) could be detected using an acceptably small-sized group of test animals (in Table 32.8 we see that 51 animals would be needed for this example case). There are, however, at least two real limitations to the highest dose level. First, the test rodent population must have a sufficient survival rate after receiving a lifetime (or 2 years) of regular doses to allow for meaningful statistical analysis. Second, we really want the metabolism and mechanism of action of the chemical at the highest level tested to be the same as at the low levels where human exposure would occur. Unfortunately, toxicologists usually must select the high-dose level based only on the information provided by a subchronic or range-finding study (usually 90 days in length), but selection of either too low or too high a dose will make the study invalid for detection of carcinogenicity and may seriously impair the use of the results for risk assessment.

There are several solutions to this problem. One of these has been the rather simplistic approach of the NTP bioassay program, which is to conduct a 3-month range-finding study with sufficient dose levels to establish a level which significantly (10%) decreases the rate of body weight gain. This dose is defined as the maximum tolerated dose (MTD) and is selected as the highest dose. Two other levels, generally one-half MTD and one-quarter MTD, are selected for testing as the intermediate- and low-dose levels. In many earlier NCI studies, only one other level was used.

The dose range-finding study is necessary in most cases, but the suppression of body weight gain is a scientifically questionable benchmark when dealing with establishment of safety factors. Physiological, pharmacologic, or metabolic markers generally serve as better indicators of systemic response than body weight. A series of well-defined acute and subchronic studies designed to determine the “chronicity factor” and to study onset of pathology can be more predictive for dose setting than body weight suppression.

Also, the NTP’s MTD may well be at a level where the metabolic mechanisms for handling a compound at real-life exposure levels have been saturated or overwhelmed, bringing into play entirely artifactual metabolic and physiological mechanisms (Gehring and Blau, 1977). The regulatory response to questioning the appropriateness of the MTD as a high-dose level (Haseman, 1985) has been to acknowledge that occasionally an excessively high dose is selected, but to counter by saying that using lower doses would seriously decrease the sensitivity of detection.

COMBINATION PRODUCTS: DRUGS AND DEVICES

33.1 COMBINATION PRODUCTS

The last four decades have seen a continuous increase in the number of new therapeutic products which are not purely drug, device, or biologic but rather a combination of two or more of these including multiples of each. Classical examples are implanted drug delivery systems (whose primary function is drug delivery) and drug-impregnated devices (in which drug delivery is an adjunct to the device function) (see Table 33.1 for a more extensive list of examples). Congress first acknowledged the need for specific regulation of such combination products in the 1990 Safe Medical Device Act, and subsequent regulations have clarified regulatory expectations (CDRH, 1994; Chapekar, 1996; FDA, 2006; Siegal, 2008; Crawford, 2015; Gad and Gad-McDonald, 2015).

33.1.1 Historical Background

The history of this category includes an ever evolving (and expanding) variety of product types, dating at least from the perfection of the hypodermic needle (1855). There are now many modern examples of implanted therapeutic delivery systems, such as the insulin pump (1980), pain drug pumps, artificial pancreas implants (device/cell combination), and more recently implanting communicating systems which both measure or externally monitor endogenous active substances and deliver supplementation in response to that measurement. One fundamental driving force for delivery systems has been the growth of new pharmaceutical products, especially since the dramatic expansion of drug research after 1945. That research has led to the synthesis and testing of millions of compounds for pharmacological and antimicrobial properties. Indeed, today much of that

development is performed in automated computer-controlled systems, leading to an even greater acceleration of the process. The continued emergence of a stream of novel and more complex combination products has blurred any distinguishing lines of regulatory authority and has complicated product designation and regulation. The issue of products combining a device and a drug, such as an asthma-metered dose inhaler, has received considerable scrutiny as more attention has been brought to bear of device leachables and extractables. But products combining a device and a biologic, such as organ replacement or assist devices, had received less attention.

Even less than drug and device combinations, device and biologic products—which include, among other things, cellular and tissue implants, infused or encapsulated cells, artificial and replacement organs, heart valves and pumps, and cardiac, neural, and neuromuscular stimulation devices—do not fit neatly into existing regulatory paradigms. For example, as part of the question of regulation, Food and Drug Administration (FDA) must take into account the possibility of tissue contamination and other hazards involved in using animal-derived tissues.

What has come to pass is a settled regulatory process. The written guidelines are fixed and the day-to-day process seemingly settled (Merrill, 1994; March, 1998; Segal, 1999; Gopaldaswamy and Gopaldaswamy, 2008; Siegal, 2008). It starts with determination of a primary mode of action (PMOA) which governs which center of FDA will have the primary regulatory oversight. The FDA Office of Combination Products (OCP) reviews requests for such determinations (RFDs—requests for designations) and advises the parties concerned as to which centers will be the primary for product review. More recently, FDA (2006) has promulgated a guidance on the nonclinical safety evaluation of drug/drug

TABLE 33.1 Examples of Existing Device/Drug Combination Products

Cardiac output catheter	Heparin	As device in the United Kingdom
Extracorporeal sets	Heparin	As device in the United Kingdom
Viscose/rayon dressings	Povidone iodine	As drug in the United Kingdom
Cardiovascular oxygenator	Heparin	As drug in UK defoamer reservoir
Paste bandages	Clioquinol, coal tar, calamine	As drug in the United Kingdom (if they have ichthammol ancillary action)
Medicated tulle dressings	Chlorhexidine	As drug in the United Kingdom
Antimicrobial drape	Iodophor	As device in the United Kingdom
Antiseptic wipes	Chlorhexidine, cetrimide, alcohol	As drug in the United Kingdom
Cardiovascular guidewires	Heparin	As device in Spain
Guidewires	Heparin	As device in Spain, Switzerland, and the United Kingdom
Antibiotic bone cement	Antibiotic (for example, Gentamicin sulfate), colistin sulfomethate, sodium, erythromycin	As drug (but soon to be regulated as device)
Extracorporeal cardiotomy reservoirs and filters	Heparin	As devices in Spain, Benelux, and Italy
Extracorporeal venous reservoirs and filters	Heparin	As devices in Spain, Benelux, and Italy
Bacteriostatic urological catheters	Silver	As devices in three Benelux countries
Antiseptic island dressing	Chlorhexidine digluconate	As device in Italy
Spermicidal condoms, vaginal rings, and INDS	Nonoxynol-9 and other contractive drugs	As device in Germany and in the United States
Pacemaker lead with a porous tip (seulte)	Dexamethasone	As device
Pacemaker lead with protector mannitol capsule (sweet tip)	Mannitol	As device
Biomedicus centrifugal pump	Heparin	Not applicable
Peripheral vascular cannulae	Heparin, Takol	Not applicable
Surgical gauzes or nonwoven fabrics impregnated with iodophor	Iodophor	Not applicable
Surgical gauzes or nonwoven fabrics impregnated with—alginates and Clioquinol	Clioquinol (NaCa alginates, clauden powder)	As device in Germany
Vascular prosthesis	Collagen, albumen	As devices in the United Kingdom

combinations. Such combinations are now frequent, most commonly seeking approval by the 505(b)(2) route. If the combination is of two approved and marketed products, the primary safety concern is for international (pharmacokinetics and pharmacodynamics). As such, the primary nonclinical safety studies that must be conducted are systemic toxicity studies of the fixed combination itself with toxicokinetic sampling components. Genetic toxicity and safety pharmacology studies of the combination are usually not required.

33.1.2 Future Trends

Table 33.2 presents anticipated developments in the device combination product category up until 2020 which lead to new clinical products. Three types of developments are generally expected. First, additional products designed for implanted delivery of insulin and other drugs. These include implanted pumps, possibly intelligent devices with improved biosensors to monitor concentrations in body fluids and make dynamic adjustments in delivery rates. Also, there is the likely development of new polymeric timed-release devices which could improve the delivery of long-acting pharmaceuticals at optimized locations and rates.

Second, new developments in drug-impregnated devices are expected. Examples included new types of cardiac implants with antithrombogenic and anti-infective drugs, as well as orthopedic implants with bacteriostatic coatings.

Finally, under development are new developments in drug delivery systems to simplify reliable use by unsophisticated patients in home settings, including the increasing elderly population. Examples included nasal and inhalation products.

Device regulation designation is by PMOA, which is generally straightforward but can become less clear as precedents accumulate, and technology becomes more complex. Table 33.3 provides some examples of classifications.

Although both extracorporeal and peritoneal dialysis systems are regulated as devices, dialysate concentrate for use with the former is a device, but prepackaged dialysate for use with the latter is a drug. Sometimes consistency was elusive even when there was no combination but just a single product. For example, *in vitro* diagnostics for detecting antibodies to HIV are regulated as biologics when they are used for screening the blood supply but as medical devices when used for diagnostic or other screening purposes. When the FDA decides quickly and unequivocally on the regulatory status of

TABLE 33.2 Likelihood New Combination Device Drug Technologies

Biosensors	Biosensors (for glucose, implantation, and systemic infection markers), genetic diagnostics, laser diagnosis and treatment, minimally invasive devices
Blood vessel prosthetics	Genetic therapy, tissue-engineered vessels, nerves, and devices
Bone prosthetics/growth	Artificial organs, tissue-engineered devices, scaffolds with bone-growth-stimulating agents
Cardiac stimulation	Intelligent devices, microminiaturized devices
Cartilage prosthetics	Tissue-engineered device
Computer-aided clinical labs	Computer-aided diagnosis, networks of devices
Drug-impregnated devices	Device/drug/biological products
Endoscopy	Minimally invasive devices, telemedicine, virtual reality diagnostics
Genetics—cancer	Genetic diagnostics, genetic therapy
Hearing aids	Intelligent devices, microminiaturized devices, non-implanted sensory aids
Heart pumps	Artificial organs
Heart valves	Artificial organs, tissue-engineered devices, device/drug/biological products
Home diagnostics	Home/self-monitoring and diagnosis
Image contrast agents	Medical imaging
Imaging: functional, content	Medical imaging, minimally invasive devices, networks of devices
Implanted drug	Biosensors, device/drug/biological products, delivery systems, home/self-therapy, intelligent devices, robotic devices
Integrated patient medical info systems	Computer-aided diagnosis, networks of devices, telemedicine
Kidney prosthetics	Artificial organs, home/self-therapy, tissue-engineered devices
Laser surgery	Laser diagnosis and treatment
Liver prosthetics	Artificial organs, tissue-engineered devices
Minimally invasive cardiology	Minimally invasive devices vascular surgery
Minimally invasive neurosurgery	Minimally invasive devices
MRI	Greater resolution imaging
Nanotechnology	Microminiaturized devices
Nerve regeneration	Tissue-engineered devices
Neural stimulation	Artificial organs, electrical stimulation, intelligent devices
Neuromuscular stimulation	Electrical stimulation, home/self-therapy
Ocular prosthetics	Artificial organs, electrical stimulation, intelligent devices
Pancreas prosthetics	Artificial organs, tissue-engineered devices
Patient smart cards	Computer-aided diagnosis, networks of devices, telemedicine
PET imaging	Combined PET and CAT imaging
Robotic surgery	Microminiaturized devices, robotic devices
Skin prosthetics	Tissue-engineered devices
Telemedicine—home use	Home/self-monitoring and diagnosis, telemedicine
Telemedicine—radiology	Telemedicine

a product, whether it was deemed a single product or was in combination with another product, there was relatively little opportunity for objection to the agency’s decisions about how to regulate combination products and products whose status was uncertain. In the case of blood devices, the European Union (EU) has affirmed this process (Anon, 2000).

In the Safe Medical Devices Act of 1990 (SMDA), Congress took these issues in hand and amended the Federal Food, Drug, and Cosmetic Act (FDCA) to make it easier for the FDA to regulate combination products in a rational fashion. The new provisions altered the substantive provisions of the FDCA only in minor respects. The main thrust of the new law was managerial, directing the FDA to make decisions about which center would have “primary jurisdiction” over a combination product, based on the agency’s understanding of the PMOA of the product.

For these products, center jurisdiction turns on the PMOA. If the PMOA is that of a drug, then the Center for Drug Evaluation and Research (CDER) has primary jurisdiction; if it is that of a device, jurisdiction is with the Center for Devices and Radiological Health (CDRH); if that of a biological product, the Center for Biologics Evaluation and Research (CBER) has this jurisdiction. As the statute prescribed, the regulations go on to state that the center with primary jurisdiction may consult with other agency components.

Although neither the statute nor the regulations explain what “primary jurisdiction” means, it seems clear that the FDA intends it to mean that the center that has primary jurisdiction will review the combination product and ordinarily give it just one approval, that is, a New Drug Application (NDA), Pharmaceutical Manufacturers Association (PMA), or biologic license application (BLA) as appropriate.

TABLE 33.3 Classification Examples of Products

Combination products that have been classified as drugs:

- Prefilled syringes
- Patches for transdermal drug delivery
- Implants whose primary purpose is to release a drug
- Wound dressings whose primary purpose is to deliver a drug
- Dental products impregnated with a drug whose primary purpose is to deliver a drug
- Red blood cell processing solutions
- Contrast media
- Peritoneal dialysis solutions
- Alcohol swabs

Combination products that have been classified as devices:

- Drug-coated devices such as catheters, shunt sensors, or pacemaker leads
- Drug-impregnated devices
- Wound dressings and surgical barriers containing an antimicrobial agent
- Wound dressings whose primary purpose is to act as a barrier to pathogens
- Blood bags containing anticoagulant or preservation solutions
- Bone cement containing antibiotic and novel bone void fillers, for example, collagen matrix with bone morphogenic protein
- Injectable collagen
- Sodium hyaluronate nasal solution
- Urea breath test (accessory to device)
- Device for *ex vivo* photodynamic cell processing

Combinations of drugs and devices to which this policy does not apply and which must comply with both the food and drug regulations and the medical devices regulations:

- Kits (e.g., epidural tray containing drugs and devices, first aid kit containing drugs and devices)

Products for which neither set of regulations applies:

- Organ preservation solutions
- Minimally manipulated tissue

Source: Adapted from Gopaldaswamy and Gopaldaswamy (2008).

Section 3.4(b) makes it clear, however, that the FDA’s designation of one agency component as having primary jurisdiction does not preclude, in appropriate cases, the requirement for separate application, for example, a 510(k) and a BLA. When separate applications are required, both can be reviewed by the lead center, but “exceptional” cases may involve a second application to be reviewed by a different center. To facilitate this, the agency published new delegations giving officials in each of the three centers the authority to clear devices and to approve devices, drugs, biologics, or any combination of two or more of them (FDA, 1991).

Contemporaneous with publication of the new regulations, the FDA made public three new intercenter agreements between CDRH and CBER, CDRH and CDER, and CDER and CBER. They describe the allocations of responsibility for

numerous categories of specific products, both combination and noncombination. According to the regulations, these intercenter agreements are not binding; they are intended to “provide useful guidance to the public” and, as a practical matter, to FDA staff as well.

The intercenter agreements are a treasure trove of information. In addition to explicit guidance about which center has the lead with respect to particular products and whether one center or two will work on particular issues, they contain information and hints about whether the FDA believes it can regulate certain products at all and, if so, how (Adams et al., 1997; Pilot and Waldemann, 1998).

The regulations and intercenter agreements, however, do not answer every question, and the regulations recognize a role for the sponsor in cases of uncertainty. When the identity of the center with primary jurisdiction is unclear or in dispute, or a sponsor believes its combination product is not covered by the intercenter agreements, a sponsor can request a designation from the FDA’s product jurisdiction officer. A sponsor “should” file a request for designation with the product jurisdiction officer before submitting its application for marketing approval or an investigational notice. In practice, though, disputes or lack of clarity may not become evident until well into the review process, and it seems likely that the FDA would, if necessary, entertain requests for designation submitted at a later time.

Section 3.7(c) of the regulations lists the information to be included in the request, all of which must fit on 15 pages or less, including the identity of the sponsor, detailed information on the product, where the developmental work stands, the product’s known modes of action and its PMOA, and, importantly, the sponsor’s recommendation for which center should have primary jurisdiction and the reasons for the recommendation.

The FDA promises to check the request for designation for completeness within 5 working days of receipt and to issue a letter of designation within 60 days of receipt of a complete request. If the FDA does not meet the 60-day time limit, then the sponsor’s recommendation for the appropriate lead center is honored.

The agency’s letter of designation can be changed only with the sponsor’s written consent or, if the sponsor does not consent, “to protect the public health or for other compelling reasons.” A sponsor must be given prior notice of any proposed nonconsensual change and must be given an opportunity to object in writing and at a “timely” meeting with the product jurisdiction officer and appropriate center officials.

The CDRH is designated the center for major policy development and for the promulgation and interpretation of procedural regulations for medical devices under the Act. The CDRH regulates all medical devices inclusive of radiation-related device that are not assigned categorically or specifically to CDER. In addition, CDRH will independently

administer the following activities (references to “sections” are the provisions of the Act):

- A. Small business assistance programs under Section 10 of the amendments (see PL 94-295). Both CDER and CDRH will identify any unique problems relating to medical device regulation for small business.
- B. Registration and listing under Section 510 including some CDER-administered device applications. The CDER will receive printouts and other assistance, as requested.
- C. Color additives under Section 706, with review by CDER, as appropriate.
- D. Good Manufacturing Practices (GMPs) Advisory Committee. Under Section 520(f)(3), CDER will regularly receive notices of all meetings, with participation by CDER, as appropriate.
- E. Medical Device Reporting: The manufacturers, distributors, importers, and users of all devices, including those regulated by CDER, shall report to CDRH under Section 519 of the Act as required. The CDRH will provide monthly reports and special reports as needed to CDER for investigation and follow-up of those medical devices regulated by CDER.

33.1.2.1 Device Programs that CDER and CDRH Each Will Administer Both CDER and CDRH will administer and, as appropriate, enforce the following activities for medical devices assigned to their respective centers (references to “sections” are the provisions of the Act):

- A. Surveillance and compliance actions involving general controls violations, such as misbranded or adulterated devices under Sections 301, 501, and 502
- B. Warning letters, seizures, injunctions, and prosecutions under Sections 302, 303, and 304
- C. Civil penalties under Section 303(f) and administrative restraint under Section 304(g)
- D. Nonregulatory activities, such as educational programs directed at users, participation in voluntary standards organizations, etc.
- E. Promulgation of performance standards and applications of special controls under Section 514
- F. Premarket notification, investigational device exemptions (IDEs) including humanitarian exemptions; premarket approval; product development protocols; classification; device tracking; petitions for reclassification; postmarket surveillance under Sections 510(k), 513, 515, 519, 520(g) and (m), and 522; and the advisory committees necessary to support these activities
- G. Banned devices under Section 516

- H. FDA-requested and firm-initiated recalls whether under Section 518 or another authority and other Section 518 remedies such as recall orders
- I. Exemptions, variances, and applications of CGMP regulations under Section 520(f)
- J. Government-wide quality assurance program
- K. Requests for export approval under Sections 801(e) and 802

33.1.2.2 Coordination The centers will coordinate their activities in order to assure that manufacturers do not have to independently secure authorization to market their product from both centers unless this requirement is specified in Section VII.

33.1.2.3 Submissions Submissions should be made to the appropriate center, as specified herein, at the addresses provided in the following:

Address update:

- Food and Drug Administration
- Center for Drug Evaluation and Research (CDER)
- Central Document Room (CDR)
- 5901-B Ammendale Road
- Beltsville, MD 20705-1266

or

- Food and Drug Administration
- Center for Devices and Radiological Health
- Document Mail Center (HFZ-401)
- 9200 Corporate Blvd.
- Rockville, MD 20850

For submissions involving medical devices and/or drugs that are not clearly addressed in this agreement, sponsors are referred to the product jurisdiction regulations (21 CFR Part 3). These regulations have been promulgated to facilitate the determination of regulatory jurisdiction but do not exclude the possibility for a collaborative review between the centers.

33.1.2.4 Center Jurisdiction The following subsections provide details concerning status, market approval authority, special label/regulatory considerations, investigational options, and intercenter consultations for the categories of products specified. Section VII provides the general criteria that CDRH and CDER will apply in reaching decisions as to which center will regulate a product:

- A. 1. (a) Device with primary purpose of delivering or aiding in the delivery of a drug that is distributed without a drug (i.e., unfilled).

Examples:

- Devices that calculate drug dosages
- Drug delivery pump and/or catheter infusion pump for implantation of iontophoreses device
- Medical or surgical kit (e.g., tray) with reference in instructions for use with specific drug (e.g., local anesthetic)
- Nebulizer
- Small particle aerosol generator (SPAG) for administering drug to ventilated patient
- Splitter block for mixing nitrous oxide and oxygen
- Syringe, jet injector, storage, and dispensing equipment

Status: Device and drug, as separate entities.

Market approval authority: CDRH and CDER, respectively, unless the intended use of the two products, through labeling, creates a combination product.

Special label/regulatory considerations: The following specific procedures will apply depending on the status of the drug delivery device and drugs that will be delivered with the device:

- (i) It may be determined during the design or conduct of clinical trials for a new drug that it is not possible to develop adequate performance specifications data on those characteristics of the device that are required for the safe and effective use of the drug. If this is the case, then drug labeling cannot be written to contain information that makes it possible for the user to substitute a generic, marketed device for the device used during developments to use with the marketed drug. In these situations, CDER will be the lead center for regulation of the device under the device authorities.
- (ii) For a device intended for use with a category of drugs that are on the market, CDRH will be the lead center for regulation for the device under the device authorities. The effects of the device use on drug stability must be addressed in the device submission when relevant. An additional showing of clinical effectiveness of the drug when delivered by the specific device will generally not be required. The device and drug labeling must be mutually conforming with respect to indication, general mode of delivery (e.g., topical, IV), and drug dosage/schedule equivalents.
- (iii) For a drug delivery device and drug that are developed for marketing to be used together

as a system, a lead center will be designated to be the contact point with the manufacturer(s). If a drug has been developed and marketed and the development and studying of device technology predominate, the PMOA will be deemed to be that of the device, and CDRH would have the lead. If a device has been developed and marketed and the development and studying of drug predominate, then, correspondingly, CDER would have the lead. If neither the drug nor the device is on the market, the lead center will be determined on a case-by-case basis.

Investigation options: IDE or IND, as appropriate.

Intercenter consultation: CDER, when lead center, will consult with CDRH if CDER determines that a specific device is required as part of the NDA process. CDRH as lead center will consult with CDER. If the device is intended for use with a marketed drug and the device creates a significant change in the intended use, mode of delivery (e.g., topical, IV), or dose/schedule of the drug.

- (b) The device with primary purpose of delivering or aiding in the delivery of a drug and distributed containing a drug (i.e., “prefilled delivery system”).

Examples

- Nebulizer
- Oxygen tank for therapy and over the counter (OTC) emergency use
- Prefilled syringe
- Transdermal patch

Status: Combination product

Market approval authority: CDER using drug authorities and device authorities, as necessary

Special label/regulatory considerations: None

Investigation options: IND

Intercenter consultations: Optional

- 2. Device incorporating a drug component with the combination product having the primary intended purpose of fulfilling a device function.

Examples:

- Bone cement containing antimicrobial agent
- Cardiac pacemaker lead with steroid-coated tip
- Condom, diaphragm, or cervical cap with contraceptive or antimicrobial agent (including virucidal) agent
- Dental device with fluoride
- Dental wood wedge with hemostatic agent
- Percutaneous cuff (e.g., for a catheter or orthopedic pin) coated/impregnated with antimicrobial agent

- Skin closure or bandage with antimicrobial agent
- Surgical or barrier drape with antimicrobial agent
- Tissue graft with antimicrobial or other drug agent
- Urinary and vascular catheter coated/impregnated with antimicrobial agent
- Wound dressing with antimicrobial agent

Status: Combination product.

Market approval authority: CDRH using device authorities.

Special label/regulatory considerations: These products have a drug component that is present to augment the safety and/or efficacy of the device.

Investigation options: IDE.

Intercenter consultation: Required if a drug or the chemical form of the drug has not been legally marketed in the United States as a human drug for the intended effect.

3. Drug incorporating a device component with the combination product having the primary intended purpose of fulfilling a drug function.

Examples:

- Skin-prep pads with antimicrobial agent
- Surgical scrub brush with antimicrobial agent

Status: Combination product.

Market approval authority: CDER using drug authorities and, as necessary, device authorities.

Special label/regulatory considerations: Marketing of such a device requires a submission of an NDA with safety and efficacy data on the drug component, or it meets monograph specifications as generally recognized as safe (GRAS) and generally recognized as effective (GRAE). Drug requirements, for example, CGMPs, registration and listing, and experience reporting, apply to products.

Investigation options: IND.

Intercenter consultation: Optional.

4. (a) Device used in the production of a drug either to deliver directly to a patient or for the use in the producing medical facility (excluding use in a registered drug manufacturing facility).

Examples:

- Oxygen concentrators (home or hospital)
- Oxygen generator (chemical)
- Ozone generator

Status: Device.

Market approval authority: CDER, applying both drug and device authorities.

Special label/regulatory consideration: May also require an NDA if the drug produced is a new drug. Device requirements, for example, CGMPs, registration and listing, and experience reporting, will apply to products.

Investigation options: IDA or NDA, as appropriate.

Intercenter consultation: Optional.

- (b) Drug/device combination product intended to process a drug into a finished package form.

Examples:

- Device that uses drug concentrates to prepare large volume parenterals
- Oxygen concentrator (hospital) output used to fill oxygen tanks for use within that medical facility

Status: Combination product.

Market approval authority: CDER, applying both drug and device authorities.

Special label/regulatory considerations: Respective drug and device requirements, for example, CGMPs, registration and listing, and experience reporting, will apply.

Investigation options: IDE or NDA, as appropriate.

Intercenter consultation: Optional but will be routinely obtained.

- B. 1. Device used concomitantly with a drug to directly activate or to augment drug effectiveness.

Examples:

- Biliary lithotripter used in conjunction with dissolution agent
- Cancer hyperthermia used in conjunction with chemotherapy
- Current generator used in conjunction with an implanted silver electrode (drug) that produces silver ions for an antimicrobial purpose
- Materials for blocking blood flow temporarily to restrict chemotherapy drug to the intended site of action
- UV and/or laser activation of oxsoresalen for psoriasis or cutaneous T-cell lymphoma

Status: Device and drug, as separate entities.

Market approval authority: CDRH and CDER, respectively.

Special label/regulatory considerations: The device and drug labeling must be mutually conforming with respect to indications, general mode of delivery (e.g., topical, I.V.), and drug dosage/schedule equivalence. A lead center will be designated to be the contact point with the manufacturer. If a drug has been developed and approved for another use and the development and studying of device technology predominate, then CDRH would have lead. If a device has been developed and marketed for another use and the development and studying of drug action predominate, then CDER would have led. If neither the drug nor the device is on the market, the lead center will be determined on a case-by-case basis. If the labeling of the drug and device creates a combination product, as defined in the combination product regulations, then the designation of the lead center for both applications will be based upon a determination of the product's PMOA.

Investigation options: IDE or IND, as appropriate.

Intercenter consultations: Required.

2. Device kits labeled for use with drugs that include both device(s) and drug(s) as separate entities in one package with the overall primary intended purpose of the kit fulfilling a device function.

Examples:

Medical or surgical kit (e.g., tray) with drug component

Status: Combination product.

Market approval authority: CDRH, using device authorities, is responsible for the kit if the manufacturer is repackaging a market drug. Responsibility for overall packaging resides with CDRH. CDER will be consulted as necessary on the use of drug authorities for the repackaged drug component.

Special label/regulatory consideration: Device requirements, for example, CGMPs, registration and listing, and experience reporting, apply to kits. Device manufacturers must assure that manufacturing steps do not adversely affect drug components of the kit. If the manufacturing steps do affect the marketed drug (e.g., the kit is sterilized by irradiation), then Abbreviated New Drug Application (ANDA) or NDA would also be required with CDRH as lead center.

Investigation options: IDA or IND, as appropriate.

Intercenter consultation: Optional if ANDA or NDA is not required.

- C. Liquids, gases, or solids intended for use as devices (e.g., implanted or components, parts, or accessories to devices).

Examples:

Dye for tissues used in conjunction with laser surgery to enhance absorption of laser light in target tissue

Gas mixtures for pulmonary function testing devices

Gases used to provide “physical effects”

Hemodialysis fluids

Hemostatic devices and dressings

Injectable silicon, collagen, and Teflon

Liquids functioning through physical action applied to the body to cool or freeze tissues for therapeutic purposes

Liquids intended to inflate, flush, or moisten (lubricate) indwelling device (in or on the body)

Lubricants and lubricating jellies

Ophthalmic solutions for contact lenses

Organ/tissue transport and/or perfusion fluid with antimicrobial or other drug agent, that is, preservation solutions

Powders for lubricating surgical gloves

Sodium hyaluronate or hyaluronic acid for use as a surgical aid

Solution for use with dental “chemical drill”

Spray on dressings not containing a drug component

Status: Device.

Market approval authority: CDRH.

Special label/regulatory considerations: None.

Investigation options: IDE, best preceded by a presubmeeting.

Intercenter consultation: Required if the device has direct contact with the body and the drug or the chemical form of the drug has not been legally marketed as a human drug.

- D. Products regulated as drugs.

Examples:

Irrigation solutions

Purified water or saline in prefilled nebulizers for use in inhalation therapy

Skin protectants (intended for use on intact skin)

Sun screens

Topical/internal analgesic–antipyretic

Status: Drug.

Market approval authority: CDER.

Special label/regulatory considerations: None.

Investigation options: IND.

Intercenter consultations: Optional.

- E. Ad hoc jurisdictional decisions.

Examples	Status	Center
Motility marker constructed of radiopaque plastic	Device	CDRH
Brachytherapy capsules, needles, etc. that are radioactive and may be removed from the body after radiation therapy has been administered	Device	CDRH
Skin markers	Device	CDRH

Status: Device or drug.

Market approval authority: CDRH or CDER as indicated.

Special label/regulatory considerations: None.

Investigation options: IDE or IND, as appropriate.

Intercenter consultation: Required to assure agreement on drug/device status.

33.1.2.5 General Criteria Affecting Drug/Device Determination The following represent the general criteria that will apply in making device/drug determinations.

- A. Device criteria:

1. A liquid, powder, or other similar formulation intended only to serve as a component, part, or accessory to a device with a PMOA that is physical in nature will be regulated as a device by CDRH.

2. A product that has the physical attributes described in 201(h) (e.g., instrument, apparatus) of the Act and does not achieve its primary intended purpose through chemical action within or on the body, or by being metabolized, will be regulated as a device by CDRH.
 3. The phrase “within or on the body” as used in 201(h) of the Act does not include extracorporeal systems or the solutions used in conjunction with such equipment. Such equipment and solutions will be regulated as devices by CDRH.
 4. An implant, including an injectable material, placed in the body for primarily a structural purpose even though such an implant may be absorbed or metabolized by the body after it has achieved its primary purpose will be regulated as a device by CDRH.
 5. A device containing a drug substance as a component with the primary purpose of the combination being to fulfill a device function is a combination product and will be regulated as a device by CDRH.
 6. A device (e.g., machine or equipment) marketed to the user, pharmacy, or licensed practitioner that produces a drug will be regulated as a device or combination product by CDER. This does not include equipment marketed to a registered drug manufacturer.
 7. A device whose labeling or promotional materials make reference to a specific drug or generic class of drugs unless it is prefilled with a drug ordinarily remains a device regulated by CDRH. It may, however, also be subject to the combination products regulation.
- B. Drug criteria
1. A liquid, powder, tablet, or other similar formulation that achieves its primary intended purpose through chemical action within or on the body, or by being metabolized, unless it meets one of the specified device criteria, will be regulated as a drug by CDER.
 2. A device that serves as a container for a drug or a device that is a drug delivery system attached to the drug container where the drug is present in the container is a combination product that will be regulated as a drug by CDER.
 3. A device containing a drug substance as a component with the primary purpose of the combination product being to fulfill a drug purpose is a combination product and will be regulated as a drug by CDER.
 4. A drug whose labeling or promotional materials make reference to a specific device or generic class

of devices ordinarily remains a drug regulated by CDER. It may, however, also be subject to the combination products regulation.

5. An imaging agent.

For the device component of combination product, required biocompatibility testing is specified in ISO 10993-1—in particular, the June 2016 FDA version (FDA, 2016).

If an approved device is being used to deliver a drug (such as the case for syringes and metered-dose inhalers), then generally only a leachables study is required to identify, quantitate, and assess the risk of any chemical entities migrating from the device into the drug (Gad and Gad-McDonald, 2015).

In cases where a new drug is intended for use with one or more existing drugs or treatments (such as radiation) that are an accepted standard of care the FDA will require that a safety study be performed that assess if the combination presents an additional risk (beyond what is present by the single of each).

QUALIFICATION OF IMPURITIES, DEGRADANTS, RESIDUAL SOLVENTS, METALS, AND LEACHABLES IN PHARMACEUTICALS

Impurities (from either materials intended to be part of the process of making a drug or formulating it), degradants (unintentionally formed by unintended reactions after the drug substance or product is produced and prone to increase in quantity over time due to instability of the product under conditions of storage), metals and elements, and residual solvents (purposely added to the synthesis product to facilitate synthesis, formulation, or dosage form production—always liquids of some degree of volatility) can become part of a drug product or substance in multiple ways. Additionally, drugs which are in containers or delivered/distributed (such as a metered-dose inhaler [MDI]) may also have substances from such a container “leach” into the drug product itself (with the safety of such leachables requiring evaluation). But the extent of their presence is now strictly governed by a series of ICH, Food and Drug Administration (FDA), and European Medicines Agency (EMA) guidelines (see Code of Federal Regulations (CFR), 2005 and FDA, 2005). These ICH guidelines call for these materials to be present at levels no greater than in product specifications and (because they serve no functional purpose in the drug) are both to be kept to a practical minimum and must be qualified for safety at the highest specification levels under the assumption of maximum potential patent use of the drug (and, therefore, exposure to the unintended substances). Contaminants, coming from the vessels and machinery used to manufacture a drug but not intended to be present, and leachables/extractants are materials which transfer to a drug product from packaging or delivery system. Undesired chemical substances which end up in pharmaceutical products may have a range of sources, but all of these must be evaluated for potential risks to patients. Depending on the source of the undesired substance, it is categorized and regulated somewhat differently. Categories of such substances include

impurities, degradants, residual solvents, contaminants, leachables, and extractables. Each of these will be considered in this chapter.

Biologics and biotechnology products have both similar and unique process impurity issues. The process needs to ensure that there are no residual cellular components in the biologic product. Biotechnology processing needs to avoid causing structural deformities to the protein. In all cases, the process must be scrutinized closely. Checking for impurities at various steps throughout the manufacturing phase may help to pinpoint where the impurities are produced.

34.1 IMPURITIES

The ICH *Guidance for Industry, Q3A Impurities in New Drug Substances*, published in February 2003 and finalized in October of 2006 (ICH, 2006a), is intended to “provide guidance for registration applications on the content and qualification of impurities in new drug substances produced by chemical syntheses and not previously registered in a region or member state.” A new drug substance is not the final marketed product but the active ingredient used in the marketed product. Impurities in new drug substances are addressed from both a chemistry and safety perspective (Ball et al., 2007; FDA, 2010).

The guidance is not intended to apply to new drug substances during the clinical research stage of development (though such drugs in development must have consideration of meeting, these requirements at the time of marketing approval and FDA frequently takes the view that such limitations must be met by a drug product entering clinical development) and addresses safety concerns associated with such substances during development. Nor does it cover natural

product or biological process-produced drugs or extraneous contaminants that should not occur in new drug substances and are more appropriately addressed as good manufacturing practice (GMP) issues. The guidance further describes the circumstances in which impurities need to be reported, identified, and qualified.

The rationale for the reporting and control, identification, and qualification of impurities is discussed in the guidance. Organic impurities need to be summarized based on the actual and potential impurities most likely to arise during the synthesis, purification, and storage of a new drug substance. This discussion can be limited to those impurities that might reasonably be expected based on knowledge of the chemical reactions and conditions involved.

Studies conducted to characterize the structure of impurities present in a new drug substance at a level greater than the identification threshold (Table 34.1) should be described, and any impurity from any batch or degradation product from stability studies should be identified. If identification of an impurity or degradant is not feasible, a summary of the laboratory studies demonstrating the unsuccessful effort should be included in the application. If an impurity is pharmacologically or toxicologically active, identification of the compound should be conducted even if the impurity level is below the identification threshold.

The guidance also states that “qualification is the process of acquiring and evaluating data that establishes the biological safety of an individual impurity or a given impurity profile at the level(s) specified. The applicant should provide a rationale for establishing impurity acceptance criteria that includes safety considerations. The level of any impurity that is present in a new drug substance that has been adequately tested in safety and/or clinical studies would be considered qualified. Impurities that are also significant metabolites present in animal and/or human studies are generally considered qualified. A level of a qualified impurity higher than that present in a new drug substance can also be justified based on an analysis of the actual amount of impurity administered in previous

TABLE 34.1 Thresholds for Action on Impurities in a Drug Product

Maximum Daily Dose (g day ⁻¹) ^a	Reporting Threshold (%) ^{b,c}	Identification Threshold ^c	Qualification Threshold ^c
≤2	0.05	0.10% or 1.0 mg day ⁻¹ intake (whichever is lower)	0.15% or 1.0 mg day ⁻¹ intake (whichever is lower)
>2	0.03	0.05%	0.05%

^aThe amount of drug substance administered per day.

^bHigher reporting thresholds should be scientifically justified.

^cLower thresholds can be appropriate if the impurity is unusually toxic.

relevant safety studies. If data are unavailable to qualify the proposed acceptance criterion of an impurity, safety studies to obtain such data can be appropriate when the usual qualification thresholds are exceeded.”

ICH *Guidance for Industry, Q3B(R2) Impurities in New Drug Products* (ICH, 2006b) describes considerations for the qualification of impurities when thresholds are exceeded. If the level of impurity cannot be decreased below the threshold, or if adequate data are not available in the scientific literature to justify safety, then additional safety testing should be considered. The studies considered appropriate to qualify an impurity will depend on a number of factors, including the patient population, daily dose, and route and duration of administration. Toxicology studies are discussed briefly later in this chapter and in more detail in other chapters in this volume. Such studies can be conducted on the new drug substance containing the impurities to be controlled, although studies using isolated impurities can sometimes be appropriate.

ICH Q3A states that “safety assessment studies to qualify an impurity should compare the new drug substance containing a representative amount of the new impurity with previously qualified material. Safety assessment studies using a sample of the isolated impurity can also be considered.” The latter is especially important to consider for genetic toxicology studies and the importance of testing the isolated impurity is discussed in more detail at the end of this chapter.

Therefore, according to the guidance, if the maximum daily dose of the drug is less than 2 g day⁻¹ and the impurity intake is more than 0.15% or 1.0 mg day⁻¹, the qualification threshold has been reached, meaning safety studies will need to be performed. Lower thresholds can be appropriate if the impurity is unusually toxic. In addition, the impurity will need to be reported and identified. These studies include general and genetic toxicology studies, and possibly other specific toxicology end points, as appropriate. Discussion of specific toxicity testing with the relevant FDA division is recommended.

If considered desirable, a minimum screen (e.g., genotoxic potential) should be conducted. A study to detect point mutations and one to detect chromosomal aberrations, both *in vitro*, are considered an appropriate minimum screen. However, for genotoxic impurities (GTIs), the concern has evolved to being focused on mutagenic impurities. Indeed, ICH M7(R1) (2017) provides several approaches to establishing that impurities are either not GTIs or that if they are, they occur at acceptable levels (most commonly, below the appropriate threshold of toxicological concern [TTC]).

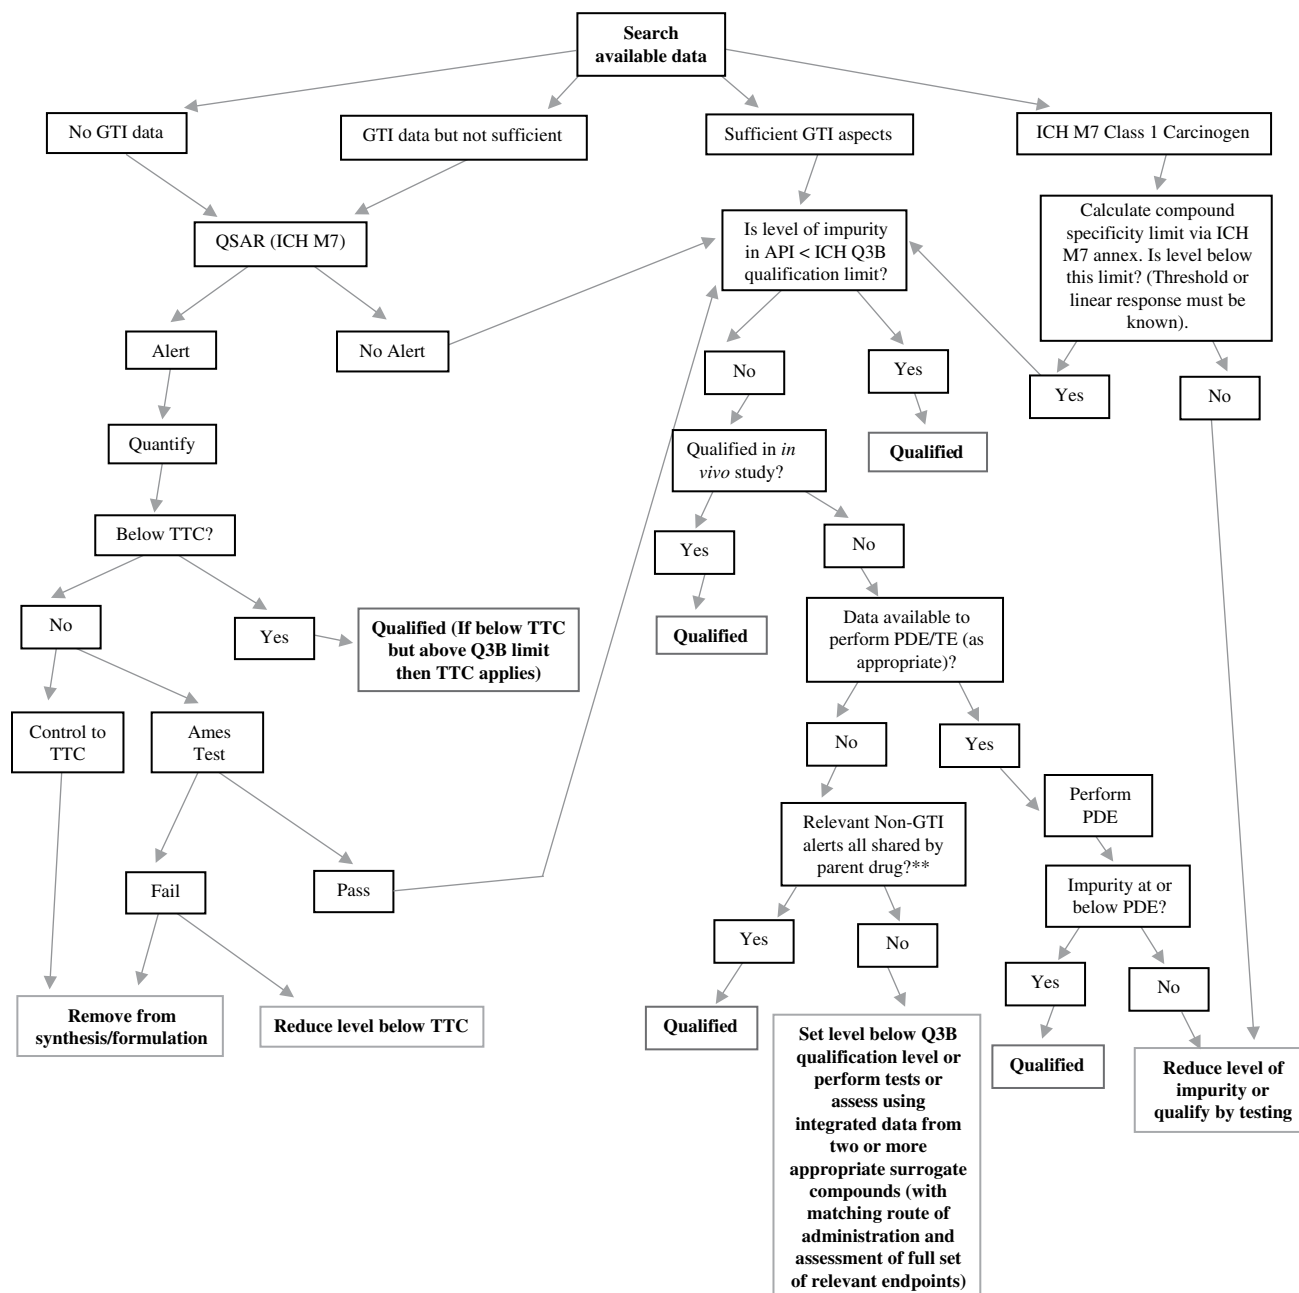

Some mutagenic impurities, identified in ICH M7 as the cohort of concern, can display extremely high carcinogenic potency and should be maintained at levels lower than the TTC. These include compounds with aflatoxin-like, *N*-nitroso-, and alkyl-azoxy structures. USFDA (2021) provides guidance on steps that manufacturers of APIs and drug products should take to detect and prevent unacceptable levels of nitrosamine impurities. This issue of nitrosamine impurities became

apparent following their discovery in a number of drugs. Given their potential for mutagenicity at low levels, nitrosamine impurities should be eliminated through changes in the manufacturing processes or controlled at an acceptable level, typically 26.5–96 ng day⁻¹.

If an impurity (in the broadest sense, including leachables, solvents, and all other subsets) is identified (“alerted”) to be mutagenic by literature or a (Q)SAR (quantitative structure-activity relationship) determination, is not identi-

fied as a member of the “cohort of concern,” and is above the relevant TTC limit, there are a number of further steps (of increasing cost) that can be taken (Lee, 2015; Figure 34.1). Among these may be *in vitro* or *in vivo* testing to determine if there is a relevant risk to patients (see Table 34.2; Teasdale, 2010).

Qualification studies for impurities are essentially bridging studies. If general toxicity studies are desirable, one or more studies should be designed to allow comparison of unqualified

FIGURE 34.1 Hierarchical approach to qualification (Q3B)*.

TABLE 34.2 Tests to Investigate the *In Vivo* Relevance of *In Vitro* Mutagens (Positive Bacterial Mutagenicity)

<i>In vitro</i> Test	Mechanistic Data to Justify Choice of Test as Fit for Purpose
Transgenic mutation assays	For any bacterial mutagenicity positive. Justify selection of assay tissue/organ
Pig-a assay (blood)	For directly acting mutagens (bacterial mutagenicity positive without S9) ^a
Micronucleus test (blood or bone marrow)	For directly acting mutagens (bacterial mutagenicity positive without S9) and compounds known to be clastogenic ^a
Rat liver UDS test	In particular for bacterial mutagenicity positive with S9 only Responsible liver metabolite known To be generated in test species used To induce bulky adducts
Comet assay	Justification needed (chemical class specific mode of action to form alkaline labile sites or single-strand breaks as preceding DNA damage that can potentially lead to mutations) Justify selection of assay tissue/organ
Others	With convincing justification

Source: Adapted from Lee (2015).

Note: UDS, unscheduled DNA synthesis.

^aFor indirectly acting mutagens (requiring metabolic activation), justification is needed for sufficient exposure to metabolites.

to qualified material. The study duration should be based on available relevant information and performed in the species most likely to maximize the potential to detect the toxicity of a degradation product. On a case-by-case basis, single-dose studies can be appropriate, especially for single-dose drugs. In general, a minimum duration of 14 days and a maximum duration of 90 days would be considered appropriate.

The genetic toxicology studies can include a minimum screen (a study to detect point mutations and one to detect chromosome aberrations, both *in vitro*). The general toxicology studies should include one or more studies designed to allow comparison of unqualified to qualified material. The study duration should be based on available relevant information and performed in the species most likely to maximize the potential to detect the toxicity of an impurity. On a case-by-case basis, single-dose studies can be appropriate, especially for single-dose drugs. In general, a minimum duration of 14 days and a maximum duration of 90 days would be considered appropriate.

Inorganic impurities are normally detected and quantified using pharmacopeial or other appropriate procedures. The need for inclusion or exclusion of inorganic impurities in a new drug substance specification should be discussed. Acceptance criteria should be based on pharmacopeia standards or known safety data. The control of residues of the solvents used in the manufacturing process for a new drug substance should be discussed and presented according to ICH Q3C.

A registration application should include documented evidence that the analytical procedures are validated and suitable for the detection and quantification of impurities (ICH Q3A(R2), 2006a; ICH Q3B(R2), 2006b; ICH Q6A, 1999b; ICH Q6B, 1999a). Organic impurity levels can be measured by a variety of techniques, including those that compare an analytical response for an impurity to that of an appropriate reference standard or to the response of the new drug substance itself. Differences in the analytical procedures used during development and those proposed for the commercial product should be discussed in the registration application.

Analytical results should be provided in an application for all batches of a new drug substance used for clinical, safety, and stability testing, as well as for batches representative of the proposed commercial process. The application should also contain a table that links the specific new drug substance batch to each safety study and each clinical study in which the new drug substance has been used. Any impurity at a level greater than the reporting threshold (Table 34.1) and total impurities observed in these batches of the new drug substance should be reported with the analytical procedures indicated. Table 34.3 is an illustration of reporting impurity results for identification and qualification in an application.

The guidance also states that when analytical procedures change, results provided in the application should be linked to the procedure used, with appropriate validation information provided, including representative chromatograms of representative batches. The applicant should ensure that complete impurity profiles (e.g., chromatograms) of individual batches are available, if requested.

TABLE 34.3 Threshold for Degradation Products in New Drug Products

Maximum Daily Dose ^a	Threshold ^{b,c}
<i>Reporting thresholds</i>	
≤1 g	0.1%
>1 g	0.05%
<i>Identification thresholds</i>	
<1 mg	1.0% or 5 μg TDI, whichever is lower
1–10 mg	0.5% or 20 μg TDI, whichever is lower
>10 mg to 2 g	0.2% or 2 mg TDI, whichever is lower
>2 g	0.10%
<i>Qualification thresholds</i>	
<10 mg	1.0% or 50 μg TDI, whichever is lower
10–100 mg	0.5% or 200 μg TDI, whichever is lower
>100 mg to 2 g	0.2% or 3 mg TDI, whichever is lower
>2 g	0.15%

^aThe amount of drug substance administered per day.

^bThresholds for degradation products are expressed either as a percentage of the drug substance or as total daily intake (TDI) of the degradation product. Lower thresholds can be appropriate if the degradation product is unusually toxic.

^cHigher thresholds should be scientifically justified.

The ICH Q3A guidance also states that the specification for a new drug substance should include a list of impurities. Individual impurities with specific acceptance criteria included in the specification for a new drug substance are referred to as specified impurities. Specified impurities can be identified or unidentified. A rationale for the inclusion or exclusion of impurities in a specification should be presented.

Acceptance criteria should be set no higher than the level that can be justified by safety data and should be consistent with the level achievable by the manufacturing process and the analytical capability. Where there is no safety concern, impurity acceptance criteria should be based on data generated on batches of a new drug substance manufactured by the proposed commercial process, allowing sufficient latitude to deal with normal manufacturing and analytical variation and the stability characteristics of the new drug substance. Although normal manufacturing variations are expected, significant variation in batch-to-batch impurity levels can indicate that the manufacturing process of the new drug substance is not adequately controlled and validated (ICH Q6A).

ICH Q3B(R2) *Impurities in New Drug Products* was published in June 2006 and is intended to provide guidance for registration applications on the content and qualification of impurities in new drug products produced from chemically synthesized new drug substances not previously registered in a region or member state. A new drug product is a finished dosage form, for example, a tablet, capsule, or solution, that contains a drug substance, generally, but not necessarily, in association with one or more other ingredients. The Q3B(R2)

guidance (ICH, 2006b) complements the ICH guidance *Q3A Impurities in New Drug Substances*, which should be consulted for basic principles along with ICH Q3C(R8) *Impurities: Residual Solvents* (ICH, 2021), and ICH Q3D *Guideline for Elemental Impurities* (ICH, 2019) when appropriate.

Q3A addresses only those impurities in new drug products classified as degradation products of the drug substance or reaction products of the drug substance with an excipient and/or immediate container closure system (collectively referred to as *degradation products*). Generally, impurities present in a new drug substance need not be monitored or specified in new drug product unless they are also degradation products. This guidance does not address impurities arising from excipients present in a new drug product or extracted or leached from the container closure system. This guidance also does not apply to new drug products used during the clinical research stages of development. It also does not cover the same types of products as in 3QA(R): biological/biotechnological, peptides, oligonucleotides, radiopharmaceuticals, fermentation products and associated semisynthetic products, herbal products, and crude products of animal or plant origin. Also excluded from this guidance are extraneous contaminants that should not occur in new drug products and are more appropriately addressed as GMP issues, polymorphic forms, and enantiomeric impurities.

Qualification of an impurity for a new drug product has similar concerns as Q3A. The main differences are the reporting, identification, and qualification thresholds (Table 34.3). The thresholds are basically higher than they were in Q3A; however, there are more categories for dosages. If the qualification thresholds given in Table 34.4 are exceeded and data

TABLE 34.4 Illustration of Reporting Degradation Product Results for Identification and Qualification in an Application

Raw Result (%)	Reported Result (%)	Total Daily Intake (TPI) of the Degradation Product	Action	
			Identification Threshold	Qualification Threshold
<i>50 mg maximum daily dose^a</i>				
0.04	Not reported	20	None	None
0.2143	0.2	100	None	None
0.349	0.3 ^{''}	150	Yes	None ^{''}
0.550	0.6 ^{''}	300	Yes	Yes ^{''}
<i>1.9 g maximum daily dose^b</i>				
0.049	Not reported	1	None	None
0.079	0.08	2	None	None
0.183	0.18 ^{''}	3	Yes	None ^{c,d}
0.192	0.19 ^{''}	4	Yes	Yes ^c

^aReporting threshold 0.1%; TDI rounded result in-micrograms; identification threshold 0.2%; qualification threshold, TDI equivalent to 0.4%.

^bReporting threshold 0.05%; TDI rounded result in milligrams; identification threshold 2 mg TDI (equivalent to 0.11%); qualification threshold 3 mg TDI (equivalent to 0.16%).

^cAfter identification, if the response factor is determined to differ significantly from the original assumptions, it can be appropriate to remeasure the actual amount of the degradation product present and reevaluate against the qualification threshold.

^dAlthough the reported result of 0.18% exceeds the calculated threshold value of 0.16%, in this case the action is acceptable since the TDI (when rounded) does not exceed 3 mg. Chromatograms with peaks labeled (or equivalent data if other analytical procedures are used) from representative batches, including chromatograms from analytical procedure validation studies and from long-term and accelerated stability studies, should be provided. The applicant should ensure that complete degradation product profiles (e.g., chromatograms) of individual batches are available, if requested.

are unavailable to qualify the proposed acceptance criterion of a degradation product, additional studies to obtain such data may be appropriate.

US FDA (Center for Drug Evaluation and Research [CDER]) *Guidance for Industry, NDAs: Impurities in Drug Substances* (FDA, 2000) was published in February 2000. The guidance refers applicants to ICH *Q3A Impurities in New Drug Substances* when seeking guidance on identification, qualification, and reporting of impurities in drug substances that are not considered new drug substances. Q3A was developed by the ICH to provide guidance on the information that should be provided in a new drug application (NDA) in support of impurities in new drug substances that are produced by chemical syntheses. The FDA believes that such guidance on identification, qualification, and reporting of impurities should also be considered when evaluating impurities in drug substances produced by chemical syntheses that are not considered new drug substances. ICH Q3A defines a new drug substance (also referred to as a new molecular entity or new chemical entity) as a designated therapeutic moiety that has not been previously registered in a region or member state. The definition also states that a new drug substance may be a complex, a simple ester, or a salt of a previously approved drug substance.

34.2 RESIDUAL SOLVENTS

ICH Q3C is intended to provide guidance for recommending acceptable amounts for residual solvents in pharmaceuticals for the safety of the patient. The guidance recommends use of less toxic solvents and describes levels considered to be toxicologically acceptable for some residual solvents. A complete list of the solvents included in this guidance is provided in Appendix 1 of the guideline but may not be complete due to ongoing qualifications effort. The list is not exhaustive, and other solvents may be used and later added to the list.

Residual solvents in pharmaceuticals are defined here as organic volatile chemicals that are used or produced in the manufacture of drug substances or excipients or in the preparation of drug products. The solvents are not completely removed by practical manufacturing techniques. Appropriate selection of the solvent for the synthesis of drug substance may enhance the yield or determine characteristics such as crystal form, purity, and solubility. Therefore, the solvent may sometimes be a critical parameter in the synthetic process. This guidance does not address solvents deliberately used as excipients nor does it address solvates. However, the content of solvents in such products should be evaluated and justified.

As there are no therapeutic benefits from residual solvents, all residual solvents should be removed to the extent possible to meet product specifications, GMPs, or other quality-based requirements. Drug products should contain no higher levels of residual solvents than can be supported by safety data.

Some solvents that are known to cause unacceptable toxicities (carcinogens), such as benzene and carbon tetrachloride (Class 1, see table 1 in ICH, 2021), should be avoided in the production of drug substances, excipients, or drug products unless their use can be strongly justified in a risk–benefit assessment. Some solvents associated with less severe toxicity (nongenotoxic animal carcinogens or possible causative agents of other irreversible toxicity such as neurotoxicity or teratogenicity), such as acetonitrile and chlorobenzene (Class 2), should be limited in order to protect patients from potential adverse effects. Ideally, less toxic solvents, such as acetic acid and acetone (Class 3), should be used where practical.

This guidance does not apply to potential new drug substances, excipients, or drug products used during the clinical research stages of development nor does it apply to previously existing marketed drug products.

The guidance applies to all dosage forms and routes of administration. Higher levels of residual solvents may be acceptable in certain cases such as short-term (30 days or less) or topical application. Justification for these levels should be made on a case-by-case basis and discussed with the appropriate FDA division.

The limits of residual solvents may include a value for the permitted daily exposure (PDE), which is the maximum acceptable intake per day of residual solvent in pharmaceutical products. These limits vary depending on the class.

For solvents where quantities are limited to set values in pharmaceutical products because of their inherent toxicity, Class 2 (table 2 of the guidance list) should be consulted. PDEs are given to the nearest 0.1 mg day^{-1} , and concentrations are given to the nearest 10 ppm.

For solvents with low toxic potential, solvents in Class 3 (table 3 of the guidance) may be regarded as less toxic and of lower risk to human health. Class 3 includes no solvent known as a human health hazard at levels normally accepted in pharmaceuticals. However, there are no long-term toxicity or carcinogenicity studies for many of the solvents in Class 3. Available data indicate that they are less toxic in acute or short-term studies and negative in genotoxicity studies. It is considered that amounts of these residual solvents of 50 mg day^{-1} or less (corresponding to 5000 ppm or 0.5% under Option 1) would be acceptable without justification. Higher amounts may also be acceptable provided they are realistic in relation to manufacturing capability and GMPs.

For solvents for which no adequate toxicological data were found, the solvents listed (table 4 in ICH, 2021) may also be of interest to manufacturers of excipients, drug substances, or drug products. However, no adequate toxicological data on which to base a PDE were found. Manufacturers should supply justification for residual levels of these solvents in pharmaceutical products.

The Gaylor–Kodell method of risk assessment (Gaylor and Kodell, 1980) is appropriate for Class 1 carcinogenic solvents. While mathematical models can be used to extrapolate

carcinogenicity data to set exposure limits, this should only be done in cases where reliable data are available. Exposure limits for Class 1 solvents could be determined with the use of a large safety factor (i.e., 10 000–100 000) with respect to the NOEL. Detection and quantitation of these solvents should be by state-of-the-art analytical techniques.

Acceptable exposure levels in this guidance for Class 2 solvents were established by calculation of PDE values according to the procedures for setting exposure limits in pharmaceuticals (*Pharmacopeial Forum*, November–December 1989) and the method adopted by International Programme on Chemical Safety (IPCS) for Assessing Human Health Risk of Chemicals (Environmental Health Criteria (EHC) 170, WHO, 1994). These methods are similar to those used by the US EPA (Environmental Protection Agency) (IRIS) and the US FDA (Red Book) and others. The method is outlined here to give a better understanding of the origin of the PDE values. It is not necessary to perform these calculations in order to use the PDE values tabulated in Section 34.4 of this document:

$$\text{PDE} = \frac{\text{NOEL} \times \text{weight adjustment}}{\text{F1} \times \text{F2} \times \text{F3} \times \text{F4} \times \text{F5}} \quad (34.1)$$

PDE is derived from the NOEL or the LOEL in the most relevant animal study as follows:

The PDE is derived preferably from a NOEL. If no NOEL is obtained, the LOEL may be used. Modifying factors proposed here, for relating the data to humans, are the same kind of *uncertainty factors* used in EHC (EHC 170, WHO, Geneva, 1994) and *modifying factors* or *safety factors* in *Pharmacopeial Forum*. The assumption of 100% systemic exposure is used in all calculations regardless of route of administration.

The modifying factors are as follows:

- F1 = A factor to account for extrapolation between species
- F1 = 5 for extrapolation from rats to humans
- F1 = 12 for extrapolation from mice to humans
- F1 = 2 for extrapolation from dogs to humans
- F1 = 2.5 for extrapolation from rabbits to humans
- F1 = 3 for extrapolation from monkeys to humans
- F1 = 10 for extrapolation from other animals to humans

F1 takes into account the comparative surface area:body weight ratios for the species concerned and for man. Surface area (S) is calculated as

$$S = kM^{0.67} \quad (34.2)$$

in which M = body mass and the constant k have been taken to be 10. The body weights used in the equation are 50 kg for an adult and 10 kg for a child.

F2 = A factor of 10 to account for variability between individuals

A factor of 10 is generally given for all organic solvents, and 10 is used consistently in this guidance:

F3 = A variable factor to account for toxicity studies of short-term exposure

F3 = 1 for studies that last at least one half-lifetime (1 year for rodents or rabbits and 7 years for cats, dogs, and monkeys)

F3 = 1 for reproductive studies in which the whole period of organogenesis is covered

F3 = 2 for a 6-month study in rodents or a 3.5-year study in nonrodents

F3 = 5 for a 3-month study in rodents or a 2-year study in nonrodents

F3 = 10 for studies of a shorter duration.

In all cases, the higher factor has been used for study durations between the time points (e.g., a factor of 2 for a 9-month rodent study).

F4 = A factor that may be applied in cases of severe toxicity (e.g., nongenotoxic carcinogenicity, neurotoxicity, or teratogenicity). In studies of reproductive toxicity, the following factors are used:

F4 = 1 for fetal toxicity associated with maternal toxicity

F4 = 5 for fetal toxicity without maternal toxicity

F4 = 5 for a teratogenic effect with maternal toxicity

F4 = 10 for a teratogenic effect without maternal toxicity

F5 = A variable factor that may be applied if the NOEL was not established

When only a LOEL is available, a factor of up to 10 could be used depending on the severity of the toxicity.

The weight adjustment assumes an arbitrary adult human body weight for either sex of 50 kg. This relatively low weight provides an additional safety factor against the standard weights of 60 or 70 kg that are often used in this type of calculation. It is recognized that some adult patients weigh less than 50 kg; these patients are considered to be accommodated by the built-in safety factors used to determine a PDE. If the solvent was present in a formulation specifically intended for pediatric use, an adjustment for a lower body weight would be appropriate.

As an example of the application of this equation, consider a toxicity study of acetonitrile in mice that is summarized in *Pharmeuropa*, vol. 9, no. 1, Supplement, April 1997, p. S24. The NOEL is calculated to be 50.7 mg kg⁻¹ day⁻¹. The PDE for acetonitrile in this study is calculated as follows:

$$\text{PDF} = \frac{50.7 \text{ mg kg}^{-1} \text{ day}^{-1} \times 50 \text{ kg}}{12 \times 10 \times 5 \times 1 \times 1} = 4.22 \text{ mg day}^{-1}$$

In this example:

F1 = 12 to account for the extrapolation from mice to humans

F2 = 10 to account for differences between individual humans

F3 = 5 because the duration of the study was only 13 weeks

F4 = 1 because no severe toxicity was encountered

F5 = 1 because the NOEL was determined

34.3 EXTRACTABLES AND LEACHABLES

Leachables are chemical entities, either organic or inorganic, that migrate from pharmaceutical container closure (or delivery) system components into a drug product formulation (Osterberg, 2005a, b). Since patients can be exposed to leachables during normal use of a drug product, leachables are of potential safety concern. Extractables are compounds that are forced out of container closure system materials and components under laboratory experimental conditions. All extractables from a given pharmaceutical container closure system and its components are, therefore, potential leachables in a drug product incorporating the same container closure system components. Regulatory concern regarding leachables and extractables is directly related to the potential for contamination and/or interaction of the drug product formulation with the container closure system, with the greatest concern focused on orally inhaled and nasal drug products (OINDP), which include MDIs, dry powder inhalers (DPIs), inhalation solutions, suspensions and sprays, and nasal sprays (Colton, 2007; Norwood, 2007; Norwood et al., 2007; Bestwick and Colton, 2009). Controlled extraction studies are an extremely important part of the pharmaceutical development process for OINDP and should be performed on critical components as identified by the manufacturer and regulatory authority. As stated in the PQRI L&E recommendations: “A controlled extraction study is a laboratory investigation into the qualitative and quantitative nature of extractables profiles of critical components of an OINDP container closure system. The purpose of a controlled extraction study is to systemically and rationally identify and quantify potential leachables, that is, extractables, to the extent practicable, and within certain defined analytical threshold parameters.”

Controlled extraction studies result in extractables profiles of OINDP components (FDA, 1998). Extractables profiles contain information which allows the identification, to the extent possible, and quantitation of individual extractables from a given component and therefore an early indication of potential leachables of concern. Controlled extraction studies generally establish a basis for the development and validation

of routine quality control methods for drug product leachables and, finally, allow for the correlation of extractables and leachables profiles. Although information on component composition from suppliers is very useful, helping to inform component selection and guide controlled extraction studies, such knowledge does not provide a complete extractables profile and therefore does not alleviate the requirement for controlled extraction studies no matter how “complete” the information might appear to be.

It is, therefore, critical that controlled extraction studies be performed properly and thoroughly. Specific expectations for “proper and thorough” controlled extraction studies will ultimately depend on the nature of the OINDP being developed. However, the PQRI L&E Working Group was able to establish some general best practice recommendations for OINDP controlled extraction studies based on the data that the group generated by conducting its own controlled extraction studies on the elastomer and polymer test articles. These recommendations are:

- Controlled extraction studies should employ vigorous extraction with multiple solvents of varying polarity.
- Controlled extraction studies should incorporate multiple extraction techniques.
- Controlled extraction studies should include careful sample preparation based on knowledge of analytical techniques used.
- Controlled extraction studies should employ multiple analytical techniques.
- Controlled extraction studies should include a defined and systematic process for identification of individual extractables.
- Controlled extraction study “definitive” extraction techniques and methods should be optimized.
- During the controlled extraction studies, sponsors should revisit supplier information describing component information.
- Controlled extraction studies should be guided by Analytical Evaluation Thresholds (AET) that are based on an accepted safety concern threshold.
- Qualitative and quantitative extractables profiles should be discussed with and reviewed by toxicologists so that any potential safety concerns regarding individual extractables, that is, potential leachables, are identified early in the development process.
- Polynuclear aromatics (PNAs), *N*-nitrosamines, and 2-mercaptobenzothiazole (MBT) are “special case” compounds, requiring evaluation by specific analytical techniques and technology defined thresholds.

The characterization and control of leachables and extractables represent possibly the most significant challenge facing

a pharmaceutical development team responsible for the development, registration, and manufacture of an OINDP. Indeed, detecting, identifying, and quantifying organic leachables are formidable tasks. In contrast to drug substance or excipient-related impurities, organic leachables can represent a diversity of chemical structures and compound classes and are potentially present at widely varying concentrations in any particular OINDP. Additionally, the information available to a pharmaceutical development team on container closure system component composition and processing, which is provided by the component supplier, is often incomplete. In some cases, the supplier may provide no information. Thus, when an extractables study is first undertaken, the development team may only have a limited idea of what to look for and what extraction techniques and analytical methods to use for identification and assessment of potential leachables.

A new guideline, ICH Q3E, on the assessment and control of extractables and leachables has been proposed but was not available when this chapter was written. According to the final concept paper (available on the ICH website) this guideline will aim to resolve a number of issues including harmonization of guidance, development of thresholds for reporting and identification, guidance on safety assessments, control options, and alignment with existing ICH guidelines (ICH Q3A-D, M7).

34.4 RESIDUAL METALS AND ELEMENTS

In early 2008, the EMA promulgated a standard for metals as impurities in pharmaceuticals (EMA, 2008). They organized metals of concern into categories, as presented in Table 34.5. United States Pharmacopeia (USP) followed with their own version of a guidance (USP, 2008), and, subsequently, an ICH guidance (Q3D(R1), 2019) was also promulgated, referring to metals and elements by which was

meant boron. A draft guideline to develop PDE levels for cutaneous and transdermal products (ICH Q3D(R2)) has been proposed and was undergoing public consultation at the time this chapter was written.

If synthetic processes of pharmaceutical substances are known or suspected to lead to the presence of metal residues due to the use of a specific metal catalyst or metal reagent, a concentration limit and validated test for residues of each specific metal should be set. All concentration limits should be realistic in relation to analytical precision, manufacturing capability, and reasonable variation in the manufacturing process. Since the use of metal catalysts or metal reagents during synthesis is restricted to validated and controlled chemical reactions, limitation of their residues in pharmaceutical substances itself will normally be sufficient. A limit for a metal residue in the pharmaceutical substance may however be replaced by a limit for that metal residue in the final medicinal product, as described in the following text.

For pharmaceutical products administered via the oral, parenteral, or inhalation route of administration, two options are available when setting a concentration limit for a metal residue:

Option 1: For each metal, the concentration limit in parts per million (ppm) as stated in ICH Q3D can be used. The concentration limits in ICH Q3D have been calculated using Eq. (34.3) in the following by assuming a daily dose of 10 g of the drug product:

$$\text{Concentration ppm} = \frac{\text{PDE } \mu\text{g day}^{-1}}{\text{daily dose g day}} \quad (34.3)$$

If all pharmaceutical substances in a drug product meet the Option 1 concentration limit for all metals potentially present, then all these substances may be used in any proportion in the drug product as long as the daily dose of the drug product does not exceed 10 g day⁻¹. When the daily dose of the drug product is greater than 10 g day⁻¹, Option 2 should be applied:

TABLE 34.5 Class Exposure and Concentration Limits for Individual Metal Catalysts and Metal Reagents

Classification	Oral Exposure		Parenteral Exposure		Inhalation Exposure ^a
	PDE (μg day ⁻¹)	Concentration (ppm)	PDE (μg day ⁻¹)	Concentration (ppm)	PDE (ng day ⁻¹)
Class 1A: Pt, pd	100	10	10	1	Pt: 70 ^a
Class 1B: Ir, Rh, Ru, Os	100 ^b	10 ^b	10 ^b	1 ^b	
Class 1C: Mo, Ni, Cr, V	250	25	25	2.5	Ni: 100
Metals of significant safety concern Class 2: Cu, Mn	2 500	250	250	25	Cr (VI): 10
Metals with low safety concern Class 3: Fe, Zn	13 000	1300	1300	130	
Metals with minimal safety concern					

^aPt as hexachloroplatinic acid.

^bSubclass limit: the total amount of listed metals should not exceed the indicated limit.

Option 2a: The PDE in terms of microgram per day as stated in Table 1 can be used together with the actual daily dose of a pharmaceutical substance in the drug product to calculate the concentration of residual metal allowed in that pharmaceutical substance.

Option 2b: Alternatively, it is not considered necessary for each pharmaceutical substance to comply with the limits given in Option 1 or the calculated limits using Option 2a.

The PDE in terms of microgram per day as stated in ICH Q3D can also be used with the known maximum daily dose of the drug product to determine the concentration of a metal residue originating from any of the pharmaceutical substances in the drug product (not the substance). This approach is considered acceptable provided that it has been demonstrated that the metal residue has been reduced to the practical minimum in every substance. This approach implies that the maximum levels of a metal in certain substances may be higher than the Option 1 or Option 2a limit, but that this should then be compensated by lower maximum levels in the other substances.

For pharmaceutical products applied via other routes of administration, the concentration limits should be set in consideration of the route of administration.

Without proper justification, parenteral limits/PDEs should be used for pharmaceutical substances that are administered by other routes of administration, including inhalation. Oral limits/PDEs may be applied if the absorption by other routes of administration is not likely to exceed the absorption following oral administration. For example, for cutaneous administration, oral concentration limits/PDEs are considered acceptable.

Platinum salts have been shown to be allergenic, with hexachloroplatinic acid being clearly the most allergenic (Malo, 2005). Consequently, a specific limit for inhalation exposure for this molecule has been set at 70 ng day^{-1} (see monograph). Chromium VI and Nickel, when inhaled, have been associated with carcinogenicity. Therefore, specific limits for inhalation exposure have been set for Chromium VI at 10 ng day^{-1} and for Nickel at 100 ng day^{-1} (see respective monographs).

For pharmaceutical products used for short-term and for life-saving indications, as the PDEs and concentration limits mentioned in the TTC guideline are based on chronic use, higher PDEs and concentration limits may be acceptable in cases of short-term use (30 days or less). For instance, this may be applicable to contrasting agents, antidotes, or products for diagnostic use. This may however only be applied if neither an Option 1 nor an Option 2 limit is feasible.

Specific risk–benefit considerations, such as for compounds used for lifesaving indications, may also warrant the use of higher limits. Justifications should be made on a case-by-case basis.

TISSUE, CELL, AND GENE THERAPY

This chapter seeks to overview three closely related therapeutic products that are either living biologic components or genetic material directly derived from such components (delivered in or by another living component—a virus). All three share many of the same potential mechanisms of adverse outcome. These are sometimes called advanced and cellular therapies:

1. Infection if improperly prepared or contaminated with pathogens
2. Inflammatory responses if contaminated with endotoxins
3. “Off-target hits”—the therapeutic entity going somewhere it is not intended to be and remaining viable

The AOPs underlying these concerns can be categorized as route related, immunologically related, or proliferation related (Amuzie and Faqi, 2017). Gene therapy medicinal products (GTMPs) have additional potential adverse effects as a result of modifying genetic function—potentially including cancer.

There are numerous regulatory guidances on the production of clinical material for these products. This is as it should be, as tight manufacturing controls and ensuring stability of cell and genetic stock involved are the key to safety, and what are to be used in any nonclinical safety evaluations are intended clinical materials. But there are limited guidances available for the nonclinical safety evaluation—EMA (2008) gene therapy product (GTPs) and Japan (Pharmaceutical and Medical Device Agency—PMDA) (2000–2008) and FDA (2013) for cellular and GTPs. In the United States, scientific advice is provided by the cellular, tissue, and gene therapeutics advisory committee (CTG-TAC).

All the cell-based “advanced therapy medicinal products” (ATMPs) have their safety assessment predicated on a risk-based approach, based on careful consideration of the product itself (both as manufactured and as administered to the intended patients). These products share specific issues such as cell gene viability, longevity, distribution, growth, replication, differentiation, and migration (of somatic cellular/tissue products) or transmission through the germline and/or reactivation of delivery vectors (for GTPs).

Specific considerations for safety assessment include what is the duration of observation after administration (with the assumption that product administrations to patients will usually be one-time events), what is the appropriate animal model to use for preclinical evaluation, and how are we to extrapolate from animals and predelivery/preexposure profiles to the relevant human situations.

Add to these the issues associated with understanding distribution, incorporation, and potential elimination of administered agents (for traditional PK/TK methods and models neither apply nor are effective here), and the problem of both evaluating safety and developing the optimal clinical product is daunting. So, any development program must proceed through a series of first exploratory and then confirmatory clinical (and potentially preclinical) studies (or study cases).

There are “tagant” compounds that can be easily incorporated in minute amounts into all the advanced therapy products to allow tracking of their distribution in the body by noninvasive means, such as MRI, they have not achieved significant use or market penetration. Because of the very small amounts tagged into or on such a product, such tagants require a strong “signal generator,” such as manganese.

Traditional toxicologic study designs and animal models are not dependably predictive for efficacy or safety in humans, particularly regarding immunogenicity and tumorigenicity.

Differences between biodistributions of introduced cells in animals and humans must be understood, and extrapolation of relative potency between species (remember TGN412, the small molecule discussed in Chapter 13) and the issues seen in the long term with administered monoclonal antibodies are just beginning to be understood.

All nonclinical safety studies should be conducted in accordance with GLP. Genetic toxicity and safety pharmacology are generally not appropriate or required for these products.

35.1 SAFETY ASSESSMENT OF CELL THERAPY (CT) PRODUCTS

The overarching consideration for an adequate preclinical program for a cell therapy product includes (Sharper et al., 2012; FDA, 2013; Galli and Serabian, 2015; Gunther et al., 2016):

1. Establishment of biological plausibility (of therapeutic efficacy).
2. Identification of biologically active administration levels.
3. Selection of potential starting dose level, dose-escalation schedule, and dosing regimen for clinical trials.
4. Establishment of feasibility and reasonable safety of the investigational product's proposed clinical route of administration (ROA).
5. Support for determination of patient eligibility criteria.
6. Identification of physiologic parameters that can guide clinical monitoring.
7. Identification of potential public health risks (e.g., to the general public, caregivers, family members, close contacts (for example, coworkers), and intimate partners).
8. Traditional and well-established transplant tissues (such as bones, corneas, skin, heart valves, and vessels) are not considered to be products subject to these evaluations.

35.1.1 Recommendations for General Preclinical Program Design

When possible, the same investigational cellular therapy (CT) product that will be administered to the patient population should be used in the definitive preclinical studies. Each lot of an investigational CT product used in the preclinical *in vitro* and *in vivo* studies should be characterized according to appropriate criteria, consistent with the stage of product development. Similarities and differences between product lots intended for preclinical use and lots

intended for clinical use should be highlighted and discussed in the IND submission. However, in certain cases, due to the species-specific nature of the clinical product (e.g., some vector-expressed human transgenes: human-derived CT products), testing the CT product intended for clinical administration in animals may not be informative, and therefore testing of an analogous product may be a suitable alternative. In these situations, the design of the preclinical testing program is considered on a product-by-product basis. Considerations regarding investigational product incompatibility issues as outlined in the operative FDA guidance are essential.

35.1.2 Model Species Selection

The selected model for assessment of bioactivity and safety should have demonstrated a biological response to the investigational CT product similar to that expected in humans in order to generate data to guide clinical trial design. Some factors that should be considered when determining the relevant species include (i) comparability of physiology and anatomy to that of humans; (ii) permissiveness/susceptibility to infection by, and replication of, viral vectors or microbial vectors for gene therapy (GT); (iii) immune tolerance to a human CT product; and (iv) feasibility of using the planned clinical delivery system/procedure.

Assessment of these factors necessitates consideration of the specific product and clinical indication. "Nonstandard" test species, such as genetically modified rodents (i.e., transgenics or knockouts) or large animals (e.g., sheep, pigs, goats, and horses) may be acceptable when adequate justification is provided. Although safety and effectiveness of the investigational CT product *in vitro* and *in vivo* can possibly be evaluated in one animal species (and usually is), other contributory factors (e.g., source of the CGT product, ROA) may result in the need for testing in more than one species. Prior to initiation of the definitive preclinical studies, it is recommended that conduct of *in vitro* studies (e.g., functional assays, immunophenotyping, morphologic evaluation) and *in vivo* pilot studies be conducted to establish the biological relevance of a specific animal species to the investigational product(s).

Detailed assessment of the relevancy of each animal species used in support of each potential clinical trial should be conducted prior to initiation of said trial. A summary of this assessment should be submitted as part of the preclinical section of the IND.

35.1.3 Selection of Animal Models of Disease/Injury

Preclinical studies performed in animal models of disease/injury may provide insight regarding the relationships of dose to activity and toxicity and are recommended where feasible. Animal models of disease/injury used in basic research or discovery science phases of product development

are also potentially useful for generating data to support clinical trials for CT products. Due to features of CT products (e.g., potentially prolonged duration of intended product effect, product persistence *in vivo*, complex mode of action (MOA) involving interaction between the CT product and the disease environment, and invasive ROA), animal models of disease/injury may be preferable to healthy animals to assess the activity and safety of these products. Therefore, preclinical studies in disease/injury models are encouraged to better define the risk/benefit ratio associated with investigational CT products. In addition, use of disease/injury models provides the opportunity for possible identification of activity-risk biomarkers that may be applicable for monitoring in clinical trials.

35.1.4 Information Describing Limitations of Potential Animal Model(s)

Potential limitations of these preclinical animal models may exist and should be identified and considered. Examples of these limitations include:

- (i) Inherent variability of the model (potentially age or gender dependent)
- (ii) Limited historical/baseline data for the model
- (iii) Technical limitations with the physiological and anatomical constraints of the model
- (iv) Animal care issues
- (v) Limited fidelity in modeling human pathophysiology of the disease/injury of interest

Every model has inherent strengths and weaknesses and these must be well understood. No single model will predict with complete accuracy the efficacy and safety outcome of the investigational CT product in the patient population. The activity and safety profile of the CT product may be influenced by the timing of administration relative to the onset of disease; thus, the disease state at the initiation of product administration should be characterized and documented in the IND submission.

35.1.5 Information Supporting the Choice of Animal Model(s)

- (i) The similarities and differences between the pathophysiology of the disease/injury animal model and the pathophysiology of the disease/injury of humans (Gad, 2015)
- (ii) The effect of the disease/injury status of the animal on the cellular viability and the pharmacology/toxicology of the investigational CT product (i.e., altered sensitivity of the animal model to the specific product under study)

- (iii) Detrimental effects of the administered product on existing disease/injury status (i.e., exacerbation of an existing disease/injury condition or induction of a new disease/toxicity)

It is recommended that consideration be given to using a tiered approach for determining selection of an appropriate animal model. Performance of pilot studies involving the intended investigational CT product may assist in evaluating the suitability of a particular animal species/model for use in the definitive preclinical studies. Moreover, multiple animal models may be necessary to adequately identify functional aspects and potential toxicities of a single product under study. In these situations, the preclinical testing paradigm may include the use of (i) large and small animal models, (ii) multiple small animal models, or (iii) only large animal models.

The number and type of studies performed should be guided by the biological attributes of the investigational product. One should refer to current CBER guidances (FDA, 1998, 2013) that include information and recommendations regarding tiered testing approaches for the products.

35.1.6 Proof-of-Concept (POC) Studies

A primary objective of proof-of-concept (POC) studies is to establish the feasibility and rationale for use of an investigational CT product in the targeted patient population. POC studies help inform the benefit side of the risk/benefit assessment of the CT product. Such data may be essential in the assessment of novel products with substantial inherent risks. In addition, data from POC studies can contribute significantly to animal species selection. POC studies should investigate the following:

- a. The pharmacologically effective dose range (i.e., minimally effective dose and optimal biological dose)
- b. Optimization of the ROA and confirmation that the product reaches the target anatomic site/tissue/cell
- c. Optimization of the timing of product administration (regimen of administration) relative to onset of disease/injury
- d. Optimization of the dosing schedule (regimen)
- e. Characterization of the putative MOA or hypothesized biological activities of the investigational product

Collectively, this information serves to establish the rationale for, and feasibility of, the proposed clinical trial. Features of study design, such as the inclusion of appropriate concurrent controls, randomization, or blinding methods, may increase the strength of the resulting study data and thus should be considered.

Preclinical *in vitro* assays intended to assess aspects of the biological activity of an investigational product (e.g., growth

factor secretion, immunological response profile, expression of a neurotransmitter) can provide supporting POC information.

Data derived from *in vitro* and *in vivo* preclinical POC testing are useful in guiding the design of both preclinical toxicology studies and the early-phase clinical trials while contributing to defining reasonable risk for the investigational product in the intended patient population.

35.1.7 Toxicology Studies

Preclinical assessment of the safety of an investigational product contributes to the definition of an acceptable risk/benefit ratio for a proposed clinical trial. The safety assessment should be sufficiently comprehensive to permit identification, characterization, and quantification of potential local and systemic toxicities, their onset (i.e., acute or delayed), the possibility for resolution of any toxicities, and the effect of product dose level on toxicity findings and provides guidance on how to monitor for this in nonclinical and clinical studies.

35.1.7.1 Primary Considerations for Toxicology Study Design Each of the following should be considered in the design of the toxicology study:

- (i) The proposed clinical indication
- (ii) The amount and quality of published preclinical or clinical safety information for the specific CT product under investigation or for a similar product (i.e., known toxicities or adverse effects)
- (iii) The amount and quality of existing pharmacology (*in vitro/in vivo*) or POC data for the specific CT product under investigation or for a similar product
- (iv) Previous preclinical/clinical experience with the proposed clinical delivery device/delivery procedure or with any related device/procedure
- (v) The biological responsiveness of the animal species to the investigational CT product
- (vi) The putative MOA of the CT product
- (vii) The intrinsic properties of the CT product
- (viii) The pathophysiology of the animal disease/injury model, if one is used

Animal species in which the product is biologically active should be used in the nonclinical safety studies. Although healthy animals represent the standard model test system employed to conduct traditional toxicology studies, study designs using animal models of disease/injury are frequently modified to incorporate important safety parameters that allow for assessment of the potential toxicology of an investigational product (i.e., hybrid pharmacology/toxicology study design). Such data can supplement or possibly be used in lieu of toxicology studies in healthy animals.

35.1.7.2 Secondary Considerations for Toxicology Study Design The overall design of the toxicology studies should mimic the proposed clinical trial design as closely as possible. Preclinical toxicology study designs should include the following, as applicable:

- (i) Adequate numbers of animals per gender randomized to each group. If the number of animals that can be dosed in a single day is limited due to the complexity of the dosing procedure or the timing of product administration relative to disease status of the model, then appropriate blocked randomization methods or other factors should be considered in an attempt to reduce study bias as much as possible. The number of animals required for each group will vary depending on the safety concerns for the investigational product, the species, the model, and the delivery system.
- (ii) Appropriate control groups. Examples include animals that are left untreated, receive sham surgery, or are administered formulation vehicle only, adjuvant alone, null vector, or scaffold alone. Justification should be provided for the specific control group(s) selected.
- (iii) Multiple dose levels of the investigational product should bracket the proposed clinical dose range, if feasible. Results obtained from POC studies should guide selection of the target dose levels for both preclinical safety assessment and for clinical development. The highest dose level used in preclinical models may be restricted due to animal size, tissue volume/size, ROA, or product manufacturing capacity. Justification, with supporting data, should be provided for the specific dose levels selected.
- (iv) A dosing schedule that reflects the intended clinical dosing regimen, to the extent possible.
- (v) An ROA that mimics the intended clinical route as closely as possible. The delivery device intended for use in the clinical studies should be used to administer the investigational product in the definitive toxicology studies; justification should be provided if the intended clinical delivery device is not used.
- (vi) Multiple sacrifice time points to capture potential acute, adaptive immune, chronic, and/or delayed-onset toxicities, as well as the potential for resolution of toxicities. The time intervals designated for the sacrifice time points will depend on the animal model used, the investigational product, the dosing schedule, the pharmacodynamic and pharmacokinetic response observed, and the proposed patient population.

- (vii) Safety end points that capture potential toxicities should be carefully identified and incorporated. Standard parameters monitored include mortality (with cause of death determined, if possible), clinical observations, body weights, physical examinations, food consumption/appetite, water consumption (as applicable), clinical pathology (serum chemistry, hematology, coagulation, urinalysis, special biomarkers), organ weights, gross pathology, and histopathology.
- (viii) Additional parameters specific to either the investigational product used or the intended patient population. Examples of product-specific study parameters include humoral or cellular immune responses, biodistribution of cell tissues, product fate, behavioral testing, neurological exams, ophthalmic exams, cardiac assessments, imaging (i.e., MRI, ultrasound, radiography—see Chapter 26 on imaging), presence of abnormal/ectopic growths (i.e., hyperplasia, tumors), putative biomarkers, and specialized histopathology (i.e., immunohistochemistry). The data collected should include both morphological and functional assessment, whenever possible, to determine whether an association exists between nonterminal and terminal findings. Reversibility of any findings should also be addressed. Refer to other sections of this document for guidance that is specific to product class.

Collected preclinical data, considered as an integrated whole, will help guide clinical trial design. For example, data generated from the toxicology studies will potentially establish a no-observed-adverse-effect level (NOAEL), which will help determine the selection of the starting dose level and subsequent dose-escalation scheme for the clinical trial. This information should potentially allow for avoidance or minimization of significant toxicities in patients.

35.1.8 Product Delivery Considerations

The ROA used to deliver the investigational product in the definitive preclinical studies should mimic the ROA to be employed in the clinical setting to the greatest degree possible. If it is not possible to replicate the clinical ROA in the animal model, then alternative routes/methods should be proposed and scientifically justified as a part of the preclinical development plan.

To assess the potential risks associated with the method of product administration, the delivery device system used in the definitive preclinical studies should be identical to the planned clinical product delivery device, if possible. In definitive studies where the planned clinical delivery device system cannot be used, justification for the delivery system that is utilized should be provided. The safety of the delivery device

and/or system must also be established. The IND submission should state whether a device master file (MAF) has been submitted to the Center for Devices and Radiological Health (CDRH) for the delivery device. If a MAF exists, the IND submission should include a letter of authorization from the MAF holder granting permission for FDA to cross-reference specific information in the MAF (a matching copy of the letter must be put in the MAF folder by the holder). CBER will consult with CDRH review staff as necessary to determine whether the information provided in the device MAF is sufficient in detail (e.g., facilities and manufacturing procedures and controls; synthesis, formulation, purification, and specifications for chemicals, materials; biocompatibility (CDRH, 1995), preclinical data; clinical study data) to support use in the clinical trial. If a MAF for the delivery device does not exist or if the information is not sufficient to support the proposed use, CDRH review staff may be consulted to determine the type and extent of information that should be included in the IND submission to support the use of the device in the proposed clinical trial.

The use of a large animal species (healthy animal or a disease/injury model) to test the safety of a delivery device may be appropriate in certain situations, such as assessment of risk associated with use of a previously untested device for intracranial product delivery or assessment of risk associated with use of an investigational delivery system for placement of the product into the heart or the brain. Safety data for the delivery device and delivery procedure may derive from existing active regulatory submissions (i.e., INDs, Investigational Device Exemptions (IDEs), MAFs). As also indicated earlier, in these circumstances, the IND submission for the investigational product should include letters of cross-reference from the sponsors of these existing submissions. Published studies that involve the use of the clinical delivery device and delivery procedure may also provide supportive safety data.

CT products vary with respect to characteristics such as formulation (including combination with a scaffold or other noncellular component), the genetic relationship of the cells to the patient (autologous, allogeneic, xenogeneic), and the cell source. CT products can be generally classified as stem cell-derived CT products or mature/functionally differentiated cell-derived CT products. If the CT product is derived from an induced pluripotent stem cell (iPSC), the product has the possibility of expressing characteristics of both stem cell-derived and mature/functionally differentiated cell-derived products; therefore, both fundamental source categories of CT products should be considered during the product development process. The *in vivo* biological activity and safety profile of the investigational CT product is influenced by product origin (donor and tissue source), as well as the level of manipulation and stage of differentiation at the time of administration. Regardless of the type of CT product, if the cells originate from animal tissue or cells (xenotransplantation products), additional considerations apply:

1. Tissue sources of stem cells include (i) adult (e.g., hematopoietic, neural, mesenchymal, cardiac, adipose, skin), (ii) perinatal (e.g., placental, umbilical cord blood), (iii) fetal (e.g., amniotic fluid, neural), and (iv) embryonic. Stem cell-derived products are characterized by a variable capacity for self-renewing replication through cycles of cell division and the capacity for differentiation into a variety of cell types with specialized properties/functions. Such differentiation and replication are primarily controlled by the physiologic milieu of the host in which the cells reside following *in vivo* administration. Similarly, contamination of a differentiated CT product with undifferentiated stem cells or incompletely differentiated progenitor/pre-cursor cells poses potential safety concerns.
2. Functionally differentiated tissue-derived CT products may be obtained from adult human donors (autologous or allogeneic) or from animal sources (xenogeneic). Source cells can include chondrocytes, pancreatic islet cells, hepatocytes, neuronal cells, and various immune cells. CT products derived from functionally mature tissues typically do not possess the property of self-renewing proliferation and the capacity to differentiate into multiple cell types; however, they may retain some cellular characteristics of their tissue of origin. Additionally, their characteristics may change after *in vivo* administration, based on specific extracellular cues.

Additional considerations for animal model selection for CT products can include:

1. The ability to access the anatomic site for product administration
2. The ability to deliver a specific absolute cell dose to the target site
3. The availability of immunodeficient animals, which may allow for long-term assessment of the safety of the human CT product

Administration of human cells into animals is complicated by the immunogenic responses of healthy immunocompetent animals, potentially resulting in the rejection of the administered human cells. This response may prevent adequate evaluation of the activity and safety of the human cellular product. When conducting preclinical studies to evaluate the activity and safety of a human cellular product, the cross-species immunogenicity may necessitate alteration of the animal model in order to create an *in vivo* immune tolerant niche for the administered human cells. Various models that have been considered include:

- Immunosuppressive agents in immunocompetent animals
- Genetically immunodeficient animals

- Humanized animals
- Administration into an immune privileged site
- A combination of these scenarios

The administration of analogous cellular products in the preclinical studies is also a potentially acceptable option. The scientific value of this approach is optimized when the analogous CT product is substantially similar to the human CT product. However, preclinical testing using an analogous cellular product can introduce uncertainty regarding the relevance of the data due to potentially different biological activities, molecular regulatory mechanisms, and impurities/contaminants. Therefore, if this preclinical testing pathway is used, the level of analogy of the animal cellular product with the intended human cellular product should be characterized. Examples may include:

- Established procedures for tissue/sample harvest
- Cell identification, isolation, expansion, and *in vitro* culture procedures
- Cell growth kinetics (e.g., cell doubling time, cell growth curve, and time to cell proliferation plateau)
- Phenotype and functional properties (e.g., secretion of growth factors and cytokines, cell population-specific phenotypic/genotypic markers)
- Final product formulation/cell scaffold seeding procedures (as applicable)
- Final product storage conditions and cell viability

The degree of similarity of these parameters for the analogous CT product should be as close to the proposed human CT product as possible in an attempt to maximize the relevance of data derived from the animal studies.

35.1.9 Study Designs

In addition to the general guidance on the preclinical testing program provided earlier, considerations when designing preclinical studies for investigational CT products include the following:

1. The targeted cellular phenotype(s)
2. The source of the cell(s)
3. The extent of *ex vivo* manipulation performed (e.g., selection, purification, expansion, activation)
4. The fate of the cell post-administration (engraftment, migration, differentiation, tumorigenicity)
5. The probability of a host's immune response to the administered cells
6. Administration site reactions
7. Potential inflammatory response in target and/or non-target tissues

8. Unregulated/dysregulated proliferation of the cells within the host

Determination of the fate of the investigational CT product following administration in animals is an important contribution to characterizing the product activity and safety profile. When conducted early in the preclinical testing program, assessment of cell fate can help characterize the putative MOA by determining if engraftment is important and necessary to achieve the desired pharmacological response. Additionally, cell fate can help justify the selection of the animal species/models, justify the duration of the definitive studies, and identify potential target organs of toxicity.

Considerations of cell fate *in vivo* include:

1. Survival/engraftment

Cell viability and subsequent engraftment may be affected by:

- a. The biocompatibility of the cell delivery device and the CT product (considerations include cell shearing and adsorption onto the walls of the catheter/syringe)
- b. The ROA
- c. The genetic relationship of the cells to the host animal (autologous/syngeneic, allogeneic, or xenogeneic)
- d. The immune status of the host animal
- e. The timing of cell administration relative to the onset of the disease/injury (i.e., the pathophysiologic status of the microenvironment)

If long-term cell survival/engraftment is necessary to achieve effectiveness of the CT product, the animals should be followed for an interval sufficient to allow for comprehensive evaluation of *in vivo* cell survival, anatomic engraftment, and biologic activity.

As a consequence of their biologic attributes, CT products administered *in vivo* are not subject to conventional chemical analyses; therefore, standard ADME and pharmacokinetic testing techniques and profiles are not applicable. Although influenced by specifics of the CT product and its ROA, cells have an inherent potential to distribute to sites other than to the target organ/tissue. Various methods, such as imaging modalities used for detection of radioisotope-labeled cells, genetically modified cells (e.g., expressing green fluorescent protein), nanoparticle-labeled cells (e.g., iron–dextran nanoparticles), or the use of polymerase chain reaction (PCR) analysis and immunohistochemistry to identify cells of human origin or cells of a karyotype different than the host (e.g., gender), have been used to assess distribution. A potential advantage of *in vivo* imaging techniques is that in many instances, the same animal can be evaluated over time, thus decreasing variability and reducing the number of animals used. Data should be provided to support

the viability and function of the CT product if the cells are modified to enable use of such imaging techniques.

Cellular differentiation capacity, the plasticity of phenotypic expression attributable to transdifferentiation or fusion with other cell types, and structural and functional tissue integration may all be influenced by physiologic factors within either the local microenvironment into which the CT product is administered or the final location/niche in which the cells ultimately reside. Therefore, conditions found within the local microenvironment into which the cells are placed are likely to have an impact on the safety and/or bioactivity of the CT product. Given the biological attributes of some CT products, the potential for ectopic expression in target and non-target tissues also exists. Depending on their differentiation status and the extent of manipulation the cells undergo prior to *in vivo* administration, parameters such as cell morphology, phenotype, and level of differentiation following *in vivo* administration should be assessed in the animal studies.

The potential for tumorigenicity, dysplasia, or hyperplasia to occur should be considered and addressed as appropriate for the specific biologic properties of each investigational CT product. Factors that may influence the tumorigenicity assessment include:

1. The differentiation status profile of cell types within the CT product (ranging from undifferentiated/embryonic to terminally differentiated/specialized)
2. The extent of cell manipulation employed during manufacture of the product and the resulting growth kinetic profile (e.g., minimal, culture expansion only, culture expansion with/without growth factors, *ex vivo* differentiation, *ex vivo* transduction with or without cell expansion)
3. The expressed transgene (e.g., various growth factors) of genetically modified cells
4. The potential to induce or enhance tumor formation from existing subclinical host malignant cells
5. The target patient population

Studies conducted in animals to assess tumorigenicity should use the intended clinical product, not analogous animal cells. There is currently no scientific consensus regarding the selection of the most relevant animal models to evaluate tumorigenic potential or the ability of current animal models to predict clinical outcome. However, it is important that animal studies designed to assess this end point for CT products show *in vivo* survival of the cells for a sufficient length of time to allow for potential tumor formation; additional study design considerations include (i) appropriate control groups (e.g., undifferentiated cells, partially differentiated cells, positive controls, vehicle controls); (ii) adequate numbers of animals per group to ensure statistical significance of any biological observations, including any background incidence

of tumor formation; (iii) inclusion of at least one dose level that constitutes the maximum absolute amount of cells that can be administered; (iv) delivery of the CT product targeting the planned clinical anatomic site; and (v) sufficient study duration.

35.1.10 CT Products with Implantable Scaffolds

Similar to all CT products, cell characterization should be provided prior to scaffold seeding to support use of the CT component of the multiple-component product.

Any scaffold construct (synthetic or nonsynthetic polymers) used should be identical in composition to the intended clinical scaffold. The scaffold should be adequately characterized for composition, degradation profile, biomechanical performance, and biocompatibility (with respect to host response to the scaffold component and to the cell component of the product). The specific tests that are needed to sufficiently characterize a scaffold are determined by its composition and intended use. The specific testing expectations for scaffold materials will share some features similar to the testing expected if the scaffold were to be used as an implant alone. However, the details of the manufacturing process and the cells used will likely influence the specific tests needed.

Depending on the material(s) that constitutes the intended clinical product, biocompatibility testing may be warranted. Biocompatibility test results in accordance with the ISO 10993-1 (June 2016) “Use of International Standard ISO-10993, Biological Evaluation of Medical Devices Part-1: Evaluation and Testing,” should be consulted for approaches to biocompatibility testing (Gad & Gad-McDonald, 2015).

Groups should consist of animals administered with the intended clinical product (i.e., scaffold seeded at varying cell densities) and appropriate controls.

Safety and POC of the administered product and product components should be demonstrated via inclusion of biochemical, morphological (i.e., composition and architecture of the tissue), and functional end points. Functional end points may include mechanical testing, which will depend on product design, product components, the method/location of product administration, putative MOA, and disease indication. The mechanical properties of the repaired, replaced, or regenerated tissue should be compared to appropriate concurrent controls.

The optimal dose and length of time needed to assess repair, replacement, or regeneration of clinical lesions (i.e., construct performance) and the durability of the effect should be determined. In addition, the biodegradation profile of the scaffold construct should be evaluated. The study duration will vary based on the product and the clinical indication but should be sufficient to provide data to show durability of effect. For example, study duration of 1 year in a relevant animal injury model is recommended for determination of

product performance and assessment of durability for products intended for repair/replacement of knee cartilage.

Local toxicities (e.g., tumorigenicity, altered tissue function at the injection site, inappropriate cellular differentiation, or inflammatory infiltrates) may be due to interactions of the product components with the tissue or to the degradation of product components at the site of administration. Cell migration outside of the target tissue may lead to systemic toxicities, such as ectopic tissue formation and tumorigenicity. The immunogenic potential of the construct (i.e., the scaffold and/or the cells) could also cause toxicity. Both acute and long-term *in vivo* safety of the product should be evaluated.

35.2 NONCLINICAL SAFETY ASSESSMENT OF GENE THERAPY PRODUCTS (GTPS)

GTPs are unusual in that they are subject to regulatory oversight not only by FDA but also by an NIH committee. This dual oversight reflects both the still in flux status of the science and the complication of the process (Takefman and Bi, 2015; Templeton, 2015).

35.2.1 CBER

- Division of Cell and Gene Therapy
 - Manufacturing.
 - Note: 20% of CBER clinical protocols are now for GT.
- Division of Clinical Trial Design and Analysis
 - Preclinical pharmacology and toxicity
 - Clinical trial design, safety, and efficiency

35.2.2 NIH

- Recombinant DNA Advisory Committee (RAC)
 - No authority for approval for clinical trials

Considerations for assessing the safety of GTPs are more complex because of the potential longer-term readouts as to adverse effects and greater difficulty of observing and evaluating tissue distribution of administered product. Such products also have both (therapeutically) active and inactive compounds.

There are two major potential contributors specific to GTPs—the viral vectors for gene delivery (for which acute toxicity, including cytotoxicity immune responses, potentially includes toxic shock and risk of insertional mutagenesis) and the toxicity of expressed proteins arising from the inserted genetic material (Verdier and Descotes, 1999).

GTPs have significant potential to evoke an immune response from the host (either animal model or human in

clinical trials or use), which have possible adverse effects and immune neutralization.

Both EMEA (2008) and FDA (2013) have provided specific guidances as to nonclinical evaluation of GTPs.

Specific considerations for the selection of relevant animal species/model for investigational GTPs include:

1. Assessment of the permissiveness/susceptibility of various animal species to infection by, and replication of, the viral vector
2. Pharmacological response of the species to the expressed transgene
3. Sensitivity of the species to the biological actions of the *ex vivo* genetically modified cells
4. Evaluation of DNA/RNA biodistribution
5. Evaluation of gene transfer and biological activity
6. Evaluation of the risk of vertical transmission of the gene
 - a. Assessment of the safety of the vector
 - b. Assess the safety of the product

If the previous parameters relevant to a specific GTP cannot be met using common laboratory animal species, modifications should be considered. For example, genetically modified animals expressing the human receptor target have been used to characterize the biologic activity, and thus the potential pathology, of some viruses. Similarly, immunodeficient animals have been used to evaluate the safety of genetically modified human cells. In instances where the expressed transgene is not biologically active in the animal species, use of the clinical vector expressing an analogous transgene that is active in the laboratory species may suffice, especially if clinical or preclinical data for the expressed protein exist. In such instances, comparison of the intended clinical product and the animal analog should be provided (e.g., sequence, target specificity, expression levels).

35.2.3 Study Designs

Safety concerns for both *ex vivo* and *in vivo* administration of an investigational GTP derive from multiple factors, such as the potential for adverse immune responses to the *ex vivo* genetically modified cells, the vector, or the expressed transgene; vector and transgene toxicities; and the potential risks of the delivery procedure. For example, administration of genetically modified cells or vector to vital organs, such as the brain or heart, generates concerns for potential toxicity from the product itself, as well as for possible risks associated with the delivery device and the delivery procedure. These issues should be addressed in the preclinical testing program before initiation of clinical trials.

Although assessment of the safety of the *in vivo* administered vector depends on the biological properties of each vector type, concerns that should be addressed include:

- a. Toxicities due to the components of the final formulation (e.g., liposomes and various excipients/contaminants)
- b. Toxicities due to the ROA used
- c. Aberrant localization to nontarget cells/tissues
- d. Level and persistence of vector and expressed transgene
- e. Level of viral replication in nontarget cells/tissues
- f. Immune activation or suppression
- g. Immune response directed against the vector
- h. Phenotype/activation state of target cell(s)
- i. Potential for insertional mutagenesis or oncogenicity
- j. Potential for germline transmission
- k. Potential horizontal transmission of replication-competent vectors from the patient to family members and healthcare providers (i.e., shedding)

Some examples of potential toxicity characteristics of specific vector types include:

- a. Nonviral vectors—Potential for immune response to the DNA or to extraneous bacterial sequences
- b. Replication-deficient viral vectors:
 - i. Adenovirus—Potential for a significant immune response and inflammatory response to the vector and possible adverse effects from any contaminating replication-competent adenovirus.
 - ii. Adeno-associated virus (AAV)—(i) Although AAV remains episomal in the transduced cell, the potential for random integration into host DNA, resulting in insertional mutagenesis and any subsequent adverse biological effects, exists and (ii) potential immune response to the capsid proteins.
 - iii. Retrovirus and lentivirus—(i) Production of a replication-competent retrovirus/lentivirus (RCR/RCL) during manufacturing; (ii) potential for insertional mutagenesis, resulting in oncogene activation; (iii) potential for germline integration; and (iv) potential for altered expression of host genes.
 - iv. Poxvirus—(i) Ability to infect and replicate in many types of human tissues and cells, (ii) potential for toxicity in immunocompromised populations such as cancer patients, and (iii) renal/cardiac concerns.
 - v. Herpes simplex virus (HSV)—Tropism to the central nervous system and the potential for latency and reactivation.

- c. Replication-competent oncolytic vectors—(i) Potential viral infection and replication in normal cells and (ii) increased viral spread and replication in nontarget tissues in immunosuppressed patients or when administered in combination with radiation, chemotherapy, prodrugs, or other agents
- d. Microbial vectors used for GT—(i) Lack of adequate attenuation of the microbe, (ii) ability to replicate in nontarget tissues, (iii) excessive induction of proinflammatory cytokines, and (iv) lack of antibiotic susceptibility

Although the appropriate duration of clinical follow-up of GT trial participants for adverse events is primarily a trial design issue, vector characteristics and preclinical data are used to inform clinical trial decisions. CBER has issued a guidance for industry entitled “Guidance for Industry: Gene Therapy Clinical Trials—Observing Subjects for Delayed Adverse Events” dated November 2006 (FDA, 2006), which discusses the potential risks of delayed adverse events following exposure to GTPs as a consequence of persistent biological activity of the genetic material or other components of the products used to carry the genetic material. As specified in that guidance, factors that are likely to increase the risk of delayed adverse events in humans include persistence of the viral vector, integration of genetic material into the host genome, prolonged expression of the transgene, and altered expression of the host’s genes. The 2006 guidance should be consulted and, if found to be applicable to the investigational GTPs under study, should be used to guide the design of relevant preclinical studies to address potential long-term safety issues that may result from administration to humans.

When determining the safety of an expressed transgene and/or translated protein, sponsors should consider the following: (i) local versus systemic expression, (ii) level and duration of expression, and (iii) acute versus chronic effects. While persistent transgene expression may be a desired end point for some GTPs, it can also be an undesired outcome for other products due to overexpression, accumulation of transgene protein, or risk of an abnormal immune response. Prolonged expression of transgenes such as growth factors, growth factor receptors, or immunomodulating agents may be associated with long-term risks due to unregulated cell growth, malignant transformation, autoimmune reactions to self-antigens, altered expression of the host’s genes, or other unanticipated adverse effects. The conduct of long-term preclinical studies should be considered to evaluate these concerns.

In addition, assessment of the *in vivo* transgene expression profile is recommended for vectors expressing a new transgene with an unknown potential to induce toxicity or vectors expressing a transgene with a known or suspected potential to induce toxicity if aberrantly expressed in nontarget tissues. Quantitation of transgene expression using methods such as a quantitative reverse transcriptase PCR (RT-PCR) assay can

help determine the threshold level of expression associated with beneficial or deleterious effects for specific tissues/organ systems and correlation of the kinetics of transgene expression with desired activity or undesired toxicity profiles.

In addition, potential immunogenic/neutralization responses directed against the expressed transgene and/or directed against self/endogenous proteins can be a concern. For example, delivery of transgenes that encode various endogenous enzymes, receptors, or structural proteins may elicit antibodies against both the transgene and the endogenous components expressed in normal cells and tissues, resulting in an adverse response. Similarly, transgenes that express fusion or chimera proteins can theoretically be immunogenic due to their foreign (xenogeneic) nature. These concerns should be addressed in the preclinical testing program.

35.2.4 *Ex Vivo* Genetically Modified Cells

The safety assessment of the cellular component of *ex vivo* transduced cells includes end points that are similar to those evaluated for CT products. The significance of the issues described in these sections will depend on the cell type(s), the vector construct, and/or the transgene used. The preclinical study designs should address relevant factors specific to each product. It should be noted that occurrence of anaphylactic responses cannot be evaluated in mice.

35.2.5 Biodistribution Considerations

The characterization of the vector biodistribution profile following *in vivo* administration is an important component of the preclinical development program for GTPs. These data are used to determine the potential for vector presence in desired target tissues/biological fluids (e.g., blood, cerebrospinal fluid), in nontarget tissues/biological fluids, and in the germline. The characterization of the vector presence, persistence, and clearance profile can inform the selection of the GTP dosing schedule, the monitoring schedule for various activity/safety parameters, and the animal sacrifice time points in the definitive preclinical studies (Table 35.1). The biodistribution data, coupled with other preclinical safety end points such as clinical pathology and histopathology, help determine whether vector presence or gene expression correlates with any tissue-specific detrimental effects in the animals.

Prior to administration in humans, biodistribution studies should be considered for:

- a. Investigational GTPs that belong to a new vector class
- b. Established vectors with significant changes in the vector backbone
- c. Established vectors with a significant formulation change

TABLE 35.1 Pharmacokinetic Considerations for Gene Therapy

Pharmacokinetic Property	Gene Therapy Property
Absorption	DNA vector distribution
Distribution	Vector fraction target cell uptake
Distribution	Genetic material traffic in organelles
Metabolism	DNA degradation
Metabolism	mRNA production
Metabolism	Protein production—quantity
Excretion	Protein production—stability
Metabolism and excretion	Protein production—compartmentalization
Excretion	Protein production—secretory fate

- d. Established vectors with a significant change in the ROA
- e. Established vectors with a significant change in the dosing schedule and/or the vector dose levels

Justification should be provided if biodistribution studies are not conducted prior to initiation of early-phase clinical trials.

Tissue/biological fluid analysis should be conducted at the molecular level using a quantitative PCR (qPCR) assay to determine the number of vector copies per microgram of genomic DNA at specified time points postvector administration. Other methods for evaluating biodistribution are radiolabeling and Southern blot. Depending on the ROA and biology of the investigational GTP (vector type and expressed transgene), additional tissues may need to be collected and analyzed. In addition, the presence of a vector sequence in tissues/biological fluids may trigger further analysis to determine the transgene expression levels. Evaluating gene transfer and biological activity would include immunohistochemistry, Western blot, ELISA, and flow cytometry.

Single-dose toxicity studies provide information about systemic and local toxicity. To assess the nonspecific toxicity of the final product, the use of a parenteral route is recommended to maximize exposure to the product. When results of acute studies are the only preclinical toxicology data to be presented prior to single-dose administration to humans, additional parameters, such as clinical pathology and histology, should be investigated.

Repeated-dose toxicity studies are required when several administrations are scheduled in clinical trials. The design of these studies should be as close as possible to the human dosing regimen. Therefore, daily treatments are often likely to be irrelevant and sequential administrations more appropriate, to mimic the human treatment design. For instance, three administrations every 3 weeks can be used to reproduce exactly the human vaccination schedule for a genetically modified vaccine or, alternatively, two injections per week for 3 weeks

in animals versus three administrations every 3 weeks in humans for an anticancer viral vector product. In the latter example, animal exposure is increased while keeping the intermittent treatment design. The immunogenicity (i.e., the potential of the product to trigger an immune response) in the selected animal species is frequently a limiting factor (remember no anaphylactic response in mice). Both humoral and cellular responses can be addressed, especially antibodies against the vector and the expressed protein (using ELISA) and lymphoproliferation and cytotoxic T-lymphocyte (CTL) activity. The latter test requires that the target cells (e.g., adenovirus-infected target cells) express the product antigens, which is technically difficult. Potential adverse reactions in relation to the immune response against the administered product (e.g., immune complex deposition) should also be investigated, as such reactions may occur in human patients. The treated animals must be examined, even during the postimmunization period. Immunogenicity can be a useful indicator of the efficacy of the product, which may be neutralized by antibodies. The information gained may also be of value for the selection of the less immunogenic vectors. For instance, doubly deleted ($\Delta E1$ and $\Delta E4$) adenovirus vectors have been shown to express fewer viral proteins than singly deleted ($\Delta E1$) adenovirus vectors and to cause diminished hepatotoxicity and lower immune response toward the vector following parenteral administration in the mouse.

35.3 DEFINITIONS

ATMPs—Advanced therapy medicinal products

Gene therapy medicinal products (GTMPs)—Biological products that contain an active substance which contains or consists of a recombinant nucleic acid used in and administered to human being with the intent of regulating, repairing, replacing, adding, or deleting a genetic sequence

Somatic cell therapy—Substantially manipulates cells or tissues with the intent of treating, preventing, or diagnosing a disease through the pharmacologic, immunologic, or metabolic action

Stem cell therapy—The use of pluripotent stem cells induced to treat degenerative diseases, inflammatory conditions, repair of damaged tissues, and cancer

Delivery device—Any material to be used with the GTP or in which the final GTP is prepared, serving to deliver/administer the GTP

ADVERSE OUTCOME PATHWAYS IN DRUG SAFETY ASSESSMENT

36.1 INTRODUCTION

While both drug discovery and the science of toxicology have been on the scene since the nineteenth century, modern drug development with accompanying formalized and regulatory assessment of potential risks to patients became the norm in the late 1950's sparked by a human disaster, thalidomide. The two are related but different. Toxicology is the science of identifying potential risks and their sources and is largely academic, and safety assessment is relating potential relevant toxic effects and the mechanism behind them to potential quantifiable and manageable (or not) risks. While the processes and procedures have become increasingly evolving technology, there are several common routes to failure for both.

Sixty years ago, Gerhard Zbinden wrote a novel on drug development (Source of the River Po, 1992) and an unpublished (but widely distributed) guide to the most common routes to error in assessing the toxicology of drugs (The Ten Deadly Sins of Toxicology). In this short chapter, we will try to share 50 years of finding common pathways to understandable outcomes in the safety assessment of drugs.

36.2 INITIAL STEPS

Before launching into full blown development of any drug, it is critical to take the time and effort to conduct thorough research on what is known about the candidate, its structural class, the therapeutic target, and mechanism of action. From these, establish a clear vision of what the intended precise therapeutic claim is going to be for the drug.

From this dossier of information arises details of the proposed patient population, route of administration, and reg-

imen for treatment. The first frequent errors come here. A study establishing or supporting efficacy (preferably from an *in vivo* model) should be performed to verify that there is data supporting that the drug will work and on which to base preparation of what is one efficacious level for clinical use.

A little time here can save a lot of time and inconvenience later, or even can serve to prevent overall failure.

Here we encounter the first (and perhaps most common) path to failure, not taking the time to develop a formulation, which at least appears viable for use to and through the first in human clinical trials. Most commonly, whatever can be rapidly made to get a drug into a deliverable form (liquid or solid) is seized upon, it can always be fixed later.

36.3 TEST ARTICLE – CONFIRMING IDENTITY AND STABILITY

One must ensure that the drug substance sample submitted for testing is truly what is intended. Check the appearance against COA (Certificate of Analysis) and have supplied a COA that stipulates identity, purity, properties and short-term stability.

It is not uncommon to have a sponsor or their agent supply the wrong material

36.4 FORMULATION

The objective of a nonclinical formulation is not just to solubilize a test material but also to do so in a manner that the resulting test solution is well-tolerated by the intended route and in the test species being used. (Gad and Spainhour, 2018)

36.5 TEST SPECIES – ANIMAL MODELS

For general or systemic toxicology studies, regulatory requirements (with rare exception) are that two studies in two different species be conducted at each required duration. This includes a rodent (usually the rat) and a nonrodent (dog, nonhuman primate, pig or rabbit (while the rabbit is technically not a rodent but rather a lagomorph, it is included in species acceptable for this category) are the most common utilized). Typically cost, compound requirements, and availability of test animals are the factors that govern species selection. Often overlooked are species peculiarities in tolerance to classes of compounds especially for excipients (Gad, 2015). Additionally, once studies are performed, the agency will expect a drug developer to use the most sensitive species to evaluate the systemic safety of the proposed drug.

36.6 DOSE LEVEL SELECTION AND DOSING ERRORS

The target dose levels in a safety assessment study are the highest level that does not evoke adverse effects (especially irreversible ones) over the duration of treatment, and the lowest level which does evoke an adverse effect over the duration of treatment. An additional interim level is required and serves to add shape to the dose response curve. Sometimes more than three separate dose levels are employed in a study to ensure that the above objectives are achieved without having to repeat a study. It is important to keep in mind that it is not imperative that the value of a NOAEL greater than a projected therapeutic effect level be identified.

Dose range finding or pilot studies are not required by regulations or guidelines, (and are not required to be conducted in accordance with GLPs) but are generally highly effective ways used to achieve accuracy under regulatory guidance requirements that require GLP studies. Such an approach saves time, money, animals and test article. Such studies should be conducted in an efficient manner (in terms of compound and animal use), only collecting such data that are useful in achieving the goal. This can become a major pitfall – do not allow oneself to become involved in an academic research project, but rather just provide the data points that the agency is seeking and potentially confuse addressal of these essential points. For therapeutic products, the two-phase dose range finding (DRF) (a single dose escalating phase followed by a 5–7 day repeat dose study) developed in the early 1980s (described at length in the repeat dose Chapter 9 of this book) has proven to be the optimal selection.

Safety pharmacology studies are not toxicology studies and are not generally required to be conducted at doses high enough to demonstrate an effect; rather, these are a form of tolerance studies. They are intended to determine if there is an effect on the functionality of critical organ systems (usually cardiovas-

cular, respiratory, or central nervous system) at exposure levels at or modestly above (usually no more than threefold higher) the highest level achieved in clinical trials or to be used therapeutically. By definition, these levels provide findings that are reversible and not such that clear characteristics of the functional effects of interest are obscured by toxic effects.

Lastly, care must be taken to not produce adverse effects by poor technique. Examples of such “dosing misadventures” include oral dosing that leads to aspiration of test solutions into the lungs, or penetration of natural channels or tissue compartments. Proper training and regular practice are the best means of avoiding these mishaps.

Always remember that the primary objective is to develop and bring into use effective and safe therapeutic agents for humans in a timely manner. While we must minimize the use of test animals and have such use be as humane as possible, such use (while significant progress has been made in reducing the number of animals used and minimize inducing pain or discomfort in test animals) remains unavoidable, and effective treatment for preventing human disease requires some risk of discomfort. The precautionary principle frequently creates risk or precludes development of treatment due to efforts to avoid the same.

36.7 POOR PLANNING

In drug development one must keep in mind that time is money. This is because delays in hitting one’s milestones can result in the loss of financing opportunities and further down the road market opportunity. The largest opportunities are typically: (i) Lack of the timely development of suitable bioanalytical and analytical methodology. (ii) Lack of the timely development of a relatively nontoxic formulation that provides adequate bioavailability and stability of the test article along with realistic storage conditions. (iii) Lack of or significantly delayed availability of animals, which of late has involved nonhuman primates, dogs, and miniature swine. This situation is getting substantially worse at the time of this writing with regard to nonhuman primates. If an individual is on top of their game, they will appropriately manage all of these potential pitfalls successfully, but it is strongly recommended that anyone that has a desire to develop an idea into a future medicament secure the services of a suitably qualified toxicology consultant (see Roundtable of Toxicology Consultants on the internet).

36.8 PAY ATTENTION TO THE REGULATORY CLOCK AND CHANGES IN REQUIREMENTS AND GUIDELINES

While more commonly mistakes are made by skipping essential tasks or performing them inadequately in a rush to

meet a promised filing date (such as using a “good enough” formulation), the other end of the chronological spectrum also must be observed. Requirements (as to both what studies must be performed or how they are performed) do change over time, having the result that studies and therefore entire filings are rejected and must be completed. A recent example is performing leachable and extractable studies in accordance with FDA expectations as to temperatures, calculation and then adherence in protocols to detection limits (AETs) in such studies. Making the study unacceptable with no way to correct other than do the entire study over. Again, here for companies that do not have dedicated staff to watch such things, retaining the services of an appropriate consultant who regularly interacts with the relevant FDA staff is a recommended approach.

36.9 MOST ADVANCES IN SAFETY ASSESSMENT ARE SMALL.

In my (SCG) almost fifty years in toxicology and drug development, I have not contributed anything worthy of a Nobel prize, nor have I cured a fatal disease. Most scientists never do these or anything that society as a whole will notice. Rather, what we do accomplish is to make small significant contributions that taken in aggregate make positive life differences for a wide variety of people with a wide range of problems. In working with friends and colleagues I look back with the most pride on five utilitarian contributions to the practice of toxicology.

1. The neurobehavioral battery which evolved into the functional observational battery used now in CNS safety pharmacology. (Gad, 1982; Gad SC and Gad SE, 2003)
2. The mouse ear swelling test used as a screen for potential dermal sensitization. (Gad et al., 1985; Gad et al., 1986a)
3. The two-phase DRF study which replaced LD50 studies followed by a 9- or 14-day pilot toxicity study. (Gad and Chengelis, 1988)

4. The single dose systemic toxicity study to facilitate phase 4 clinical studies – later adopted in entirety by the FDA (Gad et al., 1984)
5. Screening approval employing pH, dermal irritation, and only then performing eye irritation to minimize pain in animals during eye irritation testing. The resulting flow chart was adopted as OECD guidance. (Gad et al., 1986b)

APPENDIX B

DEFINITION OF TERMS AND LEXICON OF “CLINICAL” OBSERVATIONS IN NONCLINICAL (ANIMAL) STUDIES

Movement

Anesthetized	The absence of or reduced response to external stimuli, accompanied with a loss of righting reflex
Ataxia	Incoordination of muscular action involving locomotion, including loss of coordination and unsteady gait
Hyperactivity	An abnormally high level of motor activity
Hypersensitivity	An abnormally strong reaction to external stimuli such as noise or touch
Lethargy	A state of deep and prolonged depression stupor from which it is possible to be aroused, followed by an immediate relapse
Low carriage	The animal's torso is carried very close to the ground during movement
Prostrate	Animal assumes a recumbent position due to loss of strength or exhaustion and may show intermittent uncoordinated movements
Righting reflex	The ability of an animal, when placed on its back, to regain a position on all fours
Unsteady gait	An erratic manner or style of walking
Catalepsy	A condition characterized by a waxy rigidity of the muscles such that the animal tends to remain in any position in which it is placed
Paralysis	Inhibition or loss of motor function; may be characterized by affected portion of the body

Respiration

Audible respiration	An abnormal respiratory sound heard while listening to the breathing of the animal (e.g., wheezing and rales)
Bradypnea	An abnormal slowness of the respiration rate
Dyspnea	“Shortness of breath”; difficult or labored breathing
Gasping	Spasmodic breathing with the mouth open, or laborious respiration with the breath caught convulsively
Hyperpnea	Deep and rapid breathing
Cheyne–Stokes respiration	Breathing characterized by rhythmic waning and waxing of the depth of respiration, with regularly recurring periods of apnea: seen especially in coma resulting from affection of the nervous centers
Hypopnea	Shallow and slow breathing

(Continued)

(Continued)

Irregular respiration	No definite cycle or rate of breathing
Labored respiration	Forced or difficult, usually irregular breathing
Tachypnea	An excessive rapidity of the respiration rate
<i>Condition of skin and fur</i>	
Alopecia	Deficiency of hair (baldness)
Cyanosis	Visible skin and/or mucous membranes turn dusky blue due to lack of oxygenation of the blood
Necrosis	Actual tissue destruction, masses of dead/destroyed tissue
<i>Urogenital region</i>	
Anuria	An absence of or sharp decline in urine excretion
Diarrhea	An abnormal frequency and liquidity of fecal discharge
Polyuria	An abnormally sharp increase in the amount of urine excretion
<i>Convulsions and tremors</i>	
Convulsions	Transient, self-sustaining electrical dysrhythmias which have a tendency to recur. Convulsions are generally associated with a finite period of unconsciousness and have a muscular involvement manifested as disorganized limb movements
Clonic	This is often seen as a “paddling; motion of the forelegs of the animal”
Tonic	Muscular contraction, keeping limbs in a fixed position, generally extended to the rear
Torsion	Postural incoordination or rolling. This is generally associated with the vestibular (ear canal) system
Fasciculation	Rapid, often continuous contraction of a bundle of skeletal muscle fibers which does not produce a purposeful movement (twitching)
Tremor	Fine oscillating muscular movements which may or may not be rhythmic
<i>Condition of eyes</i>	
Blepharospasm	A twitching or spasmodic contraction of the orbicularis oculi muscle
Chemosis	Edema of conjunctiva(e)—The conjunctival tissue responds to noxious stimuli by swelling
Chromodacryorrhea	The response of reddish conjunctival exudate; no blood cells present in exudate (i.e., not true “bloody tears”)
Conjunctivitis	Inflammation of conjunctiva (mucous membrane which lines the eyelids and is reflected into the eyeball)
Exophthalmos	An abnormal protrusion of the eyeball from the orbit
Lacrimation	The secretion of tears
Miosis	Constriction of the pupil
Mydriasis	Dilation of the pupil
Nystagmus	An abnormal involuntary movement of the eyes. It may be rotational or horizontal or vertical plane
Ocular exudate	Secretion (usually transparent and yellow) directly from the eye
Opacity	A loss of transparency of the eyeball
Pinpoint pupils	Ultimate state of miosis
Ptoxis	Refers to a drooping of the upper eyelid, though to be due to impaired conduction in the third cranial nerve
<i>Miscellaneous</i>	
Analgesia	The absence of (or reduced response to) painful stimuli
Hunched posture	The drawing-in of both ends of the body and extremities with a sharp arching of the back
Kyphosis	Humpback—an abnormal curvature and dorsal prominence of the vertebrae column
Nasal discharge	Fluid secretion from the nostrils
Piloerection	Body hair stands on end; dilation of the pupils usually accompanies piloerection
Salivation	Excessive secretion of saliva from the mouth

(Continued)

Straub tail	Condition, especially in mice, in which the animal carries its tail in an erect (vertical or nearly vertical) position. This sign is commonly associated with chemicals (e.g., morphine) that bind to opiate receptors
<i>Reflexes</i>	
Corneal reflex	Closure of the eyelids in response to a corneal touch (e.g., with a soft brush bristle)
Grip strength (or screen grip)	Measure of the grip strength of the forelimbs or hind limbs; may be evaluated quantitatively or by subjective estimate or impairment (rodents only)
Pinna reflex	Twitch of the outer ear in response to a gentle touch
Preyer's reflex (auditory startle response)	Involuntary movement of the outer ears produced by an auditory stimulus (especially in rats)
Pupillary reflex	Contraction of the pupil in response to light stimulation of the retina
Righting reflex	The ability to land on (when dropped) or regain normal stance on all four limbs
Startle reflex	Response to sharp sound, touch, or other startling stimulus; response may range from "absent," to "normal," to "hyperreactive," including exaggerated jerking, jumping, frantic attempts to escape, and even convulsion

APPENDIX D

GLOSSARY OF TERMS USED IN THE CLINICAL EVALUATION OF THERAPEUTIC AGENTS

Abnormality A sign, symptom, or laboratory result not characteristic of normal individuals.

Adverse event Unwanted effects that occur and are detected in populations. The term is used whether there is or is not any attribution to a medicine or other cause. Adverse events may be known as parts of a disease that are observed to occur within a period of observation, and they may be analyzed to test for their frequency in a given population or trial. This is done to determine if there is an unexpectedly increased frequency resulting from nondisease factors such as medicine treatment. The term “adverse event” or “adverse experience” is used to encompass adverse reactions plus any injury, toxicity, or hypersensitivity that may be medicine-related, as well as any medical events that are apparently unrelated to medicine that occur during the study (e.g., surgery, illness, and trauma). See definition of **adverse reaction**.

Adverse experience See **adverse event**.

Adverse reaction Unwanted effect(s) (i.e., physical and psychological symptoms and signs) resulting from treatment. A less-rigid definition of adverse reaction includes the previous definition plus any undesirable effect or problem that is present during the period of treatment and may or may not be a well-known or obvious complication of the disease itself. Thus, many common personality, physical, psychological, and behavioral characteristics that are observed in medicine studies are sometimes characterized as adverse reactions even if they were present during baseline. Synonyms of adverse reactions generally include adverse medical effects, untoward effects, side effects, adverse drug experiences, and adverse

drug reactions. Specific distinctions among some of these terms may be defined operationally. For example, the term “adverse reaction” is used to denote those signs and symptoms at least possibly related to a medicine, whereas the term “adverse experiences” is used to include nonmedicine-related medical problems in a trial such as those emanating from trauma or concurrent illness. Distinctions among side effects, adverse events, and adverse reactions are illustrated in the definitions of the two former terms.

Bias (1) A point of view that prevents impartial judgement on issues relating to that point of view. Clinical trials attempt to control this through double blinding. (2) Any tendency for a value to deviate in one direction from the true value. Statisticians attempt to prevent this type of bias by various techniques, including randomization.

Clinical significance The quality of a study’s outcome that convinces physicians to modify or maintain their current practice of medicine. The greater the clinical significance, the greater is the influence on the practice of medicine. The assessment of clinical significance is usually based on the magnitude of the effect observed, the quality of the study that yielded the data, and the probability that the effect is a true one. Although this operational definition is presented from the physician’s perspective, the term could operationally be defined from the patient’s perspective. Patients are primarily concerned with results that will lead to an improved quality of life or a lengthening of their life. In addition, clinical significance may be applied to either positive data or efficacy or negative safety data such as for adverse reactions. Synonyms

include clinical importance, clinical relevance, and clinical meaningfulness.

Clinical studies The class of all scientific approaches to evaluate medical disease preventions, diagnostic techniques, and treatments. Investigational and marketed prescription medicine evaluations plus over-the-counter medicines are included.

Clinical trials A subset of those clinical studies that evaluates investigational medicines in Phases I, II, and III. Phase IV evaluations of marketed medicines in formal clinical trials using the same or similar types of protocols to those used in Phases I and III are also referred to as clinical trials.

Compliance (1) Adherence of patients to following medical advice and prescriptions. Primarily applied not only to taking medicine as directed but also to following advice on diet, exercise, or other aspects of a patient's life. (2) Adherence of investigators to following a protocol and related administrative and regulatory responsibilities. (3) Adherence of sponsors to following regulatory, legal, and other responsibilities and requirements relating to a clinical trial.

Compound A chemical synthesized or prepared from natural sources that is evaluated for its biological activities in preclinical tests.

Development of medicines The term "development" as applied to medicines is used in several different contexts, even within the pharmaceutical industry. This often leads to confusion and misunderstanding. No single definition is preferred, but the particular meaning intended should be made clear by all people using the term. Three operational definitions are presented, from the broadest to the narrowest: (1) All stages and processes involved in discovering, evaluating, and formulating a new medicine, until it reaches the market (i.e., commercial sale). (2) All stages involving the evaluation and formulation of a new medicine (after the medicine has been discovered and has gone through preclinical testing), until it reaches the market. (3) Those stages after the preclinical discovery and evaluation that involve technical development. These processes include formulation work, stability testing, scaling-up the compound for larger-scale synthesis, and providing analytical support. Clinical trials are not included in this definition.

Disease Disorders (e.g., anxiety disorders, seizure disorders), conditions (e.g., obesity, menopause), syndromes, specific illnesses, and other medical problems that are an acquired morbid change in a tissue, organ, or organism. Synonyms are illness and sickness.

Dosage regimen (1) The number of doses per given time period (usually days), (2) the time that elapses between doses (e.g., dose to be given every 6 h) or the time that the doses are to be given (e.g., dose to be given ad 8 a.m.,

noon, and 4 p.m. each day), or (3) the quantity of a medicine (e.g., number of tablets, capsules) that are given at each specific time of dosing.

Efficacy A relative concept referring to the ability of a medicine to elicit a beneficial clinical effect. This may be measured or evaluated using objective or subjective parameters and in terms ranging from global impressions to highly precise measurements. Efficacy is assessed at one or more levels of organization (e.g., subcellular, cellular, tissue, organ, whole body) and may be extrapolated to other levels.

Endpoint An indicator measured in a patient or biological sample to assess safety, efficacy, or another trial objective. Some endpoints are derived from primary endpoints (e.g., cardiac output is derived from stroke volume and heart rate). Synonyms include outcome, variable, parameter, marker, and measure. See surrogate endpoint in the text. Also defined as the final trial objective by some authors.

Incidence rate The rate of occurrence of new cases of a disease, adverse reaction, or other event in a given population at risk (e.g., the incidence of disease X in Y patients per year per 100 000 population).

Interpretation The process whereby one determines the clinical meaning or significance of data after the relevant statistical analyses have been performed. These processes often involve developing an explanation of the data that are being evaluated.

Medicine When a compound or a substance is tested for biological and clinical activity in humans, it is considered to be a medicine. Some individuals prefer to define a medicine as a compound that has demonstrated clinically useful properties in patients. This definition, however, would restrict the term to use sometime during or after Phase II. Others use the term loosely and apply it to compounds with biological properties during the preclinical period that suggest medical usefulness in humans. The author has adopted the first definition for use in this book.

Patient The term "patient" is used almost exclusively throughout this book in preference to subject or volunteer. Patient is used to cover those cases in which the term "volunteer" would be appropriate.

Pharmacodynamics The processes of the body's responses resulting from treatment with a medicine or a compound. The processes include pharmacological, biochemical, physiological, and therapeutic effects. The pharmacodynamics of a response to treatment are presented with the scientific and/or clinical language of the disciplines involved in detecting, measuring, and describing the effects.

Pharmacokinetics The processes of absorption, distribution, metabolism, and excretion of compounds and medicines.

Phases of clinical trials and medicine development Four phases of clinical trials and medicine development exist

and are defined below. Each of these definitions is a functional one and the terms are not defined on a strict chronological bases. An investigational medicine is often evaluated in two or more phases simultaneously in different clinical trials. Also, some clinical trials may overlap two different phases.

Phase I Initial safety trials on a new medicine, usually conducted in normal healthy volunteers. An attempt is made to establish the dose range tolerated by volunteers for single and for multiple doses. Phase I trials are sometimes conducted in severely ill patients (e.g., in the field of cancer) or in less ill patients when pharmacokinetic issues are addressed (e.g., metabolism of a new antiepileptic medicine in stable epileptic patients whose microsomal liver enzymes have been induced by other antiepileptic medicines). Pharmacokinetic trials are usually considered Phase I trials regardless of when they are conducted during a medicine's development.

Phase IIa Pilot clinical trials to evaluate efficacy (and safety) in selected populations of patients with the disease or condition to be treated, diagnosed, or prevented. Objectives may focus on dose–response, type of patient, frequency of dosing, or numerous other characteristics of safety and efficacy.

Phase IIb Well-controlled trials to evaluate efficacy (and safety) in patients with the disease or condition to be treated, diagnosed, or prevented. These clinical trials usually represent the most rigorous demonstration of a medicine's efficacy. Sometimes referred to as pivotal trials.

Phase IIIa Trials conducted after efficacy of the medicine is demonstrated, but prior to regulatory submission of a new drug application (NDA) or other dossier. These clinical trials are conducted in patient populations for which the medicine is eventually intended. Phase IIIa clinical trials generate additional data on both safety and efficacy in relatively large numbers of patients in both controlled and uncontrolled trials. Clinical trials are also conducted in special groups of patients (e.g., renal failure patients) or under special conditions dictated by the nature of the medicine and disease. These trials often provide much of the information needed for the packaging insert and labeling of the medicine.

Phase IIIb Clinical trials conducted after regulatory submission of an NDA or other dossier, but prior to the medicine's approval and launch. These trials may supplement earlier trials, complete earlier trials, or may be directed toward new types of trials (e.g., quality of life, marketing) or Phase IV evaluations. This is the period between submission and approval of a regulatory dossier for marketing authorization.

Phase IV Studies or trials conducted after a medicine is marketed to provide additional details about the medicine's efficacy or safety profile. Different formulations,

dosages, durations of treatment, medicine interactions, and other medicine comparisons may be evaluated. New age groups, races, and other types of patients can be studied. Detection and definition of previously unknown or inadequately quantified adverse reactions and related risk factors are an important aspect of many Phase IV studies. If a marketed medicine is to be evaluated for another (i.e., new) indication, then those clinical trials are considered Phase II clinical trials. The term “postmarketing surveillance” is frequently used to describe those clinical studies in Phase IV (i.e., the period following marketing) that are primarily observational or nonexperimental in nature, to distinguish them from well-controlled Phase IV clinical trials or marketing studies.

Prevalence The total number of people in a population that are affected with a particular disease at a given time. This term is expressed as the rate of all cases (e.g., the prevalence of disease X is Y patients per 100 000 population) at a given point or period of time.

Research (on medicines) Numerous definitions of research are used both in the literature and among scientists. In the broadest sense, research in the pharmaceutical industry includes all processes of medicine discovery, preclinical and clinical evaluation, and technical development. In a more restricted sense, research concentrates on the pre-clinical discovery phase, where the basic characteristics of a new medicine are determined. Once a decision is reached to study the medicine in humans to evaluate its therapeutic potential, the compound passes from the research to the development phase.

Research and development When research and development are used together, it refers to the broadest definition for research (see above). Some people use the term “research” colloquially to include most or all of the scientific and medical areas (discovery, evaluation, and development) covered by the single term “research and development.” “Medicine development” has several definitions and, in its broadest definition, is exactly the same as the broad definition of “research.”

Risk A measure of (1) the probability of occurrence of harm to human health or (2) the severity of harm that may occur. Such a measure includes judgment of the acceptability of risk. Assessment of safety involves judgment, and there are numerous perspectives (e.g., patients, physicians, company, and regulatory authorities) used for judging it.

Safety A relative concept referring to the freedom from harm or damage resulting from adverse reactions or physical, psychological, or behavioral abnormalities that occur as a result of medicine or nonmedicine use. Safety is usually measured with one or more of the following: physical examination (e.g., vital signs, neurological, ophthalmological, and general physical), laboratory evaluations

of biological samples (e.g., hematology, clinical chemistry, and urinalysis), special tests and procedures (e.g., electrocardiogram, pulmonary function tests), psychiatric tests and evaluations, and determination of clinical signs and symptoms.

Serious adverse reactions Multiple definitions are possible and no single one is correct in all situations. In general usage referring to patients in clinical trials, a serious adverse reaction may be (1) any bad adverse reaction that is observed, (2) any bad adverse reaction that one does not expect to observe, (3) any bad adverse reaction that one does not expect to observe and is not in the label, or (4) any bad adverse reaction that has not been reported with standard therapy. Definitions also may be based on the degree to which an adverse reaction compromises a patient's function or requires treatment.

Side effect Any effect other than the primary intended effect(s) resulting from medicine or nonmedicine treatment or intervention. Side effects may be negative (i.e., an adverse reaction), neutral, or positive (i.e., a beneficial effect) for the patient. This term, therefore, includes all adverse reactions plus other effects of treatment. See definition of **adverse reaction**.

Site This refers to the place where a clinical trial is conducted. A physician who has offices and sees patients in three separate location is viewed as having one site. A physician who is on the staff of four hospitals could be

viewed as having one or four sites, depending on how similar or different the patient populations are and whether the data from these four locations will be pooled and considered a single site. For example, a single physician who enrolls groups of patients at a university hospital, private clinic, community hospital, and Veterans Administration Hospital should generally be viewed as having four sites, since the patient populations would be expected to differ at each site. See **satellite site**.

Statistical significance This term relates to the probability that an event or a difference occurred by chance alone. Thus, it is a measure of whether a difference is likely to be real, but it does not indicate whether the difference is small or large, important or trivial. The level of statistical significance depends on the number of patients studied or observations made, as well as the magnitude of difference observed.

Therapeutic window This term is applied to the difference between the minimum and maximum doses that may be given to patients to obtain an adequate clinical response and avoid intolerable toxic effects. The greater the value calculated for the therapeutic window, the greater a medicine's margin of safety. Synonyms are "therapeutic ratio" and "therapeutic index."

Volunteer A normal individual who participates in a clinical trial for reasons other than medical need and who does not receive any direct medical benefit from participating in the trial.

APPENDIX E

COMMON VEHICLES FOR THE NONCLINICAL EVALUATION OF THERAPEUTIC AGENTS

TABLE E.1 Index of Vehicles and Excipients—Codex and Details

Excipient/Vehicle	Data in Table #s (T#)		Synonyms	Formula	Key Toxicity Review Articles/Sources	Animal Species Evaluated	Administration Routes Evaluated
	Combination #s (C:#)	CAS#					
Acacia	T2, T111 C:1–7	9000-01-5	<i>Acaciae gummi</i>	Natural product	Anderson (1986), Bachmann (1978), and TOXNET (2015a)	Nonhuman primate, rat	PO
Acetate buffer	T111 C:8, 9, 119, 138–141	71-50-1	Acetate ion	C ₂ H ₃ O ₂	TOXNET (2015b)	Nonhuman primate, minipig, mouse, rat	IM, IV, PO
Acetic acid	T3, T111 C:10, 12	64-19-7	Ethanoic acid	C ₂ H ₄ O ₂	Schonwald(2004a), Szilagyi(2012a), and TOXNET (2015c)	Dog, mouse, rat	IV, PO
Acetone	T4, T111 C:11	67-64-1	2-Propanone	C ₃ H ₆ O	TOXNET (2015d)	Guinea pig, mouse, rabbit, rat	Dermal, PO
Acetonitrile	T111 C:12	75-05-8		C ₂ H ₃ N	TOXNET (2015e)	Dog	PO
Acetylated lanolin alcohol	T111 C:174	61788-49-6		N/A	TOXNET (2015f)	Minipig	Topical
Acetylmethylamide	T5 —	79-16-3	<i>N</i> -methylacetamide	C ₃ H ₇ NO	TOXNET(2015g)	Nonhuman primate	PO
Alcohol denatured SDA	T111 C:234					Minipig	Topical
Alginic acid	T6 —	9005-32-7	Norgine		JECFA (1997) and TOXNET (2015h)	Rat	IP
Anecortave acetate	T7 —	7753-60-8		C ₂₃ H ₃₀ OS	Jockovich et al. (2006), Talsma (2004), and TOXNET (2015i)	Rat	SC
Antifoam 1510-US™	T111 C:1, 100, 101		Silicone emulsion		Dow Corning (2015)	Rat	PO
Avicel CL-611™	T8 —		Microcrystalline cellulose and carboxymethylcellulose sodium, NF, Ph. Eur		TOXNET (2015j)	Dog	PO

Balanced salt saline	T9 —					Rabbit	Intravitreal
Basal salt solution	T10 —					Mouse	Subretinal injection
Benzoic acid	T11 —	65-85-0	Benzoic acid	C ₇ H ₆ O ₂	David et al. (2012), Nair (2001), and TOXNET (2015k)	Rat	PO
Benzyl alcohol	T111 C:8, 9, 13, 14, 31	100-51-6		C ₇ H ₈ O	Nair (2001) and TOXNET (2015l)	Cat, dog, nonhuman primate, rat	IV, PO, topical
Beta-cyclodextrin	T12 —	7585-39-9	Beta-dextrin; betadex	C ₄₂ H ₇₀ O ₃₅	Albers and Muller (1995), Challa et al. (2005), Martin et al. (1998), Rajewski et al. (1995), TOXNET (2015m), Toyoda et al. (1997), and Waner et al. (1995)	Dog, mouse, nonhuman primate, rat	IP, IV, PO
BHA	T111 C:73	25013-16-5	Butylated hydroxyanisole	C ₁₁ H ₁₆ O ₂	TOXNET (2015n)	Minipig	Topical
BHT	T111 C:73, 127, 164, 165	128-37-0	Butylated hydroxytoluene	C ₁₅ H ₂₄ O	Briggs et al. (1989), Lanigan and Yamarik (2002a), Nakagawa et al. (1984), and TOXNET (2015o)	Cat, dog, minipig, mouse, rat	IV, PO, Topical
Bicarbonate buffer	T13 —	71-52-3	Bicarbonate ion	CHO ₃	TOXNET (2015p)	Mouse	PO
Calcium chloride	T14 —	10035-04-8		CaCl ₂ ·H ₂ O	TOXNET (2015q)	Mouse	IV, SC
Canola oil	T15 —	120962-03-0	Canbra oil	Natural product	Evangelista et al. (2004) and TOXNET (2015r)	Dog	PO
Capmul MCM™	T111 C:15	26402-22-2, 26402-26-6	Medium chain mono- and diglycerides	N/A	Susananta et al. (1995)	Nonhuman primate	PO
Capmul MCM NF™	T111 C:16, 255	91744-32-0, 26402-22-2, 26402-26-6	Glyceryl caprylate/caprato	N/A		Dog, rat	PO

Capmul PG 8™	T111 C:242, 243					Dog, rat	PO
Capryol 90™	T16 —	31565-12-5	Propylene glycol monocaprylate (type II) NF; Capmul PG-8™	C ₁₁ H ₂₂ O ₃	Li et al. (2005) and Cho and Gwak (2004)	Dog, rabbit, rat	Dermal, Ocular, PO
Captisol™	T17, T111 C:17, 191	182410-00-0	Beta-cyclodextrin sulfobutyl ether, sodium salt (CDSBE)	C ₄₂ H ₇₀ ηO ₃₆ * (C ₄ H ₈ SO ₃ Na) _n	Albers and Muller (1995), Challa et al. (2005), Martin et al. (1998), and TOXNET (2015s)	Dog, mouse, nonhuman primate, rat,	IV, PO, SC
Carbomer 974P™	T111 C:234, 235, 272	151687-96-6	Carbomer homopolymer type B (allyl pentaerythritol crosslinked)	N/A	TOXNET (2015t)	Minipig, mouse	Topical
Carbopol Ultrez 10™	T111 C:61	195739-91-4		N/A	TOXNET (2015u)	Minipig	Topical
Carboxymethylcellulose	T18, T111 C:20–30, 301	9000-11-7	CMC; Acetic acid; 2,3,4,5,6-pentahydroxyhexanal	N/A	Gupta et al. (1996), Mehlman (2012a), and TOXNET (2015v)	Dog, minipig, mouse, nonhuman primate, rabbit, rat	IA, PO, SC
Carboxymethylcellulose calcium	T19 —	9050_04_8	Calcium CMC; carmellose calcium	N/A	TOXNET (2015w)	Dog	PO
Carboxymethylcellulose sodium	T20, T111 C:269, 270	9004-32-4	Sodium CMC; carmellose sodium	N/A	Bachmann et al. (1978), Bar et al. (1995), Cavender (2012d), and Freeman et al. (2003), TOXNET (2015x)	Mouse, rabbit, rat	PO
Cavisol™	T111 C:185, 186					Dog, rat	PO
Cetostearyl alcohol	T111 C:288	67762-27-0		N/A	TOXNET (2015y)	Minipig	Topical
Cetyl acetate	T111 C:174	629-70-9		C ₁₈ H ₃₆ O ₂	TOXNET (2015z)	Minipig	Topical

Cetyl alcohol	T21, T111 C:163	36653-82-4	Hexadecan-1-ol; 1-hexadecanol	$C_{16}H_{34}O_1$	Bevan (2012c) and TOXNET (2015aa)	Minipig, mouse	IP, Topical
Citrate buffer	T22, T111 C:18, 19, 126, 147, 229	77-92-9	Sodium citrate-citric acid buffer	$C_6H_8O_7$	Schonwald (2004b)	Dog, nonhuman primate, rat	IV, PO, SC
Citric acid buffer	T23, T111 C:13, 38, 58, 95, 302	77-92-9		$C_6H_{807}^*H_{20}$	Szilagy (2012b)	Cat, mouse, nonhuman primate, rat	PO, Topical
Coconut oil	T111 C:288	8001-31-8		Natural product	National Toxicology Program (2001), Shadnia et al. (2005), and TOXNET (2015ab)	Minipig	Topical
Collagen matrix	T24 —	9007-34-5	Collagen human	Natural product	McCarthy et al. (2002) and Clark et al. (1989)	Nonhuman primate, rabbit	Implantation in humerus bone, implantation
Corn oil	T25, T111 C:31–33	8001-30-7	Corn germ oil, glyceridic	Natural product	DeWitt et al. (2005), Dupont et al. (1990), TOXNET (2015ac), and Wu et al. (2004)	Chicken embryo, dog, mouse, nonhuman primate, rabbit, rat	injection into egg, PO
Cottonseed oil	T26 —	8001-29-4		Natural product	TOXNET (2015ad)	Dog	SC
Cyclodextrin	T111 C:34–37	12619-70-4			TOXNET (2015ae)	Rat	PO
Cyclohexane	T27, T111 C:11	110-82-7	Hexahydrobenzene; hexamethylene; hexanaphthene	C_6H_{12}	Gad (2014), Kreckmann et al. (2000), and Malley et al. (2000), TOXNET (2015af)	Rabbit, rat	PO, dermal
Cyclomethicone NF	T111 C:174, 288	69430-24-6		N/A	TOXNET (2015ag)	Minipig	Topical
DAM	T111 C:179–182	57-71-6	Diacetylmonoxime; 2,3-butanedione 2-oxime	$C_4H_7NO_2$	TOXNET (2015ah)	Dog, rat	IV
Dextrose	T28, T111 C:17, 39, 40, 108– 111, 184, 277	50-99-7	Glucose; D-glucose, anhydrous; dextrosol	$C_6H_{12}O_6$	Buard et al. (2003), Robertson et al. (2003), and TOXNET (2015ai)	Cat, dog, minipig, nonhuman primate, rabbit, rat	IV, IV/PO, perivascular, PO, SC

Dichlorvos	T29 —	62-73-7	DDVP; dichlorophos; dichlorphos; divipan; 2,2-dichloroethenyl dimethyl phosphate	$C_4H_7Cl_2O_4P$	TOXNET (2015aj)	Nonhuman primate	IV
Diethylacetamide	T30, T111 C:41	685-91-6	<i>N,N</i> -Diethylacetamide	$C_6H_{13}NO$	Budden et al. (1978), Caujolle et al. (1970), ChemIDPlus (2015), and TOXNET (2015ak)	Cat, chicken, dog, mouse, rabbit, rat	IP, IV
Diethyleneglycol- monoethylether	T31 —	111-90-0	2-(2-Ethoxyethoxy)ethanol; DEGEE; Carbitol	$C_6H_{14}O_3$	Hardin (1983), Hardin et al. (1984), and TOXNET (2015al)	Nonhuman primate	IV
Dimethicone	T111 C:301	9006-65-9		N/A	TOXNET (2015am)	Rabbit	PO
Dimethiconol blend 20	T111 C:	70131-67-8 and 63148-62-9	Dimethicone and dimethiconol		Dow Corning (2015)	Minipig	Topical
Dimethyl acetamide	T32, T111 C:187–188	127-19-5	DMA; <i>N,N</i> -dimethylacetamide; acetdimethylamide	C_4H_9NO	TOXNET (2015an)	Chicken, dog, mouse, rabbit, rat	Dermal, inhalation, IP, IV, PO
Dimethylsulfoxide	T33, T111 C:2–5, 43–57, 91, 94, 157, 158, 193–197	67-68-5	DMSO	C_2H_6OS	Ali (2001), Augustine et al. (2000), Bartsch et al. (1976), Pestel et al. (2006), PharmPK (2002b), RTECS (2015), Ruble et al. (2006), Schonwald (2004a), Sodicoff et al. (1990), TOXNET (2015ao), White et al. (1984), and Wood et al. (1971)	Dog, guinea pig, minipig, mouse, nonhuman primate, rabbit, rat	IP, IV, PO, SC
Di-sodium hydrogen phosphate dihydrate	T111 C:42	10140-65-5	Sodium phosphate, dibasic	$H_3O_4P_2H_2O_2Na$	TOXNET (2015ap)	Nonhuman primate	SC
Docosanol	T111 C:288	661-19-8	1-Docosanol	$C_{22}H_{46}O$	TOXNET (2015aq)	Minipig	Topical

Dulbecco's modified PBSS	T34 —		Dulbecco's modified phosphate buffered saline solution			Rat	IV (tail vein)
Dulbecco's PBSS	T35 —		Dulbecco's phosphate buffered saline solution			Rat	PO
EDTA	T111 C:58-61	60-00-4	Ethylenediaminetetraacetic acid; edetic acid	C ₁₀ H ₁₆ N ₂ O ₈	Cavender (2012e), Heimbach et al. (2000), Lanigan and Yamarik (2002c), and TOXNET (2015ar)	Minipig, nonhuman primate, rat	Dermal, IV, Topical
Ethanol	T36, T111 C:32, 33, 38, 40, 61-73, 98, 99, 108-111, 124, 148-156, 160, 161, 164, 165, 175, 184, 191, 196-205, 211, 212, 223, 224, 239-250, 253, 254, 259, 260, 283, 285, 286, 290	64-17/5	Ethyl alcohol	C ₂ H ₆ O	Bartsch et al. (1976), Bevan (2012a), Church and Witting (1997), Fort et al. (1984), Moorman et al. (2001), Rowe et al. (2012), Ruble et al. (2006), Sivilotti (2004), and TOXNET (2015as)	Dog, guinea pig, minipig, mouse, nonhuman primate, rat	Dermal, IP, IV, PO, SC, topical
Fumaric acid	T111 C:90	110-17-8	2-Butenedioic acid	C ₄ H ₄ O ₄	TOXNET (2015at)	Dog	PO
Gelatin	T37, T111 C:74, 120	9000-70-8			TOXNET (2015au)	Dog, nonhuman primate	PO
Gelatin phosphate buffer	T28 —					Minipig	Topical
Gelucire™	T111 C:75					Minipig	PO
Gelucire 44/14™	T39, T111 C:76, 77	121548-04-7	PEG-32 glyceryl laurate		Cavender (2012b), Dordunoos et al. (1996), Kawakami et al. (2004), Ratsimbazafy et al. (1999), TOXNET (2015av), and Working et al. (1997)	Dog, minipig, mouse rabbit, rat	Dermal, Ocular, PO

Gelucire 50/13™	T40 —	121548-05-8	G-50-13		Fini et al. (2005), Passerini et al. (2002), Ratsimbazafy et al. (1999), Sharma (2006), and TOXNET (2015aw)	Rat	PO
Gluconic acid	T41 —	133-42-6		$C_6H_{12}O_7$	TOXNET (2015ax)	Dog, rat	PO
Glycerol	T42, T111 C:61, 90, 239, 240	56-81-5	Glycerine; Glycerin	$C_3H_8O_3$	Anderson et al. (1950), Bartsch et al. (1976), Cosmetic Ingredient Review (2004a), and TOXNET (2015ay)	Dog, guinea pig, minipig, mouse, nonhuman primate, rabbit, rat	IP, IV, PO, SC, Topical
Glyceryl stearate SE	T111 C:163	11099-07-3		$C_{18}H_{36}O_2 \cdot nC_3H_8O_3$	Cosmetic Ingredient Review (2004a)	Minipig	Topical
Glycofurol	T43 —	31692-85-0		$(C_2H_4O)_n$ mult- $C_3H_7O_2$	Ruble et al. (2006), TOXNET (2015az)	Dog	IV
Glycol dimethacrylate cross polymer	T111 C:127					Rat	Topical
Gum tragacanth	T44 —	9000-65-1		Natural product	Anderson (1989), Bachmann et al. (1978), Hagiwara et al. (1992), and TOXNET (2015ba)	Mouse	PO
Gum xanthane	T45, T111 C:163, 305	11138-66-2	Keltrol	$(C_{35}H_{49}O_{29})_n$	TOXNET (2015bb)	Minipig, rabbit, rat	PO, Topical
Hexylene glycol	T111 C:38	107-41-5		$C_6H_{14}O_2$		Minipig	Topical
Histidine	T111 C:78–80, 287	71-00-1		$C_6H_9N_3O_2$	TOXNET (2015bc)	Dog, rat	IV, SC

Hydrochloric acid	T46 —	7647-01-0	Hydrogen chloride; muriatic acid; chlorohydric acid; chlorane	HCl	TOXNET (2015bd)	Dog, rat	PO
Hydrogenated castor oil	T111 C:288	8001-78-3			TOXNET (2015be)	Minipig	Topical
Hydroxyethylcellulose	T47, T111 C:100, 101	9004-62-0	Natrosol; 2-hydroxyethyl ether cellulose		Pestel et al. (2006), and TOXNET (2015bf)	Rat	PO
Hydroxypropyl beta-cyclodextrin	T48, T111 C:91–99	128446-35-5	2-hydroxypropyl beta-cyclodextrin; HPβCD; hydroxypropyl betadex; cavasol W7 HP™	C ₅₄ H ₁₀₂ O ₃₉	Aerpio Technical Document (2015), Albers and Muller (1995), Challa et al. (2005), Coussement et al. (1990), Gerloczy et al. (1994), Gould and Scott (2005), Martin et al. (1998), Pestel et al. (2006), Ruble et al. (2006), Stella and He (2008), Thackaberry et al. (2009), and TOXNET (2015bg)	Dog, mouse, nonhuman primate, rabbit, rat	Intranasal, IP, IV, PO, SC
Hydroxypropyl cellulose	T49, T111 C:38	9004-64-2	Hypromellose (INN), 2-hydroxypropyl cellulose	N/A	Cavender (2012c), and TOXNET (2015bh)	Minipig, rat	PO, topical
Hydroxypropyl methylcellulose	T50, T111 C:81–87, 90	9004-65-3	Benecel MHPC, hypromellose, HPMC; Methocel E50 Premium LV™	N/A	Feitoza et al. (2003), Geerling et al. (2001), Maki et al. (2000), Mehlman (2012b), Obara et al. (1992), Rosen et al. (1987), Thackaberry et al. (2009), and TOXNET (2015bi)	Dog, minipig, mouse, nonhuman primate, rat	IP, PO
Hydroxypropyl methylcellulose acetate succinate	T111 C:88, 89, 291–294	71138-97-1	Hypromellose acetate succinate; HPMC AS	N/A	TOXNET (2015bj)	Dog, minipig, mouse, rabbit, rat	PO
Hymetellose	T111 C:102	9032-42-2	Methyl hydroxyethylcellulose; Tylose MH50	N/A	TOXNET (2015bk)	Rabbit	PO
Hypotonic PBS	T51 —					Dog, rat	IV
Imwitor 742™	T111 C:103–105		Caprylic/capric glycerides; glyceryl monocaprylocaprate, Type 1		Susananta et al. (1995)	Hamster, nonhuman primate, rat	PO

Isopropyl alcohol	T52, T111 C:14	67-63-0	2-Propanol; isopropanol; sec-propyl alcohol	C ₃ H ₈ O	Allen et al. (1998), Bevan (2012b), Burleigh-Flayer et al. (1998), Church and Witting (1997), Sivilotti (2004), TOXNET (2015bl), and Tyl et al. (1994)	Dog, rabbit	Dermal, topical
Isopropyl myristate	T53, T111 C:163, 234, 235	110-27-0	1-Methylethyl tetradecanoate; Crodamol IPM	C ₁₇ H ₃₄ O ₂	Campbell and Bruce (1981), Komatsu et al. (1979), and TOXNET (2015bm)	Minipig, mouse, rabbit	Dermal, topical
Isotonic saline	T111 C:					Rat	PO
Kolliphor™	T111 C:43, 48		Crephor; polyoxyn castor oil			Nonhuman primate	IV, PO
Kolliphor EL™	T54, T111 C:15, 16, 62, 63, 106, 108–111, 170–173, 209	61791-12-6	Crephor EL™; polyoxyl castor oil; polyoxyl 35 castor oil	N/A	Gelderblom et al. (2001), Gupta et al. (1996), Lorenz et al. (1977), PharmPK (2002a), Ramadan et al. (2001), Stokes et al. (2013), and TOXNET (2015bn)	Dog, mouse, nonhuman primate, rat	IV, PO
Kolliphor ELP™	T55 —	61791-12-6	Crephor EL™; polyoxyl castor oil; polyoxyl 35 castor oil	N/A	TOXNET (2015bn)	Dog	
Kolliphor HS15™ (See also: Solutol HS15)	T111 C:113					Minipig	PO
Kolliphor RH40™	T56, T111 C:107, 207–209, 231	61788-85-0	Crephor RH40™; PEG-40 hydrogenated castor oil; polyoxyl 40 hydrogenated castor oil; macroglycerol hydroxystearate	N/A	Gupta et al. (1996), Stokes et al. (2013), and TOXNET (2015bo)	Dog, rat	IV, PO
Labrafil M1944™	T57, T111 C:112, 114	62563-68-2	Labrafil™	N/A	Beckwith-Hall et al. (2002), and TOXNET (2015bp)	Dog, rabbit, rat	Dermal, PO

Labrasol™	T58, T111 C:113–115, 209	85536-07-8	Polyglycolized glycerides	N/A	Hu et al. (2001), and Hu et al. (2002)	Dog, minipig, rabbit, rat	Dermal, IV, Ocular, PO
Lactated ringer's	T111 C:116	8026-79-7	Sodium chloride, sodium lactate, potassium chloride and calcium chloride; compound sodium lactate injection	$C_3H_5O_3-CaCl_2 \cdot ClK-Na$	TOXNET (2015bq)	Nonhuman primate	IV
Lactic acid	T111 C:296–298	50-21-5	2-Hydroxypropanoic acid	$C_3H_5O_3$	TOXNET (2015br)	Dog, rat	IA, IV
Lactose	T59, T111 C:261–264, 278–281	63-42-3 (anhydrous)	O-β-D-Galactopyranosyl-(1->4)-α-D-glucopyranose	$C_{12}H_{22}O_{11}$ (anhydrous)	Ahmad et al. (2004), Baldrick and Bamford (1997), and TOXNET (2015bs)	Dog, nonhuman primate, rat	Inhalation, IV, SC
Lanolin	T60 —	8006-54-0	Wool wax	N/A	Kligman (1983), and TOXNET (2015bt)	Minipig, rabbit	Dermal, Topical
Lanolin alcohol NF	T111 C:174	8027-33-6	Eucerin	Natural product	TOXNET (2015bu)	Minipig	Topical

TABLE E.2 Acacia

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Nonhuman primate	PO	Efficacy	100 mg kg ⁻¹ day ⁻¹	Well tolerated; Some weight loss, reduction in food intake	Arabic gum; 3% solution in water
Rat	PO	1 month	500 mg kg ⁻¹	Well tolerated	
	PO	90 days	10 mL kg ⁻¹	Well Tolerated	20% solution

TABLE E.3 Acetic Acid

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	PO	1 month	5 mL kg ⁻¹	Well tolerated	15% solution
	PO (gavage)	90 days	5 mL kg ⁻¹	Well tolerated	3% solution
Rat	PO	Acute	5 mL kg ⁻¹	Well tolerated	10% solution
	PO	1 month	10 mL kg ⁻¹	Well tolerated	20% solution
	PO (gavage)	90 days	5 mL kg day ⁻¹	Well tolerated	3% in purified water (92/8)

TABLE E.4 Acetone

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Guinea Pig	Dermal	1 month	1 mL	Well tolerated	
Mouse	Dermal	2 year	0.5 mL	Well tolerated	
	PO	2 weeks	3 mL kg ⁻¹	Higher doses cause acidosis; Transient neurobehavioral effects at this dose.	
Rabbit	Dermal	90 days	1 mL	Defatting of application site	
Rat	Dermal	30 days	5 mL kg ⁻¹	Well tolerated	
	Dermal	90 days	1.5 mL kg ⁻¹ 6h daily, 5 days per week	Well tolerated	Sham treatment group included, vehicle similar to sham treatment; 100% Acetone; Age 60 days; ♂/♀
	PO	2 weeks	5 mL kg ⁻¹	Higher doses cause acidosis; Transient neurobehavioral effects at this dose.	

TABLE E.5 Acetylmethylamide

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Nonhuman primate	PO	One month (ADME)		Well tolerated	In water

TABLE E.6 Alginic Acid

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	IP	1 month	100 mg kg ⁻¹	Well tolerated	

TABLE E.7 Anecortave Acetate

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	SC (bolus)	4 doses	2 mL kg ⁻¹	Well tolerated	

TABLE E.8 Avicel CL-611

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO (gavage)	Single dose	1 mL kg ⁻¹	Soft feces	2.4% in sterile water; Age 5 months; ♂/♀

TABLE E.9 Balanced Salt Saline

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rabbit	Intravitreal	43 days	50 µL per eye q14d	None	Non-GLP; Age 5 months; 2♂/2♀

TABLE E.10 Basal Salt Solution

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	Subretinal injection	SD for 9 months	2.0 µL	None	Non-GLP; Age 5–7 weeks; 44♂

TABLE E.11 Benzoic Acid

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	PO	Acute	100 mg kg ⁻¹	Well tolerated	

TABLE E.12 Beta-cyclodextrin

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IP	1 month	50 mg kg ⁻¹	Well tolerated	
	IV	1 month	100 mg kg ⁻¹	Well tolerated	
	PO	1 month	200 mg kg ⁻¹	Well tolerated	
Mouse	IP	1 month	10 mg kg ⁻¹	Well tolerated	
Nonhuman primate	PO	12 months		Tubular hypertrophy at doses above 100 mg kg ⁻¹ day ⁻¹ at 3 months or longer	
Rat	IV	≥ 3 months		Tubular hypertrophy at doses above 100 mg kg ⁻¹ day ⁻¹ at 3 months or longer	
	PO	12 month	500 g kg ⁻¹	Hepatitis, nephrosis, acute tubular necrosis at dose levels above 20 g kg ⁻¹	

TABLE E.13 Bicarbonate buffer, pH 9.5

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	PO (gavage)	QD for 2 months	10 mL kg ⁻¹	None	Age 8–10 weeks; ♂/♀

TABLE E.14 Calcium chloride

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	IV	1×per week for 4 weeks	1.61 mL kg ⁻¹	None	0.5 M; Age 5 weeks; ♂/♀
	SC	1×per week for 4 weeks	1.61 mL kg ⁻¹	None	0.5 M; Age 5 weeks; ♂/♀

TABLE E.15 Canola oil

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO	1 month	2 mL kg ⁻¹	Well tolerated	

TABLE E.16 Capryol 90™

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO	28 days	1000 mg kg ⁻¹	Nontoxic	
	PO	28 days	2500 mg kg ⁻¹	Nontoxic	
Rabbit	Dermal	Acute	No dilution	Mildly irritant	
	Ocular	Acute	No dilution	Moderately irritant	
Rat	PO	Acute		Nontoxic LD ₅₀ > 5 g kg ⁻¹	
	PO	7 days	300, 1000, 2500 mg kg ⁻¹	Well tolerated	
	PO	28 days	500, 1500, 2500 mg kg ⁻¹	NOAEL of 2500 mg kg ⁻¹	

TABLE E.17 Captisol™

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO (gavage)	2× per week for 28 days	5 mL kg ⁻¹	None	15% in DI water; Age 5–6 months; ♂/♀
	IV (bolus)		1 mL kg ⁻¹	Well tolerated	12% solution in water pH 3–11
	IV (infusion)		2 mL kg ⁻¹	Well tolerated	12% solution in water pH 3–11
Mouse	PO	1 month	500 mg kg ⁻¹	Well tolerated	10% solution
	SC	90 days	1200 mg kg ⁻¹	NOEL	
	SC	6 month	1200 mg kg ⁻¹	NOAEL	
Nonhuman primate	PO	9 months	1 g kg ⁻¹	Well tolerated	10% solution
	SC	3× per week for 12 months	120 mg kg ⁻¹	Well tolerated	
Rat	IV	1 month	4 mL kg ⁻¹	Well tolerated	12% in water
	IV (bolus)		2 mL kg ⁻¹	Well tolerated	12% solution in water pH 3–11
	IV (infusion)		5 mL kg ⁻¹	Well tolerated	12% solution in water pH 3–11
	PO	1 month	10 mL kg ⁻¹	Well tolerated	12% in water
	PO (gavage)	2× per week for 28 days	10 mL kg ⁻¹	None	15% in DI water; Age 7–8 weeks; ♂/♀

TABLE E.18 Carboxymethylcellulose (CMC)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Minipig	PO	14 days	8.0 mL kg ⁻¹ SD	None	0.5% CMC in water; GLP; Age 3 months; 1♂/1♀
	PO	28 days	8.0 mL kg ⁻¹ QD	None	0.5% CMC in water; GLP; Age 3–4 months; 4♂/4♀
Nonhuman primate	PO	30 days		Well tolerated	5% in water
	SC	Acute	10 mL kg ⁻¹	Well tolerated	
Rat	PO		20 mg kg ⁻¹	NOEL	5 % in water
	PO	14 days	8.0 mL kg ⁻¹ SD	None	0.5% CMC in water; GLP; Age 8 weeks; 5♂/5♀
	PO	28 days	8.0 mL kg ⁻¹ QD	None	0.5% CMC in water; GLP; Age 8 weeks; 10♂/10♀
	PO (gavage)	93 weeks	10 mL kg ⁻¹ QD	None	1% CMC (medium viscosity) in DI water; Age 6 weeks; ♂/♀

TABLE E.19 Carboxymethylcellulose calcium (Calcium CMC)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO	90 days	1 mL kg ⁻¹	Well tolerated	1% solution

TABLE E.20 Carboxymethylcellulose sodium (Sodium CMC)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rabbit	PO	1 month	0.5 mL kg ⁻¹	Well tolerated	1% solution

TABLE E.21 Cetyl alcohol

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	IP	1 month	100 mg kg ⁻¹	Well tolerated	

TABLE E.22 Citrate buffer

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV infusion	8 doses	30 mL kg ⁻¹ day ⁻¹	Well tolerated	0.1 M, Aqueous
	SC	30 days	10 mL kg ⁻¹ QD	Well tolerated	
Rat	IV	4 weeks	nd	Hypoactivity, pain at injection site	100 mM at pH 5
	PO	2 weeks	10 mL kg ⁻¹	Well tolerated	50 mM
	PO	2 weeks	15 mL kg ⁻¹	Well tolerated	50 mM

TABLE E.23 Citric Acid Buffer

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	PO (gavage)	182 days	2 mL kg ⁻¹ QD	None	0.015 M at pH 4.50; Age 6–7 weeks; ♂/♀
Nonhuman primate	PO (gavage)	39 weeks	7.5 mL kg ⁻¹ QD	None	10 mM; Age 3–3.5 years; ♂/♀
Rat	PO	2 weeks	10 mL kg ⁻¹ QD	Well tolerated	50 mM
	PO	2 weeks	15 mL kg ⁻¹ QD	Well tolerated	50 mM

TABLE E.24 Collagen Matrix

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Nonhuman primate	Implantation in humerus bone	6 months	10 mL kg ⁻¹ day ⁻¹	Well tolerated	Bovine type I and hydroxyapatite
Rabbit	Implantation	6 months	Single application, 5 mL kg ⁻¹	Well tolerated	

TABLE E.25 Corn Oil

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Chicken Embryo	Injection into egg	Single dose	0.1 µL g ⁻¹	Less mortality than 1.0 µL g ⁻¹ egg	
	Injection into egg	Single dose	1.0 µL g ⁻¹	Increased mortality, decreased activity during righting reflex, running time, visual discrimination, and olfactory aversion test.	
Dog	PO	1 month	3.0 mL kg ⁻¹	Well tolerated	
Mouse	PO	1 month	2.5 mL kg ⁻¹	Well tolerated	
Nonhuman primate	PO	1 month	1 mL kg ⁻¹	Well tolerated	
Rabbit	PO	1 month	1 mL kg ⁻¹	Well tolerated	
Rat	PO (gavage)	Single dose	10 mL kg ⁻¹	Well tolerated	
	PO (gavage)	20 doses	5 mL kg ⁻¹	Well tolerated	
	PO (gavage)	90 days	5 mL kg ⁻¹ QD	None	Age 6 weeks; ♂/♀

TABLE E.26 Cottonseed Oil

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	SC	Single dose	1 mL	Well tolerated; No evidence of irritation macroscopically or histologically.	100% solution

TABLE E.27 Cyclohexane

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rabbit	PO	30 days	0.5 mL kg ⁻¹ day ⁻¹	Well tolerated	
Rat	Dermal	30 days	1 mL kg ⁻¹ day ⁻¹	Well tolerated	
	PO (gavage)	4 weeks	5 mL kg ⁻¹ day ⁻¹	Intermittent convulsive after dosing, piloerection round back, and emaciated appearance	

TABLE E.28 Dextrose

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Cat	Oral mucosa	24 hours	0.6 mL SD	None	5%; Non-GLP; Age >6 months; 3♂/3♀
Dog	IV	Single dose	150 mL h ⁻¹	Well tolerated	5%, USP
	IV/ PO	ADME	2/10 mL kg ⁻¹ day ⁻¹	Well tolerated	5% solution
Nonhuman primate	PO (gavage)	13 weeks	0.78–9.3 mL kg ⁻¹ day ⁻¹	Well tolerated	10% solution (w/w)
	PO (gavage)	ADME	5 mL kg ⁻¹ day ⁻¹	Well tolerated	5% solution
	PO (gavage)	Card. Vas.	5 mL kg ⁻¹ day ⁻¹	Well tolerated	5% solution
Rabbit	IV (slow bolus)	12 doses		Well tolerated	5%, USP
Rat	IV	Single dose	1.4 mL per animal	Well tolerated	5%, USP
	IV	7 days	5 mL kg ⁻¹ SD	None	5%; Non-GLP; Age 7–10 weeks; 2♂/2♀
	PO (gavage)	26 weeks	0.71–8.6 mL kg ⁻¹ day ⁻¹	Well tolerated	10% solution (w/w)
	PO (gavage)	Prelim	5 mL kg ⁻¹ day ⁻¹	Well tolerated	5% solution
	SC	2 weeks	0.75 mL kg ⁻¹ day ⁻¹	Well tolerated	5% solution

TABLE E.29 Dichlorvos

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Nonhuman primate	IV Infusion	2 weeks	2 mL kg ⁻¹ 10 min 3×/week	Well tolerated	10 mg mL ⁻¹ dichlorvos; Age 3–6.5 years; ♀

TABLE E.30 Diethylacetamide

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Cat	IV	Single dose	1 g kg ⁻¹ (1000 mg kg ⁻¹)	LD _{LO}	Behavioral: altered sleep time (including change in righting reflex)
Chicken	IV	Single dose	3900 mg kg ⁻¹	LD _{LO}	
Dog	IV	Single dose	1 gm kg ⁻¹ (1000 mg kg ⁻¹)	LD _{LO}	Behavioral: altered sleep time (including change in righting reflex)
Mouse	IP	Single dose	1600 mg kg ⁻¹	LD ₅₀	Sense organs and special senses: mydriasis (pupillary dilation)
	IV	Range finding	MTD: 1.4 g kg ⁻¹ ; NOEL: 468 mg kg ⁻¹		Published LD ₅₀ = 2.3–3.2 g kg ⁻¹
Rabbit	IV	Single dose	1920 mg kg ⁻¹	LD _{LO}	
Rat	IP	Single dose	1840 mg kg ⁻¹	LD ₅₀	
	IV	Single dose	1 g kg ⁻¹ (1000 mg kg ⁻¹)	LD ₅₀	Behavioral: altered sleep time (including change in righting reflex)

TABLE E.31 Diethyleneglycol-monoethylether (DEGEE)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Nonhuman primate	IV	1 month (ADME)	.355 mL kg ⁻¹ Single injection	Well tolerated	Into saphenous vein

TABLE E.32 Dimethylacetamide (DMA)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Chicken	IV	Acute	12000 mg kg ⁻¹	LD _{Lo}	Lowest published lethal dose
Dog	Dermal	6 weeks	2690.476 mg kg ⁻¹ QD	TD _{Lo} ; Fatty liver degeneration; chronic death (nutritional and gross metabolic); reproductive	
Mouse	IP	Acute	2800 mg kg ⁻¹	LD ₅₀	
	IV	Acute	3020 mg kg ⁻¹	LD ₅₀	
	IV (into tail vein)	Acute	469 mg kg ⁻¹ (dose vol 5 mL kg ⁻¹)	NOEL	10% solution
	IV (into tail vein)	Acute	1405 mg kg ⁻¹ (dose vol 5 mL kg ⁻¹)	MTD	30% solution; Mild-to-moderate hypoactivity for up to 6 minutes is typical
	PO	Acute	4620 mg kg ⁻¹	LD ₅₀	Intragastric feeding or introduction with drinking water
Rabbit	Dermal	Acute	2240 mg kg ⁻¹	LD ₅₀	Application directly onto the skin, either intact or abraded
	IV	Acute	8340 mg kg ⁻¹	LD _{Lo}	Lowest published lethal dose
	PO	13 days	3900 mg kg ⁻¹	TD _{Lo} ; Specific developmental abnormalities (eye, ear, craniofacial including nose and tongue, musculoskeletal system); postimplantation mortality; fetotoxicity (except death, e.g., stunted fetus)	Intragastric feeding or introduction with drinking water; 6–18 days of pregnancy

TABLE E.32 (Continued)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	Inhalation	6 h day ⁻¹ for 10 days	281 ppm	TD _{Lo}	Inhalation in chamber by cannulation or through mask; 6–15 days of pregnancy
	IP		2 mg kg ⁻¹	TD _{Lo} ; postimplantation mortality; fetotoxicity (except death, e.g., stunted fetus)	1 day pregnant
	IP	Acute	2750 mg kg ⁻¹	LD ₅₀	
	IV	Acute	2640 mg kg ⁻¹	LD ₅₀	
	PO	14 days	5600 mg kg ⁻¹	TD _{Lo} ; Effects on fertility, postimplantation mortality; fetal death; specific developmental abnormalities (craniofacial, including nose and tongue, musculoskeletal system, cardiovascular system, homeostasis); fetotoxicity (except death, e.g., stunted fetus)	Intragastric feeding or introduction with drinking water; 6–19 days of pregnancy
	PO	14 days	2240 mg kg ⁻¹	TD _{Lo}	Intragastric feeding or introduction with drinking water; 6–19 days of pregnancy
	PO	Acute	4300 mg kg ⁻¹	LD ₅₀	Intragastric feeding or introduction with drinking water
	PO	10 days	1500 mg kg ⁻¹ QD	TD _{Lo} ; findings in digestive system and liver; chronic	Intragastric feeding or introduction with drinking water; Lowest published toxic dose
	PO	26 weeks	2 mg kg ⁻¹ QD	TD _{Lo} ; enzyme inhibition, induction, or change in blood or tissue levels; liver	Intragastric feeding or introduction with drinking water; Lowest published toxic dose
	PO	90 days	50 mg kg ⁻¹ QD	TD _{Lo} ; changes in erythrocyte (RBC) and leucocyte (WBC) counts	Intragastric feeding or introduction with drinking water; Lowest published toxic dose

TABLE E.33 Dimethylsulfoxide (DMSO)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV	Single dose @ 0.2 mL min ⁻¹ for 18.5 min	0.43–0.46 mL kg ⁻¹	During dose administration excessive salivation and labored respiration were noted. At 1 and 4 h postdose	MUST use IV catheter; 100% solution
	IV		2 mg kg ⁻¹		
	IV		2.5 g kg ⁻¹	LD ₅₀	MUST use IV catheter; 100% solution
	IV	Intermittent for 4 weeks	57,600 mg kg ⁻¹	LD ₅₀ ; Lowest published toxic dose, hematuria, normocytic anemia, death	MUST use IV catheter
	IV		2,500 mg kg ⁻¹	LD ₅₀ ; Cardiac changes, hematuria	
		Single dose	1 mL kg ⁻¹	Well tolerated	10% solution
	IV		0.1 mL kg ⁻¹		MUST use IV catheter; 100% solution
	IV	1 month	1.25 mL/ (0.112)x(BW)	Well tolerated	
Guinea pig	IV	1 month	0.1 mL kg ⁻¹	Well tolerated	
	IP	Acute	6.5 g kg ⁻¹	LD ₅₀	100% solution
Mouse	IP	1 month	2.5 g kg ⁻¹	LD ₅₀	100% solution
	IP		3.82–10.73 g kg ⁻¹	LD ₅₀	100% solution
	IP		8.2 g kg ⁻¹	LD ₅₀	100% solution
	IP		20.06 g kg ⁻¹	LD ₅₀	100% solution
	IP	1 month	100 mg kg ⁻¹	Well tolerated	
	IP	3 days	10 mL kg ⁻¹	Well tolerated	15% solution
	IV (into tail vein)	Acute	1650 mg kg ⁻¹ (Dose vol 5 mL kg ⁻¹)	NOEL	30% solution
	IV (into tail vein)	Acute	2200 mg kg ⁻¹ (Dose vol 5 mL kg ⁻¹)	MTD; Rapid breathing, ataxia, and muscle contractions, with full recovery by 1 min is typical	40% solution
	IV	Range finding	MTD: 2.2 g kg ⁻¹ ; NOEL: 1.6 g kg ⁻¹		Published LD ₅₀ = 3.8–7.6 g kg ⁻¹
	IV		3100 mg kg ⁻¹	LD ₅₀ ; Eye hemorrhage, conjunctiva irritation	
	IV		240 gm kg ⁻¹	Lowest published toxic dose. Postimplantation mortality	Age day 1–20 presumed pregnant
	PO (gavage)		15.0–22 g kg ⁻¹	LD ₅₀	100% solution
	PO (gavage)		7.9 g kg ⁻¹	LD ₅₀	100% solution
PO		5 mL kg ⁻¹			
SC		13.9–20.5 g kg ⁻¹	LD ₅₀	100% solution	
Nonhuman primate	PO (gavage)	Efficacy	3 mL kg ⁻¹ day ⁻¹	Well tolerated	
Rabbit	SC	1 month	1 mL kg ⁻¹	Erythema, inflammation	

TABLE E.33 (Continued)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	IV		4–5 mg kg ⁻¹		
	IV		5.25–5.36 g kg ⁻¹	LD ₅₀	100% solution
	IV		5.3 g kg ⁻¹	LD ₅₀	100% solution
	IV	Single dose	200 mg kg ⁻¹	In serum, slightly and transiently changed metabolic parameters including glucose, lactate, triglycerides, free fatty acids, or creatinine as well as electrolytes (Na, Cl, Mg) and osmolality, increased ALT, impeded clinical chemistry measurements of various parameters at 4 h post dose, kidney function – induced loss of protein and albumin	2% solution
	IV		5360 mg kg ⁻¹	LD ₅₀ ; Tremors, muscle weakness, dyspnea	
	IV	1 month	200 mg kg ⁻¹	Well tolerated	
	SC		12 g kg ⁻¹	LD ₅₀	100% solution
	PO (gavage)	7 days	5 mL kg ⁻¹ day ⁻¹	Well tolerated	
	PO (gavage)	4 weeks	5 mL kg ⁻¹ day ⁻¹	Well tolerated	
	PO (gavage)		16.0–28.3 g kg ⁻¹	LD ₅₀	100% solution
	PO (gavage)		14.5 g kg ⁻¹	LD ₅₀	100% solution
	PO (gavage)	Single dose	200 mg kg ⁻¹	Did not affect stomach emptying, did not reduce intestinal transit time	2% solution
	PO (gavage)	Single dose	1000 mg kg ⁻¹	Did not affect stomach emptying, did not reduce intestinal transit time	10% solution
	IP	28 doses	5 mL kg ⁻¹	Well tolerated	15% solution
	IP		6.5–13.621 g kg ⁻¹	LD ₅₀	100% solution
	IP		8.2 g kg ⁻¹	LD ₅₀	100% solution

TABLE E.34 Dulbecco’s Modified Phosphate Buffered Saline (PBS)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	IV (into tail vein)	1 month	1 mL kg ⁻¹ day ⁻¹	Well tolerated	

TABLE E.35 Dulbecco’s Phosphate Buffered Saline (PBS)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	PO (gavage)	1 month	0.1, 0.8, and 1.2 mg kg ⁻¹ day ⁻¹	Well tolerated	

TABLE E.36 Ethanol (EtOH)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV		5 mL.kg ⁻¹ at a rate of 0.3 mL.kg ⁻¹	Hemolysis <i>in vitro</i> dog blood	30% solution
	IV		5 mL.kg ⁻¹ at a rate of 0.3 mL.kg ⁻¹	Hemolysis <i>in vitro</i> dog blood	40% solution
	IV	Single dose	1 mL.kg ⁻¹	Well tolerated	10% solution
	IV	Single dose	1 mL.kg ⁻¹	CNS depression, ataxia	30% solution
	IV	5 days	1 mL.k ⁻¹ at 2 mL.min ⁻¹	Excessive salivation	30% solution; MUST use winged infusion set
	IV	At 3, 7, 14, and 24 h after ingestion of ethylene glycol	1584 mg.kg ⁻¹	Remained recumbent or severely ataxic for 36, depressed for 72	20% solution
	IV	Every 4 h for 5 treatments then every 6 h for 4 treatments	5.5 mL.kg ⁻¹		20% solution
	PO	1 month	5 mL.kg ⁻¹	Well tolerated	7.5% solution
	PO	6 months	400 mL.kg ⁻¹	Hepatotoxicity, myopathy; CNS changes	
	PO	90 days	5 mL.kg ⁻¹	Well tolerated	5% solution
Minipig	Dermal	ADME	nd (5 mg.cm ⁻²)	Well tolerated	60/40: Purified water/ethyl alcohol absolute: v/v
Mouse	Dermal	13 weeks	100 µL per animal per day	Well tolerated	70% (62% m/m)
	Dermal	7 days	0.5 mL (fixed vol) QD	Well tolerated	80% solution; Age 6 weeks; ♂/♀
	IP	Acute	5 mL.kg ⁻¹	Well tolerated	5% solution
	IV	Range finding	MTD: 986 mg.kg ⁻¹ ; NOEL: 197 mg.kg ⁻¹		Published LD ₅₀ = 1.6–4.3 g.kg ⁻¹
	IV (into tail vein)	Acute	197 mg.kg ⁻¹ (dose vol 5 mL.kg ⁻¹)	NOEL	5% solution
	IV (into tail vein)	Acute	986 mg.kg ⁻¹ (dose vol 5 mL.kg ⁻¹)	MTD: Ventral recumbency and “swimming” behavior immediately postdose, ataxia for up to 6 min is typical	25% solution
	PO	1 month	2.5 mL.kg ⁻¹	Well tolerated	5% solution
	PO	6 month	2500 gm.kg ⁻¹	Well tolerated	

Nonhuman primate	PO	9 months	250 gm kg ⁻¹	Behavioral changes	
Rat	Dermal	ADME	nd (5 mg cm ⁻²)	Well tolerated	60/40: Purified water/ethyl alcohol absolute: v/v
	Dermal	91 days	0.5 mL (fixed vol) QD	Well tolerated	80% solution; Age 6 weeks; ♂/♀
	IP	Acute	3.75 g kg ⁻¹	LD ₅₀	
	IV	Acute	1.44 g kg ⁻¹	LD ₅₀	
	IV	Acute	5 mL kg ⁻¹ at a rate of 0.3 mL kg ⁻¹	Hematuria	30% solution
	IV	9 days	5 mL kg ⁻¹ at 2 mL min ⁻¹	Ataxia, respiratory depression, and death is dosed faster than 2 mL min ⁻¹	30% solution
	IV	12 months	250 g kg ⁻¹	Nephrosis, ATN, bladder changes, weight loss	
	PO	Acute	7.06 g kg ⁻¹	LD ₅₀	
	PO (gavage)	7 days	0.8, 2, and 5 mL kg ⁻¹ day ⁻¹	Well tolerated	70% (62% m/m)
	PO	7 days	10 mL kg ⁻¹	Well tolerated	10% solution
	PO	Acute	5 mL kg ⁻¹	Depression	
	PO (gavage)	4 weeks	2 mL kg ⁻¹ QD	Hypokinesia, dyspnea regurgitation, distended lungs/ileum, and swollen abdomen	70% (62% m/m)
	PO	28 doses	175 g kg ⁻¹	Depression, decreased RBC	
	PO	90 day	8 mL kg ⁻¹	Well tolerated	10% solution
	PO	12 month	1000 mg kg ⁻¹	Fatty liver

Rabbit	IV	Acute	10 mg kg ⁻¹	Well tolerated	
Rat	PO	Acute	1000 mg kg ⁻¹	Well tolerated	
	PO	1 month	15 g kg ⁻¹	Reduced adrenal weights	
	PO	1 month	1000 mg kg ⁻¹	Well tolerated	
	SC	Acute	10 mg kg ⁻¹	Well tolerated	

TABLE E.43 Glycofurool

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV	Single dose	1 mL kg ⁻¹	Well tolerated	50% solution

TABLE E.44 Gum Tragacanth

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	PO (gavage)	2 weeks	10 mL kg ⁻¹ QD	Well tolerated	In distilled water, 0.5%

TABLE E.45 Gum Xanthane

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rabbit	PO (gavage)	Tolerance	3 mL kg ⁻¹ day ⁻¹	Well tolerated	0.4% aqueous solution
	PO (gavage)	Segmt. II	3 mL kg ⁻¹ day ⁻¹	Well tolerated	0.4% aqueous solution

TABLE E.46 Hydrochloric Acid (HCl)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO (gavage)	4 weeks	4 mL kg ⁻¹ QD	None	0.1 N; Age 5–6 Months; ♂/♀
	PO (gavage)	Daily	10 mL kg ⁻¹	None	0.1%–10% in Water; Beagles Age 5 months; ♂/♀
Rat	PO (gavage)	26 weeks	10 mL kg ⁻¹ QD	None	0.05 M HCl; Age 6 weeks; ♂/♀
	PO (gavage)	Daily	10 mL kg ⁻¹	None	0.1%–10% in Water; Age 6–8 weeks; ♂/♀

TABLE E.47 Hydroxyethyl Cellulose

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rat	PO	Single dose	20 mg kg ⁻¹	Intestinal transit was slightly enhanced, not dose-dependent	0.5%
	PO	Single dose	100 mg kg ⁻¹	Intestinal transit was slightly enhanced, not dose-dependent	1%
	PO	28 days	50 mg kg ⁻¹	Easiest and most tolerable formulation for PO administration	

TABLE E.48 Hydroxypropyl - β -Cyclodextrin (HP β CD). FDA Has Informed Sponsors That This Excipient Is No Longer Permitted For Use in Subcutaneous Clinical Formulations Due to Perceived Risk of Carcinogenicity²⁵⁴ and Has Advised That It Not Be So Used in Repeat Dose Nonclinical Safety Studies

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV	1 dose	1 mL.kg ⁻¹	Well tolerated	40% solution
	IV (slow bolus)	1 dose	1.2 mL.kg ⁻¹	Well tolerated	6% solution
	IV (2h infusion)	1 month	10 mL.kg ⁻¹	Well tolerated	40% solution
	Intranasal	14 days	1 mL per nostril TID 2h apart	Well tolerated	45%; Beagle dogs (Marshall) age ~ 6 months; ♂/♀
	PO (gavage)	1 dose	10 mL.kg ⁻¹	Well tolerated	6% solution
	PO (gavage)	90 days	Dose vol 5 mL.kg ⁻¹ ; Daily dose 500, 1000 mg.kg ⁻¹	Loose/soft stools in high-dose group	Dose concentration 100, 200 mg mL ⁻¹ (respectively)
	PO (gelatin capsules)	28 doses		Emesis, fecal changes	6% solution
	SC	91 days	0.86 mL.kg ⁻¹ QD	None	10% solution in sterile water; Age 5.5–6 months; ♂/♀
Mouse	IV	Acute	5000 mg.kg ⁻¹	LD	Administration directly into the vein by hypodermic needle; >5 gm.kg ⁻¹
	PO (gavage)	90 days	Dose vol 10 mL.kg ⁻¹ ; Daily dose 500, 1000 mg.kg ⁻¹	Produced elevated transaminase (aspartate and alanine aminotransferase) levels Use with caution	Dose concentrations 50, 100 mg mL ⁻¹ (respectively)
	PO (gavage)	104 weeks	500 mg.kg ⁻¹ day ⁻¹	Well tolerated	
Nonhuman primate	PO (gavage)	13 doses	5 mL.kg ⁻¹	None	11% solution
	PO (gavage)	90 days	Dose vol 5 mL.kg ⁻¹ ; Daily dose 500, 1000 mg.kg ⁻¹	Loose/soft stools in high-dose group	Dose concentration 100, 200 mg mL ⁻¹ (respectively)
	IP	Acute	10000 mg.kg ⁻¹	Well tolerated, LD> 10000 mg.kg ⁻¹	
Rabbit	PO (gavage)	12 doses	2 mL.kg ⁻¹	Well tolerated	11% solution

Rat	Intranasal	14 days	50 mL per nostril TID 2 h apart	Well tolerated	45%; Sprague Dawley (Harlan) age ~8–10 weeks at initiation; ♂/♀ ; Histopathology limited to purulent exudates (minimal to mild) involving the nasal turbinates
	IP injection	Single dose	1000 mg kg ⁻¹	Increased glucose levels at 4h., minor transient changes for triglycerides and BUN, no functional changes were observed, only slight enhancement of ALT and AST.	10% solution
	IV	Single dose	1 mL kg ⁻¹	Well tolerated	20% solution
	IV	Single dose	10 mL kg ⁻¹	Death occurred within a few minute of receiving a bolus dose of the vehicle. The rate of administration was slowed to ~2min, which was tolerated and clinical observations limited to red urine	45%; Sprague Dawley (Harlan); Age ~8 weeks of age; ♂/♀
	IV (slow bolus)	10 doses	4 mL kg ⁻¹	Well tolerated	12.5% solution
	IV (1 h infusion)	1 month	10 mL kg ⁻¹	Well tolerated	40% solution
	IV (slow bolus)		2 mL kg ⁻¹	Well tolerated	12.5% solution
	PO	Acute	5000 mg kg ⁻¹	LD ₅₀ > 5000 mg kg ⁻¹	
	PO	Single dose	up to 2000 mg kg ⁻¹	No effect on gastric emptying, modestly inhibited intestinal transit.	20% solution
	PO (gavage)	Single dose	10 mL kg ⁻¹	Well tolerated	6% solution
	PO (gavage)	10 doses	10 mL kg ⁻¹	Well tolerated	11% solution
	PO (gavage)	4 weeks	10 mL kg ⁻¹ QD	None	20%; Age 6 weeks; ♂/♀
	PO (gavage)	90 days	Dose vol 5 mL kg ⁻¹ ; Daily dose 500, 1000 mg kg ⁻¹	Produced elevated transaminase (aspartate and alanine aminotransferase) levels; use with caution	Dose concentrations 100, 200 mg mL ⁻¹ (respectively)
	PO (gavage)	2 years	500 mg kg ⁻¹	No effects	
	SC	28 days	QD	Erosion/ulceration and/or necrosis generally observed. At the end of 28-day recovery period, fibrosis and subacute/chronic inflammation at the injection sites persisted but were resolving; injection site necrosis not observed	10% HPβCD
	SC	91 days	QD	At end of 28-day recovery period, fibrosis and subacute/chronic inflammation at the injection sites persisted but were resolving; injection site necrosis not observed	10% HPβCD
	SC	91 days	1.14 mL kg ⁻¹ QD	None	10% solution in sterile water; Age 7 weeks; ♂/♀

TABLE E.70 PEG 200

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Nonhuman primate	PO (gavage)	14 days	5 mL kg ⁻¹ QD	Soft/watery feces (nonadverse)	Age 2–3.5 years; ♂/♀
Rabbit	IV	Acute	>10 g kg ⁻¹ bw	LD ₅₀	
Rat	IP		8–9 g kg ⁻¹ bw	LD ₅₀	
	PO (dietary)	90 days	20, 40, 80, 160, 240 g kg ⁻¹ diet QD (1.5, 3, 6, 12, 18 g kg ⁻¹ bw QD)	NOAEL = 6 g kg ⁻¹ bw QD	At 12, 18 g kg ⁻¹ bw liver and liver/kidney weights increased (respectively); 5♂/5♀
	PO (drinking water)	90 days	4.8 g kg ⁻¹ bw QD	NOAEL	5♂
	PO (drinking water)	90 days	10.9 g kg ⁻¹ bw QD	66% mortality; Decreased body weight gain	5♂

TABLE E.71 PEG 300

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO (gavage)	28 days	1 mL kg ⁻¹ BID	None	Age 5.5–6 months; ♂/♀
Guinea pig	IV	1 month	1 mL kg ⁻¹	Well tolerated	
Mouse	PO (gavage)	ADME	10 mL kg ⁻¹ day ⁻¹	Well tolerated	
Rabbit	PO	1 month	500 gm kg ⁻¹	Well tolerated	
	IV	Acute	>10 g kg ⁻¹ bw	LD ₅₀	
Rat	IP	Acute	16–18 g kg ⁻¹ bw	LD ₅₀	
	IP	Acute	17 g kg ⁻¹ bw	LD ₅₀	
	IV	Acute	8 g kg ⁻¹ bw	LD ₅₀	
	IV	Acute	7.1 g kg ⁻¹ bw	LD ₅₀	
	PO (dietary)	90 days	20, 40, 80, 160, 240 g kg ⁻¹ diet QD (1.5, 3, 6, 12, 18 g kg ⁻¹ bw QD)	NOAEL = 3 g kg ⁻¹ bw QD	At 6, 12, 18 g kg ⁻¹ bw decreased body weight gain, liver, and kidney weight increase, and both decreased body weight gain and increased liver weight (respectively); 5♂/5♀
	PO (drinking water)	90 days	5.4 g kg ⁻¹ bw QD	NOAEL	5♂
	PO (drinking water)	90 days	20.5 g kg ⁻¹ bw QD	66% mortality; Decreased body weight gain; Liver and kidney changes	5♂
	PO (gavage)	2 weeks	7.5 mL kg ⁻¹ once, or 2.5 mL kg ⁻¹ TID	Well tolerated	50%
	PO (gavage)	4 weeks	5 mL kg ⁻¹ day ⁻¹	Well tolerated	50%
PO (gavage)	28 days	2 mL kg ⁻¹ BID	None	Age 8 weeks; ♂/♀	

TABLE E.72 PEG 400

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV	Single dose	Total Dose <2 g kg ⁻¹		100%
	IV	28 days	2–3 g kg ⁻¹	Decreased blood pressure and reversible depression in respiration. These symptoms increased at doses of 3 g kg ⁻¹ or greater and eventually resulted in complete respiratory arrest. At necropsy dogs were found to have pulmonary edema and small infarcts in the lungs, but no changes in the heart or kidneys.	100%
	IV				NS solution; Hemolysis occurs > 33% (v/v) concentration
	IV	Single dose	1 mL kg ⁻¹	Well tolerated	30%
	IV	30 days, +21 day recovery	8.45 g kg ⁻¹ QD	Dry mouth and dry nasal mucous membrane; histopathological change in kidney; reversible cloudy swelling of kidney cells and increased glomerular volume	NS solution 25% (v/v)
	IV	30 days, +21 day recovery	5 mL kg ⁻¹ day ⁻¹	Dry mouth and dry nasal mucous membrane	NS solution 25% (v/v)
	IV	30 days, +21 day recovery	4.23 g kg ⁻¹ QD	Increased values of electrolytes (Na+ and Cl-)	NS solution 25% (v/v)
	IV (bolus)		1 mL kg ⁻¹	Well tolerated	60% solution in water pH 3–11
	IV (infusion)		2 mL kg ⁻¹	Well tolerated	60% solution in water pH 3–11
	IV (infusion)		0.5 mL kg ⁻¹	Well tolerated	80% solution in water pH 3–11
	PO (dietary)	1 year	20 g kg ⁻¹ diet QD (0.5 g kg ⁻¹ bw QD)	NOAEL = 0.5 g kg ⁻¹ bw QD	3♂/1♀
	PO (gavage)	28 days	0.25 mL kg ⁻¹ QD	Soft/watery feces (nonadverse)	Age 5–5.5 months; ♂/♀
	Guinea pig	PO	1 month	1000 mg kg ⁻¹	Well tolerated
Minipig	Dermal	2 weeks	2.5 mL kg ⁻¹	Well tolerated	
	Topical	90 days	2 mL kg ⁻¹ QD	Mild dose-site inflammation after >30 days of administration	GLP; Age 4–6 months; 6♂/6♀

Mouse	IP	3 days	10 mL.kg ⁻¹	Well tolerated	35%
	IP	1 month	2.5 mL.kg ⁻¹	Well tolerated	40% solution
	IP	28 doses	500 mg.kg ⁻¹	Well tolerated	
	IP		14.5 g.kg ⁻¹ bw	LD ₅₀	
	IP		9.2 g.kg ⁻¹ bw	LD ₅₀	
	IV		8.6 g.kg ⁻¹ bw	LD ₅₀	
	IV	Range finding	MTD: 4.5 g.kg ⁻¹ ; NOEL: 1.7 g.kg ⁻¹		Published LD ₅₀ = 8.6–9.7 g.kg ⁻¹
	IV (Into tail vein)	Acute	1692 mg.kg ⁻¹ (dose vol 5 mL.kg ⁻¹)	NOEL	30% solution
	IV (Into tail vein)	Acute	4512 mg.kg ⁻¹ (dose vol 5 mL.kg ⁻¹)	MTD; tremors, ventral recumbency and splayed limbs shortly after dosing, hypoactivity for up to 12 min is typical	80% solution
	PO (gavage)	4 weeks	10 mL.kg ⁻¹ day ⁻¹	Well tolerated	
PO	13 weeks	5 mL.kg ⁻¹ BID	Well tolerated	100%; CD-1 (Harlan); Age ~7 weeks at study initiation; ♂/♀	
Nonhuman primate	PO (gavage)	28 days	1 mL.kg ⁻¹ QD	Soft/watery feces (nonadverse)	In DI water; Age 1–2 years; ♂/♀
	PO (gavage)	28 days	5 mL.kg ⁻¹ QD	Soft/watery feces (nonadverse)	In DI water; Age 1–2 years; ♂/♀
Rabbit	IV		>10 g.kg ⁻¹ bw	LD ₅₀	
Rat	Dermal	13 weeks	2.5 mL.kg ⁻¹ day ⁻¹	Well tolerated	
	Dermal	104 weeks	2.5 mL.kg ⁻¹ day ⁻¹	Well tolerated	
	IP		14.7 g.kg ⁻¹ bw	LD ₅₀	
	IP		12.3 g.kg ⁻¹ bw	LD ₅₀	
	IP	1 month	5 mL.kg ⁻¹	Well tolerated	35%
	IV		4.7 g.kg ⁻¹ bw	LD ₅₀	
	IV	Single dose	0.5 mL.kg ⁻¹	Well tolerated	
	IV (bolus)		2 mL.kg ⁻¹	Well tolerated	60% solution in water pH 3–11
	IV (infusion)		5 mL.kg ⁻¹	Well tolerated	60% solution in water pH 3–11

PO (gavage)		2 mL.kg ⁻¹	Well tolerated	
PO (gavage)	Single dose	5 mL.kg ⁻¹	Well tolerated	
PO (gavage)	10 doses	1.67 mg.kg ⁻¹	Well tolerated	
PO	1 month	5 mL.kg ⁻¹	Well tolerated	
PO (gavage)	4 weeks	5 mL.kg ⁻¹ day ⁻¹	Well tolerated	
PO (gavage)	28 days	3 mL.kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
PO (gavage)	28 days	10 mL.kg ⁻¹ QD	None	In DI water; Age 6 weeks; ♂/♀
PO	13 weeks	10 mL.kg ⁻¹ day ⁻¹	Loose feces and decreased food consumption; increased water consumption; increases in relative kidney weights; reversible renal toxicity	
PO	26 weeks	5 mL.kg ⁻¹ BID	Well tolerated	100%; Sprague-Dawley (Harlan) age ~8 weeks at initiation; ♂/♀
PO (dietary)	90 days	20, 40, 80, 160, 240 g.kg ⁻¹ diet QD (1.5, 3, 6, 12, 18 g.kg ⁻¹ bw QD)	NOAEL = 6 g.kg ⁻¹ bw QD	At 12, 18 g.kg ⁻¹ bw decreased body weight gain and liver and kidney weight increase (respectively); 5♂/5♀
PO (dietary)	2 years	10, 20, 40, 80 g.kg ⁻¹ diet QD (0.75, 1.5, 3, 6 g.kg ⁻¹ bw QD)	NOAEL = 1.5 g.kg ⁻¹ bw QD	From 3 g.kg ⁻¹ bw decreased body weight gain (male); 20♂/20♀
PO (drinking water)	90 days	4.8 g.kg ⁻¹ bw QD	NOAEL	5♂
PO (drinking water)	90 days	16.4 g.kg ⁻¹ bw QD	66% mortality, decreased body weight gain	5♂

Rat	PO	2 weeks	10 mL kg ⁻¹ QD	Well tolerated	70 mM
	PO (gavage)	90 days	10 mL kg ⁻¹ QD	None	0.1 M; pH 7.0; Age 6 weeks; ♂/♀
	PO (gavage)	91 days	10 mL kg ⁻¹ QD	None	0.1 M; pH 7.0; Age 6 weeks; ♂/♀

TABLE E.98 Sodium Sulfite

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rabbit	Ocular (topical)	28 days	50 mL dose ⁻¹ QID	None	10% in reverse osmosis DI water; Age 7 months; ♂/♀

TABLE E.99 Solutol HS15™

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	Any	1 dose	Varies	Poorly tolerated in significant amounts	Solutol® HS15/purified water
Mouse	IP	2 weeks	10 mL kg ⁻¹ 3× per week	None	10% solutol; Non-GLP; Age 4–5 weeks; 5♂/5♀
	IV	2 weeks	10 mL kg ⁻¹ 3× week	None	10% solutol; Non-GLP; Age 4–5 weeks; 5♂/5♀
Rat	PO (gavage)	Two months	10 mL kg ⁻¹ per day	Well tolerated	10% solutol HS15 in purified water; Sprague-Dawley rats

TABLE E.100 Soybean Oil

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO	Acute		Well tolerated	50%
Rat	PO	13 weeks	2000 mg kg ⁻¹	Well tolerated; Reduced food consumption at 500 mg kg ⁻¹ and above	
	PO	13 weeks	20% in diet	Well tolerated	

TABLE E.101 Sulfobutylether-β-cyclodextrin (SBECD)

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Mouse	PO	7 days	10 mL kg ⁻¹ BID	None	10%; Non-GLP; Age 7 weeks; 3♂/3♀

TABLE E.102 Tartaric Acid

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Rabbit	PO (gavage)	Prelim. Segment II	3 mL kg ⁻¹ day ⁻¹	Well tolerated	
	PO (gavage)	Segment II	3 mL kg ⁻¹ day ⁻¹	Well tolerated	
Rat	PO (gavage)	39 week	0.5 mL kg ⁻¹	Well tolerated	
	PO (gavage)	Sys. nerv	3 mL kg ⁻¹ day ⁻¹	Well tolerated	

TABLE E.103 Terbinafine HCL™ Placebo Nail Lacquer

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Pig	Dermal	1 month	600 μL kg ⁻¹	Erythema, peeling or flaking skin	

TABLE E.104 Transcutol™

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Cat	IV	1 month	2 mL.kg ⁻¹ Single dose	Well tolerated	No evidence of hemolysis or hematotoxicity
	IV	Acute	1000 mg.kg ⁻¹	LD ₅₀	
Dog	IV	Acute	3000 mg.kg ⁻¹	LD ₅₀	
	PO	90 days	1500 mg.kg ⁻¹ day ⁻¹	NOAEL	
	PO (gavage)	Acute (dose escalating)	500, 1000, 1500, 2000 mg.kg ⁻¹	MTD> 2000 mg.kg ⁻¹	Undiluted
	PO (gavage)	Subacute (7 day DRF)	0, 500, 1000, 2000 mg.kg ⁻¹ day ⁻¹	MTD> 2000 mg.kg ⁻¹ day ⁻¹	
	PO (gavage)	Subchronic 13-weeks	0, 400, 1000, 2000/1500 mg.kg ⁻¹ day ⁻¹	NOAEL = 1000 mg.kg ⁻¹ day ⁻¹	
Guinea pig	PO	Acute	300 mg.kg ⁻¹	LD ₅₀	
Minipig	PO	90 days	0, 167, 500, 1500 mg.kg ⁻¹ day ⁻¹	NOAEL = 167 mg.kg ⁻¹ day ⁻¹	Uremia, death at 1500 mg.kg ⁻¹ day ⁻¹ ; high-dose reduced to 1000 mg.kg ⁻¹ day ⁻¹ after 21 days; Histopath in doses > 500 mg.kg ⁻¹ day ⁻¹ include hydropic degeneration of liver and proximal kidney tubules; at > 1000 mg.kg ⁻¹ day ⁻¹ increased relative kidney weight and decreased RBC (males)

Mouse	IP	Acute	3900 mg kg ⁻¹	LD ₅₀	
	IV	Acute	4300 mg kg ⁻¹	LD ₅₀	
	IV (bolus, tail vein)	Acute (dose escalating)	25, 50, 100, 200, 400, 800, 1600, 6400, 3200 and 4800 mg kg ⁻¹	MTD (IV): 3200 mg kg ⁻¹	Males; Physiological saline solution
	IV (bolus, tail vein)	Acute (dose escalating)	25, 50, 100, 200, 400, 800, 1600, 8000, 6400, 4800 and 3200 mg kg ⁻¹	MTD (IV): 3200 mg kg ⁻¹	Females; Physiological saline solution
	PO	Acute	6.6 g kg ⁻¹	Tested toxic	
	PO	Acute	7250 mg kg ⁻¹	LD ₅₀	
	PO (gavage)	Developmental (dosed GD 7–14, littered and reared to PND 3)	5500 mg kg ⁻¹ day ⁻¹	No developmental toxicity	>99% pure; 50 Mated CD1 mice; 14% maternal mortality, maternal weight gain decreased, no external malformations on pups.
	PO	90 days	300, 900, 2700, and 8100 mg kg ⁻¹ bw (0%, 0.2%, 0.6%, 1.8% 5.4% in diet, respectively)	NOAEL = 850–1000 mg kg ⁻¹ bw (0.6% in diet)	At 8100 mg kg ⁻¹ bw intracellular edema of the kidney, increased organ weights, decreased RBC (males), liver cell enlargement, protein inclusions in bladder lumen (males), tubular degeneration and atrophy. At 2700 mg kg ⁻¹ bw increased relative kidney weights in males was seen.
	PO	Chronic (12 months)	850–1000 mg kg ⁻¹	NOEL	
SC	Acute	5500 mg kg ⁻¹	LD ₅₀		
Rabbit	Dermal	Skin irritation	0.5 mL over 2 cm ² area	Nonirritant	50%
	Dermal	28 days	0, 300, 1000, 3000 mg kg ⁻¹ day ⁻¹	NOEL >1000 mg kg ⁻¹ day ⁻¹	Undiluted
	IM	14 days	0, 0.62, 0.82, 1.6 mL kg ⁻¹ day ⁻¹	NOAEL = 1.6 mL kg ⁻¹ day ⁻¹	No treatment-related effects
	Ocular	Eye irritation	0.1 mL	Slight irritation	30%
	Ocular	Eye irritation	0.1 mL	Slight irritation	Undiluted
	PO	Acute	3620 mg kg ⁻¹	LD ₅₀	
	SC	Acute	2000 mg kg ⁻¹	LD ₅₀	

Rat	Inhalation (nasal)	28 days (6 h day ⁻¹ , 5 days per week)	0, 16, 49, 200 ppm (0, 90, 270, 1100 mg m ⁻³ , respectively)	NOAEL = 1100 mg m ⁻³	No systemic effects; mild local irritation; focal necrosis in larynx (males); 1100 mg m ⁻³ was higher than max concentration at which only vapor present
	Inhalation (whole body)	Developmental (7 h day ⁻¹ from GD 7–15)	0, 102 ppm	No maternal or fetal toxicity	98–99.5% pure; Sprague-Dawley rats
	IP	Acute	6300 mg kg ⁻¹	LD ₅₀	
	IV	Acute	4000 mg kg ⁻¹	LD ₅₀	
	PO	Acute	7500 mg kg ⁻¹	LD ₅₀	
	PO	Acute	5.0 g kg ⁻¹	LD ₅₀ > 5000 mg kg ⁻¹	Undiluted
	PO	90 days	0%, 0.25%, 1% and 5%	NOEL = 1%	
	PO (gavage)	90 days	250, 2500 mg kg ⁻¹ bw (0.5% and 5.0% in diet respectively)	NOAEL = 250 mg kg ⁻¹ bw	High-dose group saw reduction in growth rate and food consumption, decreased hemoglobin, RBC decreased (females), oxalate crystals in urine (females), increased organ weights, calcification of renal cortex; CFE rats
	PO (gavage)	Fertility (Segment I)	0, 300, 1000, 2000 mg kg ⁻¹ day ⁻¹	NOAEL (oral) = 2000 mg kg ⁻¹ day ⁻¹	In sterile water
	PO (gavage)	6 weeks	1340, 2680, 5360 mg kg ⁻¹ day ⁻¹	NOAEL = 1340 mg kg ⁻¹ day ⁻¹	Death, hematological/clinical signs in intermediate and high-dose groups; Lethargy during first week; 10♂; Sprague-Dawley rats
	PO (gavage)	Embryo/fetal development study (Segment II)	0, 300, 1000, 2000 mg kg ⁻¹ day ⁻¹	NOAEL (dev, mat) 1000 mg kg ⁻¹ day ⁻¹	In sterile water
	PO	Fertility and embryotoxicity range-finding study	500, 1000, 2000, 4000 mg kg ⁻¹ day ⁻¹	NOEL > 500 mg kg ⁻¹ day ⁻¹	
	SC	Acute	6000 mg kg ⁻¹	LD ₅₀	

TABLE E.105 Trisodium Citrate Dihydrate

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	PO (gavage)	52 week	10 mL kg ⁻¹ day ⁻¹	Well tolerated	2.65% aqueous (pH 6.4)
Hamster	PO (gavage)	13 week	10 mL kg ⁻¹ day ⁻¹	Well tolerated	2.65% aqueous (pH 6.4)
Mouse	PO (gavage)	13 week	10 mL kg ⁻¹ day ⁻¹	Well tolerated	2.65% aqueous (pH 6.4)
Rat	PO (gavage)	4 week	10 mL kg ⁻¹ day ⁻¹	Well tolerated	2.65% aqueous (pH 6.4)
	PO (gavage)	Segment III	10 mL kg ⁻¹ day ⁻¹	Well tolerated	2.65% aqueous (pH 6.4)
	PO (gavage)	39 week	10 mL kg ⁻¹ day ⁻¹	Well tolerated	2.65% aqueous (pH 6.4)

TABLE E.106 Tween 20™

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV, SC, IP	Single dose		Not tolerated in any significant amount	
	PO	Single dose		Poorly tolerated in significant amounts	
Mouse	PO	Acute	10 g kg ⁻¹	Well tolerated	
	PO		10 g kg ⁻¹	Well tolerated	
Nonhuman primate	IV (slow bolus)	28 days	10 mL kg ⁻¹ 3× per week	Red/back discoloration of the skin (anogenital region, and hindlimbs and forelimbs)	1.01% in sterile water for injection, USP; Age 2–3 years; ♂/♀
Rat	PO	1 month	250 mg kg ⁻¹	Well tolerated	
	PO	90 day	500 g kg ⁻¹	Diarrhea	
	IV (slow bolus)	6 months	10 mL kg ⁻¹ 3× per week	None	1.01% in sterile water for injection, USP; Age 7–8 weeks; ♂/♀

TABLE E.107 Tween 80™

Species	Route	Duration	Dose	Adverse Reactions/Toxicity	Notes
Dog	IV, SC, IP	Single dose	Varies	Not tolerated in any significant amount; hypersensitivity	
	PO	Single dose	Varies	Poorly tolerated in significant amounts	
	PO (gavage)	ADME	5 mL kg ⁻¹ day ⁻¹	Well tolerated	0.1%
	PO (gavage)	90 days	Dose vol 5 mL kg ⁻¹ , daily dose 10 mg kg ⁻¹ (0.2% w/v)	Well tolerated	Dose concentration 2 mg mL ⁻¹
Mouse	Intranasal	3 days	10 µL per nostril	Well tolerated	0.2%
	IP	1 month	10 mL kg ⁻¹	Well tolerated	2% solution
	PO (gavage)	35 days	10 mL kg ⁻¹ BID	Distended abdomen, skin cold to the touch, feces few/absent, limb function impaired, head tilt, swollen abdomen, death; Vehicle was not tolerated following 35 days of daily administration	10% in distilled water; Age 6 weeks; ♂/♀
	PO (gavage)	90 days	Dose vol 10 mL kg ⁻¹ , Daily dose 10 mg kg ⁻¹ (0.2% w/v)	Well tolerated	Dose concentration 1 mg mL ⁻¹

TABLE E.110 Xylitol

Species	Route	Duration	Dose	Adverse Reactions/ Toxicity	Notes
Nonhuman primate	Intranasal	1 month	Control and high dose of 1200 µL day ⁻¹ ; Intermediate dose of 400 µL day ⁻¹ ; Low dose of 200 µL day ⁻¹	Well tolerated at 1200 µL day ⁻¹	3.3% in water (w/v)

TABLE E.111 Combination Formulations

#	Formulation	Species	Route	Duration	Dose	Adverse Reactions/ Toxicity	Notes
1	Acacia (10%)/Antifoam 1510-US™ (0.05%)/Water (purified)	Rat	PO (gavage)	14 days	10 mL.kg ⁻¹ QD	Well tolerated	Age 9–11 weeks; ♂/♀
2	Acacia gum (10%)/DMSO (1%)	Non-human Primate	PO (gavage)	2 months (ADME)	5 mL.kg ⁻¹	Well tolerated	
3	Acacia gum (10%)/DMSO (1%)	Rat	PO (gavage)	1 week (ADME)	5 mL.kg ⁻¹	Well tolerated	Sprague-Dawley
4	Acacia gum (10%)/DMSO (1%)	Rat	PO (gavage)	1 month (ADME)	5 mL.kg ⁻¹	Well tolerated	Sprague-Dawley
5	Acacia gum (10%)/DMSO (1%)	Rat	PO (gavage)	1 month (ADME)	5 mL.kg ⁻¹	Well tolerated	Sprague-Dawley
6	Acacia gum (10%) /Tween 80™ (0.5%)	Rat	PO (gavage)	Prelim/Segment II	5 mL.kg ⁻¹ day ⁻¹	Well tolerated	
7	Acacia gum (10%) /Tween 80™ (0.5%)	Rat	PO (gavage)	Segment II	5 mL.kg ⁻¹ day ⁻¹	Well tolerated	
8	Acetate buffer (pH 5)/Benzyl alcohol (1% pH 5.0)(acetate: 100 mM, citrate: 10 mM)	Non-human Primate	IV (into saphena vein)	2 weeks	0.92 mL.kg ⁻¹	Well tolerated	
9	Acetate buffer pH 5 with 1.0% Benzyl alcohol (acetate: 100 mM, citrate: 10 mM), pH 5.0	Rat	IV (into tail vein)	28 days	0.92 mL.kg ⁻¹	Well tolerated	Sprague-Dawley
10	Acetic acid (0.01 M)/DMA (95/5)	Dog	30 minute infusion	1 day	3 mL.kg ⁻¹ in single infusion	None	99% solution; Beagles age 5 months; ♂/♀
11	Acetone/Cyclohexane (50/50)	Rat	Dermal	6h daily, 5 days per week over 14 days	1.5 mL.kg ⁻¹	None	100% solution; No sham group; Age ~60 days; ♀
12	Acetonitrile/Acetic acid (99/1)	Dog	PO (dietary)	ad libitum over 1 year		None	Age 7–8 months; ♂/♀
13	Benzyl alcohol: 60.2%/Citric acid: 0.1%/BHT: 0.1%	Cat	Topical	24 hours	0.3 mL SD	None	Non-GLP; Age 1 Year; 1♂/1♀
14	BHT/Benzyl Alcohol/Isopropanol	Dog	Topical	q7d x 2 doses over 7 weeks	1.4 mL.kg ⁻¹ divided into 3 doses 60 minutes apart	None	Non-GLP; Age 7 weeks; 4♂/4♀
15	Capmul MCM™/Kolliphor EL™ (50/50)	Non-human Primate	PO (gavage)	Once weekly over 4 weeks	5 mL.kg ⁻¹	None	Age 3–6 years; ♂/♀
16	Capmul MCM NF™/Propylene Glycol/ Kolliphor EL™ in a ratio of 1 : 1 : 1 (by weight)	Rat	PO	13-weeks	3 mL.kg ⁻¹ BD	Well tolerated	Wistar Hans (CRL) Age ~7–9 weeks at study initiation; ♂/♀
17	Captisol™ (5.4%)/Dextrose (2.5%)/ Water (pH 4)	Dog	IV (infusion)	3 days	2 mL.kg ⁻¹ h ⁻¹ , 24h ⁻¹ day ⁻¹	None	Age 7–8 months; ♂/♀

18	Citrate buffer (50 mM containing 0.5% Methocel E50 Premium LV™ and 0.2% Tween 20™, pH 4 ± 0.1)	Rat	PO (gavage)	14 days	10 mL kg ⁻¹ QD	None	Age 8–9 weeks; ♂/♀
19	Citrate buffer (53.8–54.9 mM containing 0.5% Methocel E50 Premium LV™ and 0.2% Tween 20™, pH 4 ± 0.1)	Nonhuman primate	PO (gavage)	1 day	5 mL kg ⁻¹ SD	None	Age 3–6 years; ♂
20	CMC (0.5%)/Tween 80™ (0.1% (w/w))	Rabbit	PO (gavage)	Prelim/Segment III	5 mL kg ⁻¹ day ⁻¹	Well tolerated	
21	CMC (1%)/Tween 80™ (0.5%)	Dog	PO	28 days	10 mL kg ⁻¹	Well tolerated	
22	CMC (1%)/Tween 80™ (0.5%)	Rat	PO	28 days	20 mL kg ⁻¹	Well tolerated	
23	CMC (high viscosity, 0.25%)/Tween 80™ (0.2%)/Water (sterile for injection, USP)	Mouse	PO (gavage)	102 weeks	10 mL kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
24	CMC (low viscosity, 1%)/Tween 80™ (0.01%)/Water (distilled)	Rat	PO (gavage)	105 weeks	10 mL kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
25	CMC (low viscosity, 1%)/Tween 80™ (0.01%)/Water (distilled)	Non-human Primate	PO (gavage)	≤ 365 days	10 mL kg ⁻¹ QD	None	Age 4.5–8 years; ♂/♀
26	CMC (low viscosity, 1%)/Tween 80™ (0.01%)/Water (distilled)	Mouse	PO (gavage)	91 weeks	10 mL kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
27	CMC (Medium viscosity, 0.5% w/v), Tween 80™ (0.1%, v/v)/Water (sterile for injection, USP)	Mouse	PO (gavage)	13 weeks	10 mL kg ⁻¹ QD	None	Age 5 weeks; ♂/♀
28	CMC: 0.5%/Tween 80™; 0.05%/in PBS pH 7.4	Dog	IA	2 days	0.35 mL SD	1 day postdosing, 1 animal had moderate hemorrhage of right stifle fat pad and mildly increased synovial fluid volume on necropsy, 2 had lameness 2 days postinjection, resolved within 24 h	GLP; Age 8 months; 6♂/6♀
29	CMC: 0.5%/Tween 80™; 0.05%/in PBS pH 7.4	Dog	IA	q30d over 3 months	350 µL	None	GLP; Age 5–6 months; 5♂/5♀
30	CMC: 0.5%/Tween 80™; 0.05%/in PBS pH 7.4	Dog	IA	q30d over 9 months	350 µL	None	GLP; Age 5–6 months; 5♂/5♀

31	Corn oil/Benzyl alcohol (99:1)	Rat	PO (gavage)	1 month	1 mL kg ⁻¹ day ⁻¹	Well tolerated	Sprague-Dawley; during the first 3 days of the study, the vehicle was di(ethyleneglycol) ethylether. From the 4th day it was replaced by corn oil/benzyl alcohol
32	Corn oil/EtOH 20%	Rat	PO (gavage)	1 month	2.5 mL kg ⁻¹ day ⁻¹	Well tolerated	Sprague-Dawley
33	Corn oil/EtOH 20%	Rat	PO (gavage)	1 month	5 mL kg ⁻¹ day ⁻¹	Well tolerated	Sprague-Dawley
34	Cyclodextrin/OraPlus™ suspension	Rat	PO (gavage)	28 doses	15 mL kg ⁻¹	Fecal changes (soft, watery, or mucoid); kidney lesions	
35	Cyclodextrin/OraPlus™ suspension	Rat	PO (gavage)	Single dose	20 mL kg ⁻¹	None	
36	Cyclodextrin/OraPlus™ suspension	Rat	PO (gavage)	Single dose	20 mL kg ⁻¹	None	
37	Cyclodextrin/OraPlus™ suspension	Rat	PO (gavage)	5 doses		None	
38	Dehydrated EtOH (200 proof): 86.249% / Hexylene Glycol: 10.000%/ Dimethiconol blend 20: 2.500%/ Hydroxypropylcellulose: 1.250%/ Anhydrous Citric Acid: 0.001%	Minipig	Topical	28 days	5 mL QD	None	GLP; Age 3–5 months; 5♂/5♀
39	Dextrose/Trehalose (25%)	Rat	Bolus injection	28 doses	10 mL kg ⁻¹	None	5% solution
40	Dextrose for Injection (USP)/EtOH (5%)	Rat	PO (gavage)	Single dose		None	5% solution
41	Diethylacetamide/NaCl	Mouse	IV		MTD: 1.4 g kg ⁻¹ ; LD ₅₀ : 2.3– 3.2 g kg ⁻¹ ; NOEL: 468 mg kg ⁻¹		CD-1 mice; 30% of a 5 mL kg ⁻¹ dose volume at MTD; (%v/v) in NaCl
42	Di-sodium hydrogen phosphate dihydrate (8 mM)/Sodium dihydrogen phosphate dihydrate (7 mM)/NaCl (50 mM)/ Sucrose (146 mM)/Poloxamer 188™ (0.12 mM)/Water (for injection, pH 6.9 ± 0.4)	Nonhuman primate	SC	26 weeks	2 mL kg ⁻¹ Once Weekly	None	Age 1–1.5 years; ♂/♀
43	DMSO (1.25%)/5% Mannitol (5%)/ Kolliphor™ (1.25%)	Nonhuman primate	PO (gavage)	ADME	1 mL kg ⁻¹ day ⁻¹	Well tolerated	

44	DMSO (2%)/PEG 400 (10%)	Nonhuman primate	IV	1 month (ADME)	1.5 mL.kg ⁻¹	Well tolerated	
45	DMSO (2%)/PEG 400 (10%)	Nonhuman primate	IV	1 week (ADME)	1.5 mL.kg ⁻¹	Well tolerated	
46	DMSO (2%)/PEG 400 (10%)	Nonhuman primate	IV	2 month (ADME)	1.5 mL.kg ⁻¹	Well tolerated	
47	DMSO (3.5%)/PEG 400	Nonhuman primate	PO (gavage)	Prelim.	5 mL.kg ⁻¹ day ⁻¹	Soft liquid feces	
48	DMSO (5%)/Mannitol (4.5%)/Kolliphor™ (5%)	Nonhuman primate	IV	2 weeks	2 mL.kg ⁻¹ day ⁻¹	Well tolerated	
49	DMSO/NaCl	Mouse	IV		MTD: 2.2 g.kg ⁻¹ ; LD ₅₀ : 3.8–7.6 g.kg ⁻¹ ; NOEL: 1.6 g.kg ⁻¹		CD-1 mice; 40% of a 5 mL.kg ⁻¹ dose volume at MTD; (%v/v) in NaCl
50	DMSO/PEG 400 (99%)	Rat	PO (gavage)	11 doses		None	1% solution
51	DMSO/PEG 400 (99%)	Rat	PO (gavage)	11 doses	2 mL.kg ⁻¹	None	1% solution
52	DMSO/PEG 400/Tris Buffer	Nonhuman primate	IV (bolus)	ADME	2 mL.kg ⁻¹	Well tolerated	
53	DMSO/PEG 4000/Water (DI) (15/35/50)	Rat	IP	28 days	10 mL.kg ⁻¹	Well tolerated	
54	DMSO/PEG 4000/Water (DI) (15/35/50)	Mouse	IP	28 days	10 mL.kg ⁻¹	Well tolerated	
55	DMSO/Solutol HS15™/Water (pH 3–11) (20/5/75)	Rat	IV (bolus)		2 mL.kg ⁻¹	Well tolerated	
56	DMSO/Tetraglycol (50/50)	Minipig	IV	1 day	0.4 mL.kg ⁻¹ SD	Immediate cardiac arrest; study was canceled after first dose	Age 3 months; 1♂
57	DMSO + 1% Tween 80™ at 0.12% in water for injection	Mouse	SC	RNA extraction, 7 days	4/10 mL.kg ⁻¹ per injection	Well tolerated	
58	EDTA (0.2 mg mL ⁻¹)/Citric Acid Anhydrous (0.8 mg mL ⁻¹)/NaCl (4.6 mg mL ⁻¹ , low iron)/Water (sterile for injection, USP, pH 3.9–4.0)	Rat	IV (slow bolus)	13 weeks	4.5 mL.kg ⁻¹ QD	Red/blue skin discoloration and edema of the tail (nonadverse)	Age 6 weeks; ♂/♀

59	EDTA pH 7.3 (Phosphate 10 mM; NaCl 150 mM; EDTA 0.5 mM)	Rat	IV (into tail vein)	1 month	0.92 mL.kg ⁻¹	Well tolerated	Sprague-Dawley
60	EDTA pH 7.3(Phosphate 10 mM; NaCl 150 mM; EDTA 0.5 mM)	Nonhuman primate	IV (into saphena vein)	2 weeks	0.92 mL.kg ⁻¹	Well tolerated	
61	EiOH (190 Proof): 63.37%/Glycerol: 3%/ Carbopol Ultrez™ 10: 2.5%/Tween 20™: 2%/Propylene Glycol: 2%/ Panthenol: 0.15%/Salicylic Acid: 0.15%/ EDTA: 0.05%/Water (DI): 26.78%	Minipig	Topical	92 days	1 g QD	None	GLP; Age 3–4 Months; 5♂/5♀
62	EiOH/Kolliphor EL™/Water for injection (10/5/85)	Nonhuman primate	IV	ADME	0.4 mL.kg ⁻¹	Well tolerated	
63	EiOH/Kolliphor EL™/Water for injection (10/5/85)	Rat	IV	ADME	2 mL.kg ⁻¹	Well tolerated	
64	EiOH/NaCl	Mouse	IV		MTD: 986 mg.kg ⁻¹ ; LD ₅₀ : 1.6–4.3 g.kg ⁻¹ ; NOEL: 197 mg.kg ⁻¹		CD-1 mice; 25% of a 5 mL.kg ⁻¹ dose volume at MTD; (%v/v) in NaCl
65	EiOH/Propylene glycol/Water (12.5/15.5/75, v/v/v)	Rat	PO (gavage)	2 weeks	5 mL.kg ⁻¹ day ⁻¹	Well tolerated	
66	EiOH/Propylene glycol/Water (12.5/15.5/75, v/v/v)	Rat	SC	2 weeks	2 mL.kg ⁻¹ day ⁻¹	Well tolerated	
67	EiOH/Propylene glycol/Water (30/10/60)	Dog	IV		5 mL.kg ⁻¹ at a rate of 0.3 mL.kg ⁻¹	Hemolysis <i>in vitro</i> dog blood	
68	EiOH/Propylene glycol/Water (30/20/50)	Dog	IV		5 mL.kg ⁻¹ at a rate of 0.3 mL.kg ⁻¹	Hemolysis <i>in vitro</i> dog blood.	
69	EiOH/Propylene glycol/Water (40/10/50)	Dog	IV		5 mL.kg ⁻¹ at a rate of 0.3 mL.kg ⁻¹	Hemolysis <i>in vitro</i> dog blood	
70	EiOH/Solutol HS15™/Water	Nonhuman primate	PO (gavage)	39 weeks	1 mL.kg ⁻¹ day ⁻¹	Well tolerated	
71	EiOH/Solutol HS15™/Water	Nonhuman primate	PO (gavage)	4 weeks	1 mL.kg ⁻¹ day ⁻¹	Well tolerated	
72	EiOH/Water (30/70)	Rat	IV		5 mL.kg ⁻¹ at a rate of 0.3 mL.kg ⁻¹	Hematuria	
73	EiOH: 50%/Propylene glycol: 50%/with BHA: 0.05%/BHT: 0.05%	Minipig	Topical	16 weeks	1 mL TID	All males had increased AST at end of study, up to 500 IU/L (ref: 19–263 IU/L)	GLP; Age 3–4 months; 6♂/6♀

74	Gelatin (0.5% m/v)/Mannitol (5% m/v)/ Water for injection	Nonhuman primate	PO (gavage)	Prelim.	5 mL kg ⁻¹ day ⁻¹	Well tolerated	
75	Gelucire™/PEG 400/NMP/Transcutol HP™ (50/30/10/10)	Minipig	PO	4 days	5 mL kg ⁻¹ QD	None	Non-GLP; Age 4–6 months; 3♀
76	Gelucire 44/14™/PEG 400/NMP/ Transcutol HP™ (50/30/10/10)	Minipig	PO	3 days	5 mL kg ⁻¹ QD	Mild transient diarrhea 24–30 hours post-first dose	Non-GLP; Age 7–8 months; 3♀
77	Gelucire 44/14™/PEG 400/NMP/ Transcutol HP™ (50/30/10/10)	Mouse	PO	5 days	5 mL kg ⁻¹ QD	None	Non-GLP; Age 9–14 weeks; 6♂/6♀
78	Histidine (20 mM, pH 6.5)/Sucrose (8.8%)	Rat	IV (slow bolus)	14 days	5 mL kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
79	Histidine (20 mM, pH 6.5)/Sucrose (8.8%)	Dog	SC	14 days	1 mL kg ⁻¹ QD	None	Age 5–6 months; ♂/♀
80	Histidine buffered solution (10 mM, pH 6.5)/NaCl (130 mM)/Water (sterile)	Rat	IV (bolus)	1 day	7.14 mL kg ⁻¹ Single dose	None	Age 5 months; ♂
81	HPMC (0.5%)/Tween 80™ (0.1%)/ Water (DI)	Nonhuman primate	PO (gavage)	28 days	5 mL kg ⁻¹ QD	Soft/watery feces	Age 2–4 years; ♂/♀
82	HPMC (0.5%)/Tween 80™ (5%)	Rat	PO (gavage)	2 weeks	5/1 mL kg ⁻¹ day ⁻¹	Well tolerated	
83	HPMC (1%)/Poloxamer 188™ (1%)	Dog	PO	2 weeks	5 mL kg ⁻¹ day ⁻¹	Well tolerated	Beagle
84	HPMC (1%)/Poloxamer 188™ (1%)	Dog	PO	2 weeks	10 or 20 mL kg ⁻¹ day ⁻¹	Well tolerated	Beagle
85	HPMC (1%)/Poloxamer 188™ (1%)	Dog	PO	2 months	10 mL kg day ⁻¹	Well tolerated	Beagle
86	HPMC (1%)/Tween 80™ (0.25%)/Water (purified)	Rat	PO (gavage)	11 days	10 mL kg ⁻¹ QD	None	Age 8–10 weeks; ♀
87	HPMC/Sodium lauryl sulfate (2%)/Water (distilled)	Rat	PO (gavage)	Single dose	10 mL kg ⁻¹	None	0.5% solution
88	HPMC acetate succinate (90 mg mL ⁻¹)/ Methylcellulose (0.5%)	Mouse	PO	14 days	5 mL kg ⁻¹ EOD	None	GLP; Age 61–63 days; 20♂/20♀
89	HPMC acetate succinate (90 mg mL ⁻¹)/ Methylcellulose (0.5%)	Minipig	PO	14 days	6 mL kg ⁻¹ EOD	None	GLP; Age 3–5 months; 5♂/5♀
90	HPMC: 1%/Fumaric acid: 0.5%/Tween 80™: 0.1%/Glycerol: 0.1%/in water	Dog	PO	14 days	5 mL kg ⁻¹ QD	None	Non-GLP; Age 7–9 months; 1♂/1♀

91	HPβCD (20% solution)/DMSO (99/1)	Dog	IV	ADME	4 mL kg ⁻¹ day ⁻¹	Well tolerated	
92	HPβCD (20%)/Sodium acetate (25 mM, pH 4)	Rat	PO (gavage)	28 days	5 mL kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
93	HPβCD (20%)/Sodium acetate (25 mM, pH 4)	Nonhuman primate	PO (gavage)	28 days	2.5 mL kg ⁻¹ per dose BID	None	Age 2–3.5 years; ♂/♀
94	HPβCD (30%)/DMSO (5%)/Water (purified) (Acidic solution, w/w)	Nonhuman primate	IV	4 weeks	1 mL kg ⁻¹ day ⁻¹	Well tolerated	
95	HPβCD/Citric acid solution (0.05 M)	Dog	PO (gavage)	14 doses	3 mL kg ⁻¹	None	20% solution
96	HPβCD/NaCl solution (0.9%)	Dog	IV	Single dose	1 mL kg ⁻¹	None	10% solution
97	HPβCD/NaCl solution (0.9%)	Rat	IV	Single dose	1 mL kg ⁻¹	None	10% solution
98	HPβCD: 12%/EtOH: 8%/Propylene glycol: 2%/Water for injection	Dog	IV (1 hour infusion)	q7d × 3 doses over 16 days	2 mL kg ⁻¹	May cause temporary mild diarrhea	Non-GLP; Age 1–4 Years; 2♂/2♀
99	HPβCD: 12%/EtOH: 8%/Propylene glycol: 2%/Water for injection	Dog	IV (1 hour infusion)	q7d × 3 doses over 16 days	1.5 mL kg ⁻¹	May cause diarrhea	Non=GLP; Age 1–4 years; 2♂/2♀
100	Hydroxyethylcellulose (1%)/Tween 80™ (0.25%)/Antifoam™ (0.05%)/Water (purified)	Rat	PO (gavage)	1 day	10 mL kg ⁻¹ Single dose	None	Age 6 weeks; ♂
101	Hydroxyethylcellulose (1%, w/v)/Tween 80™ (0.25%)/Antifoam 1510-US™ (0.05%)/Water (purified)	Rat	PO (gavage)	4 days	10 mL kg ⁻¹ QD	None	Age 8–9 weeks; ♀
102	Hymetellose (1%)/Poloxamer 188™ (0.1%)	Rabbit	PO (gavage)	1 month	3 mL kg ⁻¹ day ⁻¹	Well tolerated	
103	Imwitor 742™/Tween 80™ (1:1, w/w)	Rat	PO (gavage)	7 days	10 mL kg ⁻¹ QD	None	Age 7 weeks; ♂/♀
104	Imwitor 742™/Tween 80™ (1:1, w/w)	Nonhuman primate	PO (gavage)	7 days	5 mL kg ⁻¹ QD	Soft/watery feces	Age 2–3 years; ♂/♀
105	Imwitor 742™/Tween 80™ (1:1, w/w)	Hamster	PO (gavage)	7 days	5 mL kg ⁻¹ QD	None	Age 5 weeks; ♂/♀
106	Kolliphor EL™/PEG 300/(4:1, w/w)	Mouse	PO (gavage)	104 weeks	3 mL kg ⁻¹ day ⁻¹	Well tolerated	
107	Kolliphor RH40™: 41.5%/PEG 400: 20%/TPGS: 20%/Propylene Glycol: 10%/Tween 80™: 8.5%	Rat	PO (gavage)	92 days	10 mL kg ⁻¹ QD	None	Age 10–23 weeks; ♂/♀
108	Kolliphor EL™/ 10% 190 proof EtOH/ 80% 5% dextrose in water (D5W)	Rabbit	IV	Single dose	5 mL kg ⁻¹	None	10 % solution
109	Kolliphor EL™/10% 190 proof EtOH/ 80% 5% dextrose in water (D5W)	Rabbit	IV	Single dose	5 mL kg ⁻¹	Local irritation, very slight to well-defined erythema	10 % solution

110	Kolliphor EL™/10% 190 proof EtOH/ 80% 5% dextrose in water (D5W)	Rabbit	Perivascular injection	Single dose	0.5 mL.kg ⁻¹	None	10 % solution
111	Kolliphor EL™/ 10% 190 proof EtOH/ 80% 5% dextrose in water (D5W)	Rabbit	Perivascular injection	Single dose	0.5 mL.kg ⁻¹	Erythema	10 % solution
112	Labrafil™/Tween 80™ (0.1%)	Rat	PO (gavage)	2 doses	2 mL.kg ⁻¹ dose ⁻¹	None	
113	Labrasol™/Kolliphor HS15™/Transcutol HP™ (60/30/10)	Minipig	PO (gavage)	Once weekly over 4 weeks	3.75 mL.kg ⁻¹	None	Age 6–7 months; ♂/♀
114	Labrasol™/Labrafil™/Transcutol™	Rat	PO	4 weeks	0, 5, 10, or 20 mL.k ⁻¹ day ⁻¹	Tolerated at 5 mL.kg day ⁻¹	Changes in appearance and behavior at 10 mL.kg ⁻¹ day ⁻¹ ; lethality and renal and hepatic effects at 20 mL.kg ⁻¹ day ⁻¹ ; Wistar rats
115	Labrasol™/PEG-400 (60/40)	Rat	PO	7-days	5 mL.kg ⁻¹ BD	Well tolerated	Sprague-Dawley rats (Harlan) Age ~8–10 weeks; ♂/♀
116	Lactated Ringer's Injection (USP)	Nonhuman primate	IV	28 days	2 mL.kg ⁻¹ QD	None	
117	L-Ascorbic acid/Isotonic NaCl	Rat	PO	90 days	500 g.kg ⁻¹	Hematologic changes, weight loss	
118	Mannitol (47 mg mL ⁻¹)/Succinic acid (1.181 mg mL ⁻¹)/Water (Sterile, USP)	Dog	SC	28 days	0.1 mL.kg ⁻¹ QD	None	Age 5 months; ♂/♀
119	Mannitol (5%)/Acetate buffer pH4 (4:6)	Minipig	IM	Tolerance	0.8/1.2 mL.kg ⁻¹ day ⁻¹	Well tolerated	
120	Mannitol (5%)/Gelatin (0.5%)/Tween 80 ™ (0.2%) (Aqueous solution, % m/v)	Nonhuman primate	PO (gavage)	2 weeks	2 mL.kg ⁻¹ day ⁻¹	Well tolerated	
121	Mannitol: 120 mg/Na ₂ HPO ₄ ; 12 mg/NaCl: 10.5 mg/Water: 4 mL	Dog	IV	One week (placebo) then one-day (with the test item)	0.15 mL.kg ⁻¹	Well tolerated	Beagle dogs
122	Mannitol: 250 mM/Sodium Succinate: 25 mM/Water pH 4.9	Rat	SC	28 days	4 mL.kg ⁻¹	Well tolerated	

123	Mannitol: 250 mM/Sodium succinate: 25 mM/Water pH 4.9	Mouse	SC	28 days	20 mL.kg ⁻¹	Well tolerated	
124	Methane sulfonic acid (5%)/EtOH (5%)/Water	Rat	PO	28 days	10 mL.kg ⁻¹	Well tolerated	
125	Methocel™ (0.5%)/Tween 80™ (0.1%)/Water (reverse osmosis)	Rat	PO (gavage)	182 days	10 mL.kg ⁻¹ QD	None	Age 6 weeks; ♀
126	Methocel™ (A4M Premium, 0.5%)/Simethicone (0.1%)/TPGS (10%)/Citrate buffer (17 mM, pH 4 ± 0.05)	Rat	PO (gavage)	28 days	10 mL.kg ⁻¹ QD	None	Age 8 weeks; ♂/♀
127	Methyl Methacrylate/Glycol Dimethacrylate Cross polymer, Propylene Glycol Dicaprylate/Dicaprate, BHT	Rat	Topical	90 days	2.4 mL.kg ⁻¹ × 44–46 days, then 0.75 mL.kg ⁻¹ QD	None	GLP; Age 8 weeks; 15♂/15♀
128	Methyl Paraben, Propyl Paraben	Minipig	Topical	91 days	0.05 mL.cm ⁻² TID	None	Age 2–3 months; 6♂/6♀
129	Methylcellulose (0.5% w/v)/Tween 80™ (0.1%)	Guinea Pig	PO	28 days	10 mL.kg ⁻¹	Well tolerated	
130	Methylcellulose (Aqueous, 0.5% w/w)/Tween 80™ (0.5% w/w)	Rat	PO (gavage)	Prelim/Segment III	5 mL.kg ⁻¹ day ⁻¹	Well tolerated	
131	Methylcellulose/PEG 200 (5%)	Rat	PO (gavage)	Single dose	10 mL.kg ⁻¹	None	0.5% solution
132	Methylcellulose/Tween 80™ (0.1% v/v)	Rat	PO (gavage)	Single dose	7.5 mL.kg ⁻¹	None	0.5% solution
133	Methylcellulose/Tween 80™ (0.1% v/v)	Rat	PO (gavage)	Single dose	5 mL.kg ⁻¹	None	0.5% solution
134	Methylcellulose/Tween 80™ (0.1% v/v)	Rat	PO (gavage)	28 doses	5 mL.kg ⁻¹ dose ⁻¹	None	0.5% solution
135	Methylcellulose/Tween 80™ (0.1% v/v)	Dog	PO (gavage)	28 doses	1 mL.kg ⁻¹ dose ⁻¹	None	0.5% solution
136	Methylcellulose/Tween 80™ (0.1% v/v)	Dog	PO (gavage)	Single dose	5 mL.kg ⁻¹ dose ⁻¹	None	0.5% solution
137	Methylcellulose/Tween 80™ (0.1%)	Rat	PO (gavage)	Single dose	10 mL.kg ⁻¹	None	0.5% solution
138	Methylcellulose 1500 cps (0.5%)/Tween 80™ (0.1%)/Acetate buffer (10 mM)/Water (Distilled, pH 4.5 ± 0.1)	Mouse	PO (gavage)	28 days	10 mL.kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
139	Methylcellulose 1500 cps (0.5%)/Tween 80™ (0.1%)/Acetate buffer (10 mM)/Water (Distilled, pH 4.5 ± 0.1)	Mouse	PO (gavage)	13 weeks	10 mL.kg ⁻¹ QD	None	Age 6 weeks; ♂/♀

140	Methylcellulose 1500 cps (0.5%)/Tween 80™ (0.1%)/Acetate Buffer (10 mM)/Water (Distilled, pH 4.5 ± 0.1)	Nonhuman primate	PO (gavage)	91 days	5 mL.kg ⁻¹ QD	None	Age 2–4 years; ♂/♀
141	Methylcellulose 1500 cps (0.5%)/Tween 80™ (0.1%)/Acetate buffer (10 mM)/Water (Distilled, pH 4.5 ± 0.1)	Rat	PO (gavage)	91 days	10 mL.kg ⁻¹ QD	None	Age 6 weeks; ♂/♀

248	Propylene Glycol/EtOH/Water (pH 3–11) (40/5/55)	Rat	IV (infusion)		5 mL.kg ⁻¹	Well tolerated	
249	Propylene Glycol/EtOH/Water (pH 3–11) (40/5/55)	Dog	IV (bolus)		1 mL.kg ⁻¹	Well tolerated	

250	Propylene Glycol/EtOH/Water (pH 3–11) (40/5/55)	Dog	IV (infusion)		2 mL.kg ⁻¹	Well tolerated	
251	Propylene glycol/NaCl	Rat	PO (gavage)	4 weeks	2 mL.kg ⁻¹ day ⁻¹	Well tolerated	
252	Propylene glycol/NaCl	Mouse	IV		MTD: 1.5 g.kg ⁻¹ ; LD ₅₀ : 5.0– 8.6 g.kg ⁻¹ ; NOEL: 1 g.kg ⁻¹		CD-1 mice; 30% of a 5 mL.kg ⁻¹ dose volume at MTD; (%v/v) in NaCl
253	Propylene glycol/NaCl (0.9%)/EtOH (50/40/10)	Dog	IV		5 mL.kg ⁻¹ at a rate of 0.3 mL.kg ⁻¹	Hemolysis <i>in vitro</i> dog blood.	
254	Propylene glycol/PEG 400/Water/EtOH (40/25/25/10)	Nonhuman primate	PO (gavage)	4 weeks	2 mL.kg ⁻¹ day ⁻¹	Well tolerated	
255	Propylene glycol/TPGS/Capmul MCM NF™ (5:5:2 by weight)	Dog	PO	13-weeks	5 mL.kg ⁻¹ BD	Administration of the vehicle was associated with emesis and abnormal fecal quality throughout the 13-weeks of the study	Beagle Dogs (Marshall) Age ~6 months at study initiation; ♂/♀
256	PVP K30 (10%)/Sodium citrate buffer (50 mM, pH 5)	Rat	PO (gavage)	1 day	10 mL.kg ⁻¹ Single dose	None	Age 6 weeks; ♂/♀
257	PVP K30 (10%)/Sodium citrate buffer (50 mM, pH 5)	Nonhuman primate	PO (gavage)	4 weeks	5 mL.kg ⁻¹ Once weekly	None	Age 5–7 years; ♂/♀
258	PVP K30 (10%)/Sodium citrate buffer (50 mM, pH 5)	Nonhuman primate	PO (gavage)	28 days	5 mL.kg ⁻¹ QD	None	Age 2–3 years; ♂/♀
259	Sesame oil/EtOH (96/4)	Dog	PO	28 days	2 mL.kg ⁻¹	Well tolerated	
260	Sesame oil/EtOH (96/4)	Rat	PO	28 days	2 mL.kg ⁻¹	Well tolerated	
261	Sodium acetate (25 mM, USP)/Lactose (70 mg mL ⁻¹)/Water (sterile for injection, USP, pH 4.5)	Dog	SC	14 doses	1 mL.kg ⁻¹	Red discoloration and swelling at injection sites; chronic active inflammation and hemorrhage	
262	Sodium Acetate (25 mM, USP)/Lactose (70 mg mL ⁻¹)/Water (sterile for injection, USP, pH 4.5)	Rat	SC	14 doses	10 mL.kg ⁻¹	Scabbing at injection site	
263	Sodium Acetate (25 mM, USP)/Lactose (70 mg mL ⁻¹)/Water (sterile for injection, USP, pH 4.5)	Rat	SC	14 doses	4 mL.kg ⁻¹	None	
264	Sodium acetate (USP, 25 mM)/Lactose (USP/EP, 70 mg mL ⁻¹)/Water (pH 4.5)	Rat	SC	28 days	10 mL.kg ⁻¹	Well tolerated	

265	Sodium acetate in NaCl, 5 mM	Rat	IV	1 month	1 mL.kg ⁻¹	Well tolerated	
266	Sodium acetate trihydrate buffer (50 mM)/Tween 80™ (1%)	Mouse	PO (gavage)	26 weeks	10 mL.kg ⁻¹ day ⁻¹	Well tolerated	
267	Sodium acetate trihydrate buffer (50 mM)/Tween 80™ (1%)	Mouse	PO (gavage)	7 days	10 mL.kg ⁻¹ day ⁻¹	Well tolerated	
268	Sodium citrate/NaCl Buffer	Rat	IV	2 weeks	4 mL.kg ⁻¹ bolus, 2/10min	Well tolerated	
269	Sodium CMC (0.1%)/Methylparaben sodium (0.1%)/Propylparaben Sodium (0.02%)/Water (purified) (w/v)	Mouse	PO (gavage)	105 Weeks	10 mL.kg ⁻¹ day ⁻¹ BID	None	Age 7 weeks; ♂/♀
270	Sodium CMC (0.1%)/Methylparaben sodium (0.1%)/Propylparaben Sodium (0.02%)/Water (purified) (w/v)	Rat	PO (gavage)	104 weeks	10 mL.kg ⁻¹ day ⁻¹ BID	None	Age 6 weeks; ♂/♀
271	Sodium hydroxide (0.1 M)/NaCl for injection, USP (0.9%)	Nonhuman primate	IV (30 minute infusion)	14 days	10 mL.kg ⁻¹ QD	None	Age 2–4.5 years; ♂/♀
272	Sodium hydroxide (10% solution): 2%/Phenoxyethanol: 1%/Carbomer 974P NF™: 1%/in purified water	Mouse	Topical	28 days	3.4 mL.kg ⁻¹ QD	None	GLP; Age 7 weeks; 12♂/12♀
273	Sodium phosphate (10 mM)/NaCl (0.8%)/Tween 20™ (0.05%)/Water (sterile for injection, USP, pH 6.0 ± 0.3)	Rat	SC	26 weeks	1500 µL.kg ⁻¹ Twice weekly	None	Age 6 weeks; ♂/♀
274	Sodium phosphate (20 mM)/Sucrose (1%)/Mannitol (4%)/Water (for injection)	Rat	SC	26 weeks	1.38 mL.kg ⁻¹ QD	None	Age 7 weeks; ♂/♀
275	Sodium phosphate (20 mM)/Sucrose (1%)/Mannitol (4%)/Water (for injection)	Rabbit	SC	39 weeks	0.58 mL.kg ⁻¹ QD	None	Age 5–6 months; ♂/♀
276	Sodium phosphate buffer (0.3 M)/PEG 400, pH:8 (70:30, w/w)	Nonhuman primate	PO (gavage)	4 weeks	2 mL.kg ⁻¹ day ⁻¹ (0.4 mL.min ⁻¹ kg ⁻¹)	Well tolerated	
277	Sodium phosphate buffer (20 mM)/Dextrose (4%)/Sodium Hydroxide (pH 7.9–8.1)	Rat	Infusion	4 days	2 mL.kg ⁻¹ hr ⁻¹	None	Age 8 weeks; ♀

278	Sodium succinate (25 mM)/Lactose (45 mg mL ⁻¹)/NaCl (0.45%)/Water (sterile for injection, USP)	Dog	IV	7 doses	1 mL kg ⁻¹	None	
279	Sodium succinate (25 mM)/Lactose (45 mg mL ⁻¹)/NaCl (0.45%)/Water (sterile for injection, USP)	Dog	SC	14 doses	1 mL kg ⁻¹	None	
280	Sodium succinate (25 mM)/Lactose (45 mg mL ⁻¹)/NaCl (0.45%)/Water (sterile for injection, USP)	Rat	IV	7 doses	1 mL kg ⁻¹	None	
281	Sodium succinate (25 mM)/Lactose (45 mg mL ⁻¹)/NaCl (0.45%)/Water (sterile for injection, USP)	Rat	SC	14 doses	1 mL kg ⁻¹	None	
282	Sodium succinate (25 mM)/Mannitol™ (250 mM)/Water (sterile for injection, pH 4.6)	Rat	SC	Single dose	4 mL kg ⁻¹	None	
283	Solutol HS 15™/EtOH/Water (40/10/50, v/v/v)	Dog	PO	q7d over 8 weeks	1.5 mL kg ⁻¹	None	Non-GLP; Age 1–4 Years; 3♂/3♀
284	Solutol HS 15™; 15%/EtOH: 5%/PBS	Dog	PO	5 days	20 mL kg ⁻¹ QD	May cause vomiting, loose stool	Non-GLP; Age 1–2 years; 2♂
285	Solutol™; 10%/in NaCl	Rat	IV	14 days	6 mL kg ⁻¹ SD	None	Non-GLP; Age 10 weeks; 3♂/3♀
286	Solutol HS 15™/EtOH/Water(40/10/50)	Nonhuman primate	PO (gavage)	9 months	3 mL kg ⁻¹ day ⁻¹	Well tolerated	
287	Sorbitol (5%)/Histidine (10 mM)/Tween 80™ (0.01%)/Water (sterile for injection, USP, pH 5.8)	Dog	IV (bolus)	5 weeks	4.98 mL kg ⁻¹ Once weekly	None	Age 2–3 years; ♂/♀
288	Soybean oil: 50.00%/Coconut oil: 23.60%/Mineral oil: 5.80%/Cyclomethicone: 5.00%/Cetostearyl alcohol: 3.50%/Stearic acid: 3.00%/Myristyl alcohol: 2.50%/Hydrogenated castor oil: 2.00%/White wax (beeswax): 2.00%/Stearyl alcohol: 1.50%/Docosanol: 1.10%	Minipig	Topical	3 weeks	0.25 mL kg ⁻¹ QD	None	GLP; Age 3–4 months; 5♂/5♀
289	Sucrose (1%)/NaCl (100 mM)/L-arginine hydrochloride (25 mM)/Sodium phosphate (25 mM, pH 6.3)/Water (for injection, USP)	Nonhuman primate	SC	4 weeks	2 mL kg ⁻¹ Twice weekly	Soft/watery feces	Age 2.5–3.5 years; ♂/♀
290	Sucrose Acetate Isobutyrate/EtOH/PEG 300 (90/5/5)	Cat	Oral mucosa	8 hours	0.1 mL SD	None	Non-GLP; Age >6 months; 3♀

291	TPGS (2%)/HPMC acetate succinate (1% HF grade)/PVP K30 (0.25%)/Water (DI)	Rat	PO (gavage)	91 days	10 mL.kg ⁻¹ QD	None	Age 6 weeks; ♂/♀
292	TPGS (2%)/HPMC acetate succinate (1% HF grade)/PVP K30 (0.25%)/Water (DI)	Dog	PO (gavage)	91 days	10 mL.kg ⁻¹ QD	None	Age 6–7 months; ♂/♀
293	TPGS (2%)/HPMC acetate succinate (1% HF grade)/PVP K30 (0.25%)/Water (DI)	Rabbit	PO (gavage)	14 days	10 mL.kg ⁻¹ QD	None	Age 5–8 months; ♂/♀
294	TPGS (2%)/HPMC acetate succinate (1.5% HF grade)/PVP VA 64 (1.5%)/Sodium citrate (50 mM pH 5)/Water (DI)	Rat	PO (gavage)	28 days	10 mL.kg ⁻¹ QD	None	Age 6–8 weeks; ♂/♀
295	TPGS (5%)/Methylcellulose 400 cps (0.5%)/Water (DI)	Rat	PO (gavage)	1 day	10 mL.kg ⁻¹ Single dose	None	Age 6 weeks; ♂/♀
296	Trehalose (9%)/Lactic acid (10mM)	Dog	IA	q28d × 4 doses over 85 days	0.4 mL	None	GLP; Age 9–11 Months; 5♂/5♀
297	Trehalose (9%)/Lactic acid (10mM)	Dog	IV	2× per week × 8 doses over 28 days	0.5 mL.kg ⁻¹	None	GLP; Age 1 Year; 3♀
298	Trehalose (9%)/Lactic acid (10mM)	Rat	IV	14 days	0.5–5 mL.kg ⁻¹ SD	None	GLP; Age 16–20 weeks; 6♂/6♀
299	Tween 20™ (0.01%)/Sodium acetate (10 mM)/Sorbitol (5%, pH 5)	Nonhuman primate	IV (bolus)	12 weeks	5 mL.kg ⁻¹ Once weekly	None	Age 2–4 years; ♂/♀
300	Tween 20™ (0.01%)/Sodium acetate (10 mM)/Sorbitol (5%, pH 5)	Rat	IV (bolus)	12 weeks	5 mL.kg ⁻¹ Once weekly	None	Age 7 weeks; ♂/♀
301	Tween 80™/CMC/Dimethicone (0.01 %) (Ratio PSS0/CMC of 1: 1, 0.2 % de PSS0 and CMC)	Rabbit	PO (gavage)	1 month	3 mL.kg ⁻¹ day ⁻¹	Well tolerated	
302	Tween 80™ (10%)/Citric acid (10.5 mg.mL ⁻¹)/Water (sterile solution)	Rat	IV	2 doses	3 mL.kg ⁻¹	None	
303	Vitamin E (20%)/Sodium citrate buffer (50 mM, pH 5)	Rat	PO (gavage)	28 days	10 mL.kg ⁻¹ QD	None	Age 8 weeks; ♂/♀
304	Water (sterile for injection, USP)/Sodium hydroxide	Rat	SC	Single dose	1 mL.kg ⁻¹	Necrosis of the subcutaneous muscle panniculus carnosus, inflamed injection	
305	Xanthan Gum NF (aka: Xantural 180™) (0.2%, w/v)/Tween 80™ NF (0.255%, w/v)/Water (sterile for injection, USP)	Rat	PO (gavage)	5 days	10 mL.kg ⁻¹ dose ⁻¹ BID	None	Age 8–10 weeks; ♀
