Limit of Liability/Disclaimer of Warranty

In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of experimental reagents, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each chemical, piece of equipment, reagent, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. While the publisher and authors have used their best efforts in preparing this work, they make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of merchantability or fitness for a particular purpose. No warranty may be created or extended by sales representatives, written sales materials or promotional statements for this work. The fact that an organization, website, or product is referred to in this work as a citation and/or potential source of further information does not mean that the publisher and authors endorse the information or services the organization, website, or product may provide or recommendations it may make. This work is sold with the understanding that the publisher is not engaged in rendering professional services. The advice and strategies contained herein may not be suitable for your situation. You should consult with a specialist where appropriate. Further, readers should be aware that websites listed in this work may have changed or disappeared between when this work was written and when it is read. Neither the publisher nor authors shall be liable for any loss of profit or any other commercial damages, including but not limited to special, incidental, consequential, or other damages.

Library of Congress Cataloging-in-Publication Data

Names: Gad, Shayne C., 1948- author. | Sullivan, Dexter W., Jr. author.

Title: Drug safety evaluation / Shayne Cox Gad, Dexter W. Sullivan Jr.

Description: 4th edition. | Hoboken, NJ : Wiley, 2023. | Includes bibliographical references and index.

Identifiers: LCCN 2022042520 (print) | LCCN 2022042521 (ebook) | ISBN

9781119755852 (cloth) | ISBN 9781119755869 (adobe pdf) | ISBN

9781119755876 (epub)

Subjects: MESH: Drug Evaluation, Preclinical | Drug Evaluation | Product Surveillance, Postmarketing

Classification: LCC RA1238 (print) | LCC RA1238 (ebook) | NLM QV 771 |

DDC 615/.19—dc23/eng/20221110

Set in 10/12pt Times LT Std by Straive, Chennai, India

*To my beloved Novie Beth, for years of love and support, and to my aunt Ernestine, who is
our matron and always a firecracker.*

—Shayne Cox Gad

*To Adrienne and Ayden, for your patience and support, and to my mother, Debby Mandeville,
who never fails to inspire me with her courage.*

—Dexter W. Sullivan, Jr.

ACKNOWLEDGMENT

Katina Gad's support and assistance were essential to the completion of this book.

CONTENTS

PREFACE	xxix
ABOUT THE AUTHORS	xxxii
1 The Drug Development Process and The Global Pharmaceutical Marketplace	1
1.1 Introduction	1
1.2 The Marketplace	1
1.3 History of Modern Therapeutics	7
1.4 The Drug Development Process	11
1.5 Strategies For Development: Large Versus Small Company or The Short Versus Long Game	12
1.5.1 Do Only What You Must (The Short Game)	13
1.5.2 Minimize the Risk of Subsequent Failure	13
1.6 Safety Assessment And The Evolution Of Drug Safety	14
1.7 The Three Stages of Drug Safety Evaluation In The General Case	16
References	17
2 Regulation of Human Pharmaceutical Safety: Routes To Human Use and Market	19
2.1 Introduction	19
2.2 Brief History of Us Pharmaceutical Law	19
2.2.1 1906: Pure Food and Drug Act	19
2.2.2 1938: Food, Drug, and Cosmetic Act	21
2.2.3 1962: Major Amendment	23
2.2.4 1992, 1997, 2002, 2007, 2012, and 2017: PDUFA, FDAMA, and FDARA	24
2.2.5 PREA: The Pediatric Research Equity Act	27
2.2.6 ICH: International Conference on Harmonization	27
2.2.7 Electronic Recordings: Electronic Submissions Impact	27
2.2.8 COVID-19	27
2.3 Fdama Summary: Consequences and Other Regulations	28
2.4 Overview of us Regulations	28
2.4.1 Regulations: General Considerations	28
2.4.2 Regulations: Human Pharmaceuticals	28

2.4.3	Regulations: Environmental Impact	30
2.4.4	Regulations: Antibiotics	30
2.4.5	Regulations: Biologics	30
2.4.6	Regulations Versus Law	31
2.5	Organizations Regulating Drug And Device Safety In The United States	32
2.6	Process Of Pharmaceutical Product Development and Approval	32
2.7	Testing Guidelines	34
2.7.1	Toxicity Testing: Traditional Pharmaceuticals	34
2.7.2	General or Systematic Toxicity Assessment	34
2.7.3	Genetic Toxicity Assessment	34
2.7.4	Safety Pharmacology	36
2.7.5	Local Tissue Tolerance	36
2.7.6	Reproductive and Developmental	37
2.7.7	Carcinogenicity	37
2.7.8	Toxicity Testing: Biotechnology Products	37
2.8	Toxicity/Safety Testing: Cellular And Gene Therapy Products	39
2.8.1	Cellular Therapies	40
2.8.2	Gene Therapies	40
2.8.3	ex vivo	40
2.8.4	in vivo	40
2.8.5	Preclinical Safety Evaluation	41
2.8.6	Basic Principles for Preclinical Safety Evaluation of Cellular and Gene Therapies	41
2.8.7	Additional Considerations for Cellular Therapies	41
2.8.8	Additional Considerations for Gene Therapies	41
2.9	Toxicity Testing: Special Cases	41
2.9.1	Oral Contraceptives	42
2.9.2	Life-Threatening Diseases (Compassionate Use)	42
2.9.3	Vaccines	42
2.9.4	Oncology Drugs and Imaging Agents	43
2.9.5	Optical Isomers	43
2.9.6	Special Populations: Pediatric and Geriatric Claims	43
2.9.7	Orphan Drugs	45
2.9.8	Expedited and Augmented Routes to Approval (Once you have an IND)	45
2.9.9	Botanical Drug Products	45
2.9.10	Types of New Drug Applications (NDAs)	48
2.10	International Pharmaceutical Regulation and Registration	48
2.10.1	International Council for Harmonization	48
2.10.2	Other International Considerations	52
2.10.3	Safety Pharmacology	58
2.11	Combination Products	58
2.11.1	Device Programs That Are CDER and CBRH Each Will Administer	59
2.11.2	Coordination	59
2.11.3	Submissions	59
2.12	Meetings And Submissions To Fda Toxicologists	63
2.13	Conclusion	64
	References	64
	Further Reading	66

3	Data Mining: Sources of Information For Consideration In Study And Program Design and In Safety Evaluation	67
3.1	Introduction 67	
3.1.1	Claims 67	
3.1.2	Time and Economies 67	
3.1.3	Prior Knowledge 67	
3.1.4	Miscellaneous Reference Sources 68	
3.1.5	Search Procedure 70	
3.1.6	Monitoring Published Literature and Other Research in Progress 70	
3.1.7	Kinds of Information 71	
3.1.8	Toxic Release Inventory (TRI) 71	
3.1.9	Material Safety Data Sheets (MSDS) 71	
3.1.10	Canadian Centre for Occupational Health and Safety (CCINFO) 72	
3.1.11	Pollution and Toxicology (POLTOX) 72	
3.1.12	Medline 72	
3.2	Pc-Based Information Products: Laser Disc 72	
3.2.1	International Veterinary Pathology Slide Bank (Ivpsb) 72	
3.3	Conclusion 73	
	References 73	
	Further Reading 74	
4	Electronic Records, Reporting, and Submission: eCTD and Send	75
4.1	Introduction 75	
4.2	Submission of Send Data In Module 4 of The eCTD 76	
4.3	Send Background 76	
4.4	Send Regulatory 77	
4.5	Send Features 77	
4.6	Send Study Submission Package 80	
4.7	Determination of Studies That Need Data To Be Submitted As Send Files 80	
4.7.1	FDA Center 80	
4.7.2	Type of Application 80	
4.7.3	Study Start Date 80	
4.8	Storage of Files At The Fda 81	
4.9	Recommended Regulatory Resources 81	
	References 81	
5	Screens in Safety and Hazard Assessment	83
5.1	Introduction 83	
5.2	Characteristics of Screens 84	
5.3	Uses of Screens 86	
5.4	Types of Screens 87	
5.4.1	Single Stage 87	
5.4.2	Sequential 87	
5.4.3	Tier (or Multistage) 87	
5.5	Criterion: Development And Use 87	
5.6	Analysis Of Screening Data 88	
5.7	Univariate Data 89	
5.7.1	Control Charts 89	
5.7.2	Central Tendency Plots 90	
5.7.3	Multivariate Data 90	
5.7.4	The Analog Plot 91	
	References 92	

6 Formulations, Routes, and Dosage Regimens	95
6.1 Introduction	95
6.2 Mechanisms	97
6.2.1 Local Effects	97
6.2.2 Absorption and Distribution	98
6.2.3 Metabolism	99
6.3 Common Routes	99
6.3.1 Dermal Route	99
6.3.2 Parenteral Routes	100
6.3.3 Bolus versus Infusion	102
6.3.4 Oral Route	103
6.3.5 Minor Routes	111
6.3.6 Route Comparisons and Contrasts	113
6.4 Formulation Of Test Materials	113
6.4.1 Preformulation	114
6.4.2 Dermal Formulations	117
6.4.3 Interactions Between Skin, Vehicle, and Test Chemical	119
6.4.4 Oral Formulations	120
6.4.5 Parenteral Formulations	121
6.5 Dosing Calculations	122
6.6 Calculating Material Requirements	122
6.7 Excipients	123
6.7.1 Regulation of Excipients	123
References	128
7 Mechanisms And End Points Of Drug Toxicity	131
7.1 Manifestations	131
7.2 Mechanisms Of Toxicity	132
7.3 End Points Measured In General Toxicity Studies	132
7.3.1 Clinical Observations	132
7.3.2 Body Weights	132
7.3.3 Food and Water Consumption	133
7.3.4 Clinical Signs	133
7.3.5 Clinical Chemistry and Pathology	136
7.3.6 Hematology	137
7.3.7 Gross Necropsy and Organ Weights	137
7.3.8 Histopathology	137
7.3.9 Ophthalmology	140
7.3.10 Cardiovascular Function	140
7.3.11 Neurotoxicology	140
7.3.12 Immunotoxicology	140
7.3.13 Imaging and Telemetry	141
7.4 Complications	141
References	141
8 Pilot Toxicity Testing In Drug Safety Evaluation: MTD and DRF	143
8.1 Introduction	143
8.2 Range-Finding Studies	143
8.2.1 Lethality Testing	144
8.2.2 Using Range-Finding Lethality Data in Drug Development: The Minimum Lethal Dose	150
8.3 Acute Systemic Toxicity Characterization	153
8.3.1 Minimal Acute Toxicity Test	153

- 8.3.2 Complete Acute Toxicity Testing 157
- 8.3.3 Acute Toxicity Testing with Nonrodent Species 161
- 8.3.4 Factors that Can Affect Acute Tests 163
- 8.3.5 Selection of Dosages 164
- 8.4 Screens 165
 - 8.4.1 General Toxicity Screens 165
 - 8.4.2 Specific Toxicity Screening 168
- 8.5 Pilot And DRF Studies 169
- References 171

9 Repeat-Dose Toxicity Studies 173

- 9.1 Objectives 173
- 9.2 Regulatory Considerations 175
 - 9.2.1 Good Laboratory Practices 175
 - 9.2.2 Animal Welfare Act 175
 - 9.2.3 Regulatory Requirements for Study Design 176
- 9.3 Study Design and Conduct 176
 - 9.3.1 Animals 176
 - 9.3.2 Routes and Setting Doses 177
 - 9.3.3 Parameters to Measure 178
 - 9.3.4 Study Designs 179
- 9.4 Study Interpretation and Reporting 180
- 9.5 Read Across For Program Wide Evaluation 180
- References 181

10 Genotoxicity 183

- 10.1 ICH Test Profile 183
- 10.2 DNA Structure 184
 - 10.2.1 Transcription 185
 - 10.2.2 Translation 185
 - 10.2.3 Gene Regulation 185
 - 10.2.4 DNA Repair 185
 - 10.2.5 Error-Prone Repair 186
 - 10.2.6 Mismatch Repair 186
 - 10.2.7 The Adaptive Repair Pathway 186
 - 10.2.8 Plasmids 186
 - 10.2.9 Plasmids and DNA Repair 187
 - 10.2.10 Nature of Point Mutations 187
 - 10.2.11 Suppressor Mutations 187
 - 10.2.12 Adduct Formation 187
 - 10.2.13 Mutations Due to Insertion Sequences 188
 - 10.2.14 The Link Between Mutation and Cancer 188
 - 10.2.15 Genotoxic Versus Nongenotoxic Mechanisms of Carcinogenesis 188
 - 10.2.16 Genetic Damage and Heritable Defects 189
 - 10.2.17 Reproductive Effects 190
- 10.3 Cytogenetics 190
 - 10.3.1 Cytogenetic Damage and Its Consequences 190
 - 10.3.2 Individual Chromosomal Damage 190
 - 10.3.3 Chromosome Set Damage 191
 - 10.3.4 Test Systems 191
 - 10.3.5 *In vitro* Test Systems 192
 - 10.3.6 Bacterial Mutation Tests 194
 - 10.3.7 Controls 195

- 10.3.8 Plate Incorporation Assay 198
- 10.3.9 Eukaryotic Mutation Tests 199
- 10.3.10 *In vitro* Tests for the Detection of Mammalian Mutation 199
- 10.3.11 *In Vivo* Mammalian Mutation Tests 207
- 10.4 *In vitro* Cytogenetic Assays 208
 - 10.4.1 Cell Types 208
 - 10.4.2 Chinese Hamster Cell Lines 208
 - 10.4.3 Human Peripheral Blood Lymphocytes 208
 - 10.4.4 Positive and Negative Controls 209
 - 10.4.5 Treatment of Cells 209
 - 10.4.6 Scoring Procedures 210
 - 10.4.7 Data Recording 210
 - 10.4.8 Presentation of Results 210
- 10.5 *In vivo* Cytogenetic Assays 210
 - 10.5.1 Somatic Cell Assays 211
 - 10.5.2 Germ Cell Assays 211
 - 10.5.3 Heritable Chromosome Assays 211
 - 10.5.4 Germ Cell Cytogenetic Assays 211
- 10.6 Sister Chromatid Exchange Assays 212
 - 10.6.1 Relevance of SCE in Terms of Genotoxicity 212
 - 10.6.2 Experimental Design 212
- 10.7 How to Deal with Positive Test Results 213
- References 214

11 QSAR Tools For Drug Safety 223

- 11.1 Structure–Activity Relationships 223
 - 11.1.1 Basic Assumptions 224
 - 11.1.2 Molecular Parameters of Interest 224
- 11.2 Sar Modeling Methods 224
- 11.3 Applications In Toxicology 226
 - 11.3.1 Metabolism 227
 - 11.3.2 Reproductive 227
 - 11.3.3 Eye Irritation 227
 - 11.3.4 Lethality 227
 - 11.3.5 Carcinogenicity 228
- 11.4 Genotoxicity 230
 - 11.4.1 QSAR for Mutagenicity 230
- 11.5 Comparison Of Available Models/Applications 231
 - 11.5.1 QSAR of Metabolism 231
 - 11.5.2 Meteor 232
 - 11.5.3 Derek 232
 - 11.5.4 Leadscope 233
 - 11.5.5 VEGA 233
 - 11.5.6 Derek versus Leadscope 235
- 11.6 Near Neighbor Surrogates And Their Use 237
- References 238

12 Toxicogenomics 241

- 12.1 Introduction 241
- 12.2 Uses of Toxicogenomics 242
- References 243

13 Immunotoxicology In Drug Development	247
13.1 Introduction	247
13.2 Overview of The Immune System	249
13.3 Immunotoxic Effects	250
13.4 Immunosuppression	251
13.4.1 Immunosuppressive Drugs	253
13.5 Immunostimulation	256
13.5.1 Hypersensitivity (or Allergenicity)	257
13.5.2 Photosensitization	259
13.5.3 Autoimmunity	260
13.6 Regulatory Positions	262
13.6.1 CDER Guidance for Investigational New Drugs	263
13.7 Evaluation of The Immune System	265
13.7.1 Immunopathologic Assessments	267
13.7.2 Humoral (Innate) Immune Response and Possible Entry Points for Immunotoxic Actions	268
13.7.3 Cell-Mediated Immunity	271
13.8 Nonspecific Immunity Function Assay	273
13.8.1 Natural Killer Cell Assays	273
13.8.2 Macrophage Function	273
13.8.3 Mast Cell/Basophil Function	273
13.9 T-Cell-Dependent Antibody Response (TDAR)	274
13.9.1 Treatment	274
13.9.2 Hypersensitivity	275
13.9.3 Local Lymph Node Assay (LLNA)	277
13.9.4 Photosensitization	279
13.10 Approaches To Compound Evaluation	280
13.10.1 Use of <i>in vivo</i> Tests	280
13.10.2 Use of <i>in vitro</i> Tests	281
13.10.3 Assessment of Immunotoxicity and Immunogenicity/Allergenicity of Biotechnology-Derived Drugs	282
13.10.4 Suggested Approaches to Evaluation of Results	282
13.11 Problems And Future Directions	283
13.11.1 Data Interpretation	284
13.11.2 Appropriate Animal Models	284
13.11.3 Indirect Immunotoxic Effects	284
13.11.4 Hypersensitivity Tests	284
13.11.5 Anaphylaxis Tests	284
13.11.6 Autoimmunity	285
13.11.7 Functional Reserve Capacity	285
13.11.8 Significance of Minor Perturbations	285
13.11.9 Biotechnology Products	286
13.12 Summary	286
References	286
14 Nonrodent Animal Studies	293
14.1 Introduction	293
14.2 Comparison Between Rodent And Nonrodent Experimental Design	293
14.2.1 Number of Animals	293
14.3 Differences In Study Activities	294
14.3.1 Blood Collection	294
14.3.2 Dosing	294
14.3.3 Handling of Animals	294
14.3.4 Behavioral Evaluation	294

14.4	Nonrodent Models	294
14.5	Dog	294
14.5.1	Environmental and Dietary Requirements	294
14.5.2	Common Study Protocols	295
14.5.3	General Study Activities	296
14.5.4	Advantages and Disadvantages	297
14.6	The Ferret	297
14.6.1	Environmental and Dietary Requirements	297
14.6.2	Study Protocols	298
14.6.3	General Study Activities	298
14.6.4	Advantages and Disadvantages	299
14.7	The Pig	299
14.7.1	Background	299
14.7.2	Clinical Laboratory	300
14.7.3	Xenobiotic Metabolism	301
14.7.4	Dermal Toxicity	302
14.7.5	Cardiovascular Toxicity	303
14.7.6	Advantages and Disadvantages	303
14.8	The Rabbit	303
14.8.1	Excretion	304
14.8.2	Husbandry	304
14.8.3	Dosing Techniques	305
14.8.4	Collection Techniques	307
14.8.5	Study Designs	308
14.8.6	Metabolism	308
14.9	Nonhuman Primates	315
14.9.1	Environmental and Dietary Requirements	316
14.9.2	Common Study Protocols	316
14.9.3	General Study Activities	317
14.9.4	Advantages and Disadvantages	319
14.10	Issues In Animal Model Selection	319
14.11	Statistics In Large Animal Studies	319
14.11.1	Reasons for Small Sample Sizes in Large Animal Toxicology	319
14.11.2	Cross-Sectional or Longitudinal Analysis?	320
14.11.3	Repeated Measures: Advantages	320
14.11.4	Repeated Measures: Disadvantages	320
14.11.5	Common Practices in Large Animal Toxicology	320
14.11.6	Univariate (Repeated Measures) Techniques: Advantages	320
14.11.7	Univariate (Repeated Measures) Techniques: Disadvantages	321
14.11.8	Multivariate Techniques: Advantages	321
14.11.9	Multivariate Techniques: Disadvantages	321
14.11.10	Some Other Design Factors to Be Considered in Analysis	321
14.11.11	Covariates: Advantages	321
14.11.12	Covariates: Disadvantages	321
14.11.13	Missing Values	324
14.12	Read Across For Cross Species Data Integration	325
14.13	Summary	325

15 Developmental And Reproductive Toxicity Testing **331**

15.1	Introduction	331
15.2	Ich Study Designs	333
15.2.1	Male and Female Fertility and Early Embryonic Development to Implantation	333

- 15.2.2 Embryo–Fetal Development 335
- 15.2.3 Adverse Effects 335
- 15.2.4 Pre- and Postnatal Development 335
- 15.2.5 Single-Study and Two-Study Designs for Rodents 336
- 15.2.6 Preliminary Studies 336
- 15.2.7 Potential Male Mediated Developmental Effects 337
- 15.2.8 Toxicokinetics 338
- 15.2.9 Timing of Studies 338
- 15.3 Methodological Issues 339
 - 15.3.1 Control of Bias 339
 - 15.3.2 Diet 339
 - 15.3.3 Clinical Pathology 340
 - 15.3.4 Gravid Uterine Weights 340
 - 15.3.5 Implant Counts and Determination of Pregnancy 341
 - 15.3.6 Fetal Examinations 342
 - 15.3.7 Developmental Signs 343
 - 15.3.8 Behavioral Tests 344
 - 15.3.9 Detecting Effects on Male Reproduction 344
- 15.4 Developmental Studies In Primates 344
- 15.5 Data Interpretation 345
 - 15.5.1 Use of Statistical Analyses 345
 - 15.5.2 Potential Hazard Categories of Developmental Toxins 347
 - 15.5.3 Associations Between Developmental and Maternal Toxicity 349
 - 15.5.4 Assessment of Human Risk 349
- 15.6 Juvenile And Pediatric Toxicology 351
- 15.7 *In Vitro* Tests For Developmental Toxicity 353
- 15.8 Appraisal of Current Approaches For Determining Developmental And Reproductive Hazards 357
- References 358

16 Carcinogenicity Studies

363

- 16.1 Introduction 363
 - 16.1.1 History Of Xenobiotic Carcinogenesis 365
- 16.2 Mechanisms And Classes Of Carcinogens 365
- 16.3 Genotoxic Carcinogens 365
- 16.4 Epigenetic Carcinogens 368
- 16.5 Regulatory Requirements And Timing 371
 - 16.5.1 Waivers of Required Testing 371
- 16.6 Species And Strain 372
- 16.7 Animal Husbandry 373
- 16.8 Dose Selection 373
 - 16.8.1 Number of Dose Levels 373
 - 16.8.2 Number of Control Groups 374
 - 16.8.3 Criteria for Dose Selection 374
- 16.9 Group Size 375

PREFACE

This fourth edition of *Drug Safety Evaluation* is a revision of the third edition that maintains the central objective of presenting an all-inclusive practical guide for those who are responsible for ensuring the safety of drugs and biologics to patients and shepherding valuable candidates to market, healthcare providers, those involved in the manufacture of medicinal products, and all those who need to understand how the safety of these products is evaluated. The many changes in regulatory requirements, pharmaceutical development, technology, and the effects of Covid on our society and science have required both extensive revision to every chapter and the addition of four new chapters.

This practical guide presents a road map for safety assessment as an integral part of the development of new drugs and therapeutics. Individual chapters also address specific approaches to evaluation hazards, including problems that are encountered and their solutions. Also covered are the scientific and philosophical bases for evaluation of specific concerns (e.g. carcinogenicity and development toxicity) to provide both understanding and guidance for approaching the new problems that have come to face both our society and the new challenges they brought. *Drug Safety Evaluation* specifically aims at the pharmaceutical and biotechnology industries. It addresses not only the general cases for safety evaluation of small and large molecules but also all of the significant major subcases: imaging agents, dermal and inhalation route drugs, vaccines, and gene therapy products. It is hoped that the approaches and methodologies presented here will show a utilitarian yet scientifically valid path to the everyday challenges of safety evaluation and the problem solving that is required in drug discovery and development.

Shayne Cox Gad
Raleigh, North Carolina

ABOUT THE AUTHORS

Shayne Cox Gad, B.S. (Whittier College, Chemistry and Biology, 1971) and Ph.D. in Pharmacology/Toxicology (Texas, 1977) DABT, ATS, is the principal of Gad Consulting Services, a 24-year-old consulting firm with 7 employees and more than 450 clients (including 200 pharmaceutical companies in the United States and 50 overseas). Before this, he served in the director level and in the abovementioned positions at Searle, Synergen, and Becton Dickinson. He has published 48 books and more than 350 chapters, articles, and abstracts in the fields of toxicology, statistics, pharmacology, drug development, and safety assessment. He has more than 39 years of broad-based experience in toxicology, drug and device development, statistics, and risk assessment. He has specific expertise in neurotoxicology, *in vitro* methods, cardiovascular toxicology, inhalation toxicology, immunotoxicology, and genotoxicology. He was the past president of the American College of Toxicology (ACT), the Roundtable of Toxicology Consultants, and three of Society of Toxicology (SOT's) specialty sections. He has direct involvement in the preparation of Investigational New Drugs (INDs) (110 successfully to date), New Drug Application (NDA), Product License Application (PLA), Abbreviated New Drug Application (ANDA), 501(k), Investigational Device Exemption (IDE), Common Technical Document (CTD), clinical databases for phase 1 and 2 studies, and PMAs. He has consulted for Food and Drug Administration (FDA), Environmental Protection Agency (EPA), and National Institutes of Health (NIH) and has trained reviewers and been an expert witness for FDA. He has also conducted the triennial toxicology salary survey as a service to the profession for the past 27 years.

Dr. Shayne Cox Gad is also a retired line officer in Navy.

Dexter W. Sullivan Jr., MS, DABT, is the senior toxicologist of Gad Consulting Services where he consults on issues related to toxicology, pharmaceutical and medical device development, regulatory affairs, and human health risk assessment. He has authored and co-authored over 40 peer-reviewed publications, journal articles, book chapters, and abstracts in the abovementioned fields. Dexter is a Diplomate of the American Board of Toxicology and a member of the SOT as well as a member of the ACT. As an active member of the ACT, he has served as a member of the ACT Social Media Subcommittee and currently chairs the ACT Webinar Subcommittee. As a service to the scientific community, he has co-authored the toxicology salary survey for the past 10 years. As a consultant, Dexter has supported the successful preparation and filings for countless INDs as well as NDAs. He has consulted for EPA and performed thousands of human health risk assessments, including assessments for the EPA National Center for Environmental Assessment (NCEA) and the EPA Office of Water (OW). Dexter received his BS in Toxicology from the University of Louisiana at Monroe and his MS in Biology from Western Kentucky University.

1

THE DRUG DEVELOPMENT PROCESS AND THE GLOBAL PHARMACEUTICAL MARKETPLACE

1.1 INTRODUCTION

Pharmaceuticals are a global industry, grossing \$1.25 trillion (US dollars) in 2019. They are developed to benefit (and sell to) individuals and societies worldwide. Their effectiveness and costs affect, directly or indirectly, all of us.

This fourth edition focuses (as its predecessors did) on the assessment of the safety of new drugs. In the broadest sense, this means it must address not only the traditional “small molecules” that have dominated the field for the last century and the large therapeutic molecules derived from biotechnology sources but also vaccines, biologics such as blood and blood products, cell therapies, and excipients. The globalization of the regulation of the safety, efficacy, and manufacture of pharmaceutical products comes from the success of the International Conference on Harmonization (ICH) process. But, as will be seen, the same globalization of the industry and continuous advances of science have also led to market diversification of the types and uses of drugs, and with this, regulatory drug safety evaluation requirements continue to fragment, which has made things more complex rather than simpler (Alder and Zbinden, 1988; Gad, 2018; Norman 2016a, 2016b).

1.2 THE MARKETPLACE

The world marketplace for drugs is large, although the majority of sales are in three regions: in 2019 about 35% of the pharmaceutical market (by sales) resided in the United States, 24% in Europe, 12% in Japan, with the remaining 29% in emerging markets (Christel, 2019). This does not mean, however, that marketing applicants can or should ignore the requirements of other countries, for example, China and

Indonesia. Approval processes in these countries can at times be as rigorous as in any other regulatory authority’s domain.

Pharmaceuticals in all their forms compete today as part of a global market, though one which serves (and is available to) different parts of the world’s population to varying extents.

The term “pharmaceuticals” is here used in the broadest sense of man-made therapeutics: small molecules, large protein moieties, vaccines, blood products, and as must be, their attendant components (excipients, impurities, and all) to different degrees and in different types of products.

According to the Statista (2019) global pharmaceutical market and therapy report, the global market for regulated drugs (as differentiated from dietary supplements, herbal products, and nutraceuticals) is estimated to have been some \$1.25 trillion in 2019 (US dollars) (Drugs.com, 2014). In 2015, there were 143 individual products with annual sales in excess of \$1 billion (i.e., “blockbusters”) which have tended to be the focus of pharmaceutical development until recently and the impending demise of patents on which is changing the industry (Table 1.1). It remains to be seen how the Covid-19 pandemic influences 2020 and 2021 statistics.

This concentration of total sales in a limited number of products (e.g., there are currently more than 22 000 approved prescription drugs in the United States) is widely held to have distorted the therapeutic aspects of new drug development but is now starting to undergo change (back to) a paradigm that looks at a decreased emphasis on the billion dollar “blockbuster” drugs.

Widely misunderstood is the extent and diversity of the pharmaceutical R&D sector. While precise numbers are unavailable (and meaningless, as companies are continuously being started, merged, or going out of business, though the overall trend is to increased numbers), best estimates place the number of companies directly involved in discovering

TABLE 1.1 Top 20 Selling Pharmaceuticals (2019) (Sharma, 2020)

Rank	Drug	Current manufacturer	Total sales 2019	Total sales 2018	Total sales 2017	Primary disease/ medical use	Route(s)
			In billions, USD				
1	Humira (adalimumab)	AbbVie, Inc. and Eisai	19.16	20.3	Not available	Rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, adult, and pediatric Crohn's disease, plaque psoriasis, juvenile idiopathic arthritis, ulcerative colitis, axial spondyloarthritis (EU only), hidradenitis suppurativa, pediatric enthesitis-related arthritis (EU only), panuveitis, Behcet's disease (Japan only)	Injection
2	Keytruda (pembrolizumab)	Merck & Co.	11.08	7.17	3.8	Non-small cell lung cancer, melanoma, head, and neck squamous cell cancer, urothelial bladder cancer, kidney cancer, microsatellite instability-high cancer, classical Hodgkin lymphoma, gastric cancer, cervical cancer, primary mediastinal B-cell lymphoma, hepatocellular carcinoma, Merkel cell carcinoma	Injection
3	Revlimid (lenalidomide)	Bristol-Myers Squibb and Ono Pharmaceutical	9.37	9.69	8.19	Anemia, multiple myeloma, myelodysplastic syndromes, mantle cell lymphoma, follicular lymphoma	Oral
4	Elquis (apixaban)	Bristol-Myers Squibb	7.92	9.87	7.4	Reduce risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation; deep vein thrombosis and pulmonary embolism	Oral
5	Eylea (aflibercept)	Regeneron Pharmaceutical, Bayer, Saten Pharmaceutical	7.54	7.16	6.39	Neovascular (wet) age-related macular degeneration, macular edema following central retinal vein occlusion, diabetic macular edema, diabetic retinopathy	Intraocular

and developing new drugs in the United States and Canada at about 3800, 10% of which are publicly traded. There are an equal number in Europe and significant numbers in many other parts of the world (Japan, China, Australia, India, and Israel, to name just a few other countries). While most of the public focuses on very large companies, such as those in Table 1.2, there are many more midsize and small companies.

Starting in 1984 with the Drug Price Competition and Patent Term Restoration Act (better known as the Hatch–Waxman Act), members of small-molecule drugs leaving the

period of patent protection could be introduced into the marketplace by an ANDA-approved route—a much simpler and quicker route to market approval. Such generics constituted 81% of the prescriptions in the United States by 2019, though their market share by sales (\$260 billion in 2012) is only 21% of revenues (Statista, 2019).

One factor to consider in the regulatory requirements for early development of new therapeutic entities is the higher degree to which costs may present barriers to smaller, innovative companies. This is commonly overlooked by many

TABLE 1.2 Top 20 Drug Companies Worldwide by Pharma and Biopharma Sales (2019) (PMLive, 2015; Wright, 2020)

Rank	Company HQ Location	Sales (in billions, USD)	R&D Spend (in billions, USD)	Revenue (in billions, USD)	Top three selling drugs (in billions, USD)

who also do not recognize that such small companies (most of which fail) are the primary initial source of new therapeutics. Increasing regulatory requirements (both new required data and electronic data) such as SEND have increased the upfront (pre-Phase 2) barriers to small companies developing new drugs.

A second complicating factor in considering the “pharmaceutical” market sector is the diversity of products involved. The most basic expression of this is the division of drugs into “small molecules” (which currently still constitute approximately two-thirds of both INDs—applications for clinical evaluation of a new drug in humans and 70% of current new drug approvals) and biotechnology products (which constitute the bulk of the remainder—biologics such as vaccines are increasing in importance). The challenges in both developing and assessing the safety of these are very different. As will also be seen, if one considers further division into therapeutic claim areas (oncology, anti-infectives, cardiovascular, CNS, etc.), the differences become even more marked. Most of what will be presented and discussed in this volume speaks to regulatory requirements for non-clinical safety assessment in the general case for either small molecules or protein therapeutics. It should be kept in mind that this general case development model never fully applies.

Additionally, there is now a significant hybrid area—combination products, which include both device and drug (small-molecule or biologic) components. These will be addressed in a separate chapter of the book, though there is no single dedicated regulatory arm (such as a center within

the FDA truly dedicated to only their regulation) in any major market country or such. For that reason, more exploration of regulatory considerations will be provided in the chapter on these products.

The extent of regulations and practices for drug approval causes pharmaceutical companies to spend an enormous amount of resources on developing applications, following different standards for preclinical and nonclinical programs for specific therapeutic areas, as well as time and resources to satisfy the regulatory processes for clinical trials. Because of the regulatory diversity that existed, representatives from the regulatory authorities and trade associations came together in the late 1980s and early 1990s to attempt at harmonizing the process for drug approvals. Clearly, this was a daunting task. With time, however, the ICH of Technical Requirements for Registration of Pharmaceuticals for Human Use has become increasingly more effective. Fortunately, the abbreviation for this very long title is ICH. Japan, Europe, and the United States represent the major pharmaceutical market for the world, and these regions have the most influence on developments within ICH and tend to follow the guidance documents that are prepared. However, other countries (rest of the world [ROW]) follow the developments within ICH and tend to follow the guidance offered by ICH. However, it remains important, when seeking for the registration of pharmaceuticals, to be aware of local country regulations. For example, China has become a major economic force in many aspects. Placement of pharmaceutical manufacturing facilities and the marketing of drugs in China may potentially represent a

significant marketing advantage to companies. With this new market area in Asia, regulatory processes are being developed; sometimes, it seems at the whim of the government. With time, it is hoped that China will align itself more with the processes and guidance that have been developed by ICH, FDA, and other further developed countries.

There are two recent changes to regulatory drug development and approval. The first, which will be discussed in detail in Chapter 2, are various routes to drug approval that have become prominent since 2012. The most significant of these are accelerated approval, breakthrough therapy, and fast-track designation. The summary of approvals/filings of each of these is described in Tables 1.3–1.5 (National Institute of Health).

Orphan drug designation has also become a significant influence on drug development. Though such a designation does not influence requirements for drug approval, it does confer significant financial benefits post approval. The 2020 COVID-19 pandemic with resulting efforts to rapidly provide both new (or repurposed) therapeutics and vaccines has had significant influence on both what drugs are being developed and in providing (under the CARES act) its own accelerated route to clinical use and approval. On the negative side, COVID-19 has made the conduct of clinical trials for other uses more difficult due to concern for protecting patients in trial from infection.

1.3 HISTORY OF MODERN THERAPEUTICS

Although, prior to the nineteenth century, preventive medicine had made some spectacular advances, for example, through nutrition (scurvy), control of infectious diseases (such as smallpox, polio, and tuberculosis), and public health through sanitation, and control of childbirth fever and surgical infections using antiseptic techniques, truly therapeutic medicine was virtually nonexistent until the end of the nineteenth century.

Oliver Wendell Holmes (a physician and US Supreme Court Justice) wrote in 1860: “I firmly believe that if the whole material medica, as now used, could be sunk to the bottom of the sea, it would be all the better for mankind—and the worse for the fishes.” While there were a few effective medicines—digitalis, extract of willow bark, and quinine, for example—on balance, Holmes was quite correct, medicines did more harm than good.

The first edition of the *British Pharmacopoeia* (1864), which listed 311 preparations, gives an idea of the state of therapeutics at the time. Of those listed, 187 preparations were plant-derived materials and only nine of which were purified substances. Most of the plant products—lemon juice, rose hips, yeasts, etc.—lacked any components we would now regard as therapeutically relevant, but some (digitalis, castor oil, ergot, and colchicum) were pharmacologically active. Of the 311 preparations, 103 were truly synthetic

inorganic chemicals such as iodine, ferrous sulfate, sodium bicarbonate, and toxic salts of bismuth, arsenic, lead, and mercury, with but a few synthetic chemicals (diethyl ether and chloroform). The remainders were miscellaneous materials and a few animal products, such as lard, cantharidin, and cochineal.

For the pharmaceutical industry, the transition to an actual industry and discipline occurred late in the nineteenth

^aIn FY 2013, an upgrade to the system of record changed how Fast Track Designation Requests are recorded. Beginning 2013, data are reported as of 12/31 of the stated fiscal year. Data prior to FY 2013 come from a legacy report, and are reported through 5/21/2013.

^bOther accounts for scenarios where the Fast Track Designation Request could not be granted or denied (Withdrawn Fast Track Designation request, Withdrawn Application, Inactivated IND, etc.).

century when three essential technologies came together. These were the science of biomedicine (especially pharmacology), synthetic organic chemistry, and the development of a chemical industry in Europe, coupled with a medical supplies/products trade.

Science began to be applied wholeheartedly to medicine—as to almost every other aspect of life—only late in the nineteenth century. Among the most important milestones from the point of view of drug discovery was the elab-

TABLE 1.5 CDER Breakthrough Therapy Designation Requests Received by Fiscal Year

Fiscal Year	Total			
	Requests Received	Granted	Denied	Withdrawn
2012	2	1	1	0
2013	92	31	52	9
2014	96	31	51	14
2015	93	32	43	18
2016	106	46	48	12
2017	111	50	49	12
2018	136	59	60	17
2019	156	67	68	21

Breakthrough therapy designation was enacted in the Food and Drug Administration Safety and Innovation Act on July 9, 2012.

oration in 1858 of cell theory. This tremendous reductionist leap of the cell theory gave biology—and the pharmaceutical industry—the fundamental scientific underpinning it required. It is only by thinking of living systems in terms of the function of their cells that one can begin to understand how molecules affect them.

A second milestone was the birth of pharmacology as a scientific discipline when the world’s first Pharmacological Institute was set up in 1874 at Dorpat (then in Germany—now in Estonia) by Rudolf Buchheim—literally by Buchheim himself, as the Institute was in his own house and funded by his estate. This was advanced by pioneers, such as Magendie and Claude Bernard, and linked to therapeutics.

Another vital spark on this road came with Louis Pasteur’s germ theory of disease, proposed in Paris in 1878. A chemist in training, Pasteur’s initial interest was in the process of fermentation of wine and beer and the souring of milk. He showed, famously, that airborne infection was the underlying cause and concluded that the air was actually alive with microorganisms. Particular types, he argued, were pathogenic to humans and accounted for many forms of disease including anthrax, cholera, and rabies. Pasteur successfully introduced several specific immunization procedures to give protection against infectious diseases. Robert Koch, Pasteur’s rival and near-contemporary, clinched the infection theory by observing anthrax and other bacilli in the blood of infected animals.

The founder of chemotherapy—some would say the father of molecular pharmacology—was Paul Ehrlich. He invented “vital staining”—staining by dyes injected into living animals—and described how the chemical properties of the dyes, particularly their acidity and lipid solubility, influenced the distribution of dye to particular tissues and cellular structures. Thence came the idea of specific binding

of molecules to particular cellular components. This led not only to Ehrlich's study of chemotherapeutic agents but also became the basis of pharmacological thinking to the present day. "Receptors" and "magic bullets" were Ehrlich's terms, though he envisaged receptors as targets for toxins rather than physiological mediators. Working in Koch's Institute, Ehrlich developed diphtheria antitoxin for clinical use and put forward a theory of antibody action based on specific chemical recognition of microbial molecules, a work for which he won the 1908 Nobel Prize.

The first synthetic organic chemicals to be used for medical purposes were not therapeutic agents at all, but rather anesthetics. Diethyl ether ("sweet oil of vitriol") was first made and described in 1540. Early in the nineteenth century, diethyl ether and nitrous oxide (prepared by Sir Humphrey Davy in 1799 and found—by self-experimentation—to have stupor-inducing properties) had their usefulness as surgical anesthetics demonstrated only in the 1840s, by which time chloroform had also made its appearance. Synthetic chemistry at the time could deal only with very simple molecules, made by recipe rather than rational understanding of the underlying chemistry reasons, as our understanding of chemical processes, and molecular structure was still in its infancy. The first therapeutic drug to truly come from synthetic chemistry was amyl nitrite, prepared in 1859 by Guthrie and used in treating angina by Brunton in 1864. This was the first example of a drug born in a recognizably "modern" way through the application of synthetic chemistry, physiology, and clinical medicine. This was a landmark indeed, for it was nearly 40 years before synthetic chemistry made any further significant contribution to therapeutics and not until well into the twentieth century that physiological and pharmacological knowledge began to be applied to the invention of new drugs.

During the latter half of the nineteenth century, the foundations of synthetic organic chemistry were laid, the impetus coming from work on aniline, a copious by-product of the coal-tar industry, with the discovery of how to produce a purple dye. This discovery gave birth to the synthetic dyestuffs industry, which played a major part in establishing the commercial potential of synthetic organic chemistry—a technology which later became the underpinning of the evolving pharmaceutical industry for the next century. A systematic approach to organic synthesis went hand in hand with improved understanding of chemical structure.

Despite the limited efficacy of the pharmaceutical preparations that were available in the nineteenth century ("patent medicines"), the pharmacists trade flourished; then, as now, physicians felt themselves obligated to issue prescriptions to satisfy the expectations of their patients for some therapeutic action—or at least cause for hope. Early in the nineteenth century, a few enterprising chemists undertook the task of isolating the active substances from these plant extracts. The

trend began with Friedrich Serturner, a junior apothecary in Westphalia, who in 1805 isolated and purified morphine, barely surviving a test of its potency on himself. This was the first "alkaloid," so named because of its ability to neutralize acids and form salts. This discovery in turn led to the isolation of other plant alkaloids, including strychnine, caffeine, and quinine. The recognition that medicinal plants owed their properties to their individual chemical constituents, rather than to some intangible property associated with their living nature, marks a critical point in the history of the pharmaceutical industry which can be recognized as the point of origin of two of the three roads from which the industry grew—namely, the beginnings of the "industrialization" of the pharmaceutical trade. This revelation hinted at the future and the possibility of making drugs artificially.

The first local apothecary business to move into large-scale production and marketing of pharmaceuticals was the old, established Darmstadt firm Merck originally founded in 1668. This development, in 1827, was stimulated by the advances in purification of natural products. Merck was closely followed in this astute business move by other German- and Swiss-based apothecary businesses, giving rise to some which later also became giant pharmaceutical companies, such as Schering and Boehringer. The American pharmaceutical industry emerged in the middle of the nineteenth century; Squibb began in 1858 with ether as its main product. The move into pharmaceuticals was also followed by several chemical companies such as Bayer, Hoechst, Agfa, Sandoz, Geigy, and others, which began as dyestuffs manufacturers. The dyestuffs industry at that time was also based largely on plant products, which had to be refined and were sold in relatively small quantities, so the commercial parallels with the pharmaceutical industry were plain.

After 1870, with the crucial discovery by Kekule of the structure of benzene, the dyestuffs industry turned increasingly to synthetic chemistry as a source of new compounds, starting with aniline-based dyes. A glance through any modern pharmacopeia will show the overwhelming preponderance of synthetic aromatic compounds, based on the benzene ring structure, among the list of useful drugs. Understanding the nature of aromaticity was critical.

Thus, the beginnings of the pharmaceutical industry as we now know it, at the latest, date from about third of the 1800s, with origins in the apothecaries and patent medicine trades on the one hand and the dyestuffs industry on the other. Unfortunately, these enterprises had rather few effective products to sell (mainly inorganic compounds of varying degrees of toxicity and others most charitably described as concoctions).

Entering the 1900s, synthetic drugs had been made and tested, including the "antipyretics" and various central nervous system depressants. Chemical developments based on

chloroform had produced chloral hydrate, the first nonvolatile CNS depressant, which was in clinical use for many years as a hypnotic drug. Independently, various compounds based on urea were found to act similarly, and von Mering followed this lead to produce the first barbiturate, barbitone (since renamed barbital), which was introduced in 1903 by Bayer and gained widespread clinical use as a hypnotic, tranquilizer, and antiepileptic drug—the first blockbuster. Barbitone and procaine were triumphs for chemical ingenuity but owed little or nothing to physiology or indeed pharmacology. The physiological site or sites of action of barbiturates remain unclear to this day, and their mechanism of action at the molecular level was unknown until the 1980s. Large-scale research laboratories for pharma studies appeared in the 1930s. But it was the development and commercialization of penicillin during and immediately after World War II that changed the practice of medicine and certainly the world of pharmaceuticals. It is a fascinating history (Posner, 2020).

The pattern of drug discovery driven by synthetic chemistry—with biology often struggling to keep up—became the established model in the early part of the twentieth century and prevailed for at least 50 years. The balance of research in the pharmaceutical industry up to the 1970s placed chemistry clearly as the key discipline in drug discovery, the task of biologists being mainly to devise and perform assays capable of revealing possible useful therapeutic activity among the many anonymous white powders that arrived for testing. Research management in the industry was largely in the hands of chemists. This strategy produced many successes, including benzodiazepine tranquilizers, several antiepileptic drugs, antihypertensive drugs, antidepressants, and antipsychotic drugs. The practice of classifying many drugs based on their chemical structure rather than on the more logical basis of their site or mode of action (therapeutic class) stems from this era. It has since shifted to classifying drugs by either broad therapeutic claim or mechanism of action.

We have mentioned the early days of pharmacology, with its focus on plant-derived materials, such as atropine, tubocurarine, strychnine, digitalis, and ergot alkaloids, which were almost the only drugs that existed until well into the twentieth century. Despite the rise of synthetic chemistry, natural products not only remain a significant source of new drugs, particularly in the field of chemotherapy, but also in other applications. Following the discovery of penicillin by Fleming in 1929, and its development as an antibiotic for clinical use by Chain and Florey in 1938, an intense search was undertaken for antibacterial compounds produced by fungi and other microorganisms, which yielded many useful antibiotics, including chloramphenicol (1947), tetracyclines (1948), streptomycin (1949), and others. The same fungal source that yielded streptomycin also produced actinomycin D used in cancer chemotherapy.

Higher plants have continued to yield useful drugs, including vincristine and vinblastine (1958), paclitaxel (or taxol, 1971), and ixabepilone (2007). Demain and Vaishnav (2011) provide an excellent review of this from the perspective of cancer chemotherapy.

Outside the field of chemotherapy, successful drugs derived from natural products include cyclosporin (1972) and tacrolimus (1993), both of which come from fungi and are used to prevent transplant rejection. Soon after came Mevastatin (1976), another fungal metabolite, which was the first of the “statin” series of cholesterol-lowering drugs which act by inhibiting the enzyme HMG-CoA reductase.

Overall, the pharmaceutical industry continues to have something of an on-again, off-again relationship with natural products. They often have weird and wonderful structures that cause hardened chemists to turn pale; they are often near-impossible to synthesize, troublesome to produce from natural sources, and “optimizing” such molecules to make them suitable for therapeutic use is prone to frequent failure. But nature continues to unexpectedly provide some of our most useful drugs, and most of its potential remains untapped.

Although chemistry was the preeminent discipline in drug discovery until at least the 1970s, the seeds of the biological revolution were sown long before. Starting foremost in the field of chemotherapy, where Ehrlich defined the principles of drug specificity in terms of a specific interaction between the drug molecule and a target molecule—the “receptor site”—in the organism, although we now take it for granted that in almost all cases a highly specific chemical target molecule, as well as the “pharmacophore” or an outline portion of the drug molecule, determines what effects a therapeutic will yield, before Ehrlich no one had envisaged drug action in this way. By linking chemistry and biology, Ehrlich defined the parameters of modern drug discovery.

Despite these discoveries in Ehrlich’s field, chemotherapy remained empirical rather than target directed. That said, for many years, Ehrlich’s preoccupation with curing syphilis and the binding of chemical dyes, as exemplified by biological target-based drug development from the 1950s onwards, steadily shifted the industry’s focus from chemistry to biology (Hill and Rang, 2012). The history of successes in the field of chemotherapy prior to the antibiotic era (Table 1.3) demonstrates the diversity of sources of new therapeutic entities. The popular image of “magic bullets”—(a phrase first used by Ehrlich in 1905)—is the essence of today’s target-directed approaches to drug discovery.

More recently, as this book will show, all new categories of therapeutic entities (biotechnology-derived monoclonal antibodies, cell tissue therapies, and gene therapies) have entered use in medicine as “drugs” (Table 1.6).

TABLE 1.6 Examples of Drugs from Different Sources

Natural Products	Synthetic Chemistry ^a	Biopharmaceuticals Produced by Recombinant DNA Technology
Antibiotics (penicillin, streptomycin, tetracyclines, cephalosporins, etc.)	Early successes include	Human insulin (the first biotech product, registered 1982)
Anticancer drugs (doxorubicin, bleomycin, actinomycin, vincristine, vinblastine, taxol, etc.)	Antiepileptic drugs	Human growth hormone
Atropine, hyoscine	Antimetabolites	α -interferon, γ -interferon
Ciclosporin	Barbiturates	Hepatitis B vaccine
Cocaine	Bronchodilators	Tissue plasminogen activator (t-PA)
Colchicine	Diuretics	Hirudin
Digitalis (digoxin)	Local anesthetics	Blood-clotting factors
Ephedrine	Sulfonamides	Erythropoietin
Heparin		Granulocyte and granulocyte–monocyte
Human growth hormone ^b		Colony-stimulating factor (G-CSF, GM-CSF)
Insulin (porcine, bovine) ^b		
Opium alkaloids (morphine, papaverine)		
Physostigmine		
Rauwolfia alkaloids (reserpine)		
Statins		
Streptokinase		
Tubocurarine		
Vaccines		

^aSince about 1950, synthetic chemistry has accounted for the great majority of new drugs.

^bNow largely or entirely replaced by material prepared by recombinant DNA technology.

1.4 THE DRUG DEVELOPMENT PROCESS

While the processes for the discovery of new potential therapeutic drugs are very diverse (Gad, 2005; Choerghade, 2006; Mathieu, 2008; Gad, 2016), once the decision is made to move a candidate compound forward to (hopefully) market approval, the general process is well defined in the components of its regulatory requirements (though with significant variability and frequent change in its details). It has many components which are beyond the scope of safety assessment, and therefore of this volume (including chemical development, clinical evaluation, and a host of regulatory actions.)

The process generally proceeds by way of getting regulatory concurrences for entering clinical trials, then proceeding through three (not strictly defined) stages of clinical trials (Phase I, Phase II, and finally Phase III), followed by submission of a full set of documents, data, and a proposed label seeking regulatory approval for a marketing application.

The metrics of this process as it now operates make cancer the most prevalent therapeutic target for new drugs, with perhaps as many as one-third of all new drug candidates being in this claim area. Heart diseases, CNS diseases, nervous system diseases, and immune system disorders follow in order of current popularity (Table 1.4).

According to the Center for Drug Evaluation and Research (CDER) 12328 different new (NME) drugs and nonbiosimilar INDs are in development in 2019, spread across the entire course of the development process. A total of 7471 of these were commercial INDs, while 4857 were “research” INDs.

At the same time, the metrics of regulatory applications for the development of new drugs in the United States (where the best data is available) show a continued increase in the number of candidates entering the development process as indicated by the number of new (or original) INDs filed, with the proportion of these that are commercial (or traditional INDs) continuing to increase (see Table 1.7).

TABLE 1.7 Potential New Drugs in US Clinical Trials by Primary Disease/Medical Use as of July 2020

Disease/Medical Use	No. of Potential New Drugs in US Clinical Trials
Total number of new drugs currently in clinical trials in the USA	346 614
Cancers and other neoplasms	395 916
Symptoms and general pathology	318 839
Nervous system diseases	244 326
Behaviors and mental disorders	180 152
Heart and blood diseases	177 166
Digestive system diseases	175 900
Rare diseases	161 355
Urinary tract, sexual organs, and pregnancy conditions	150 677
Immune system diseases	134 658
Nutritional and metabolic diseases	133 083
Respiratory tract (lung and bronchial) diseases	123 817
Blood and lymph conditions	122 547
Skin and connective tissue diseases	97 820
Viral diseases	90 721
Muscle, bone, and cartilage diseases	73 073
Diseases and abnormalities at or before birth	65 143
Gland and hormone-related diseases	62 863
Eye diseases	34 793
Wounds and injuries	32 781
Mouth and tooth diseases	24 592
Ear, nose, and throat diseases	19 731
Substance-related disorders	12 492
Bacterial and fungal diseases	11 499

Vitamins	35 551
Other dietary supplements	11 362
Herbal and botanical	10 292
Amino acids	5 314
Mineral	656
Flavonoid	546

Source: Data from clinicaltrials.gov.

Also, at the same time, the rate of approval of new molecular entities has only recently recovered to levels of 30 a year for the last 2 years. This preceding multiyear “drought” finally caused recognition that the traditional/existing system of development focused on blockbusters is irretrievably broken (Table 1.8).

1.5 STRATEGIES FOR DEVELOPMENT: LARGE VERSUS SMALL COMPANY OR THE SHORT VERSUS LONG GAME

While harmonization and societal concern for safety are driving the changes in regulatory processes for device and drug development to become more confused, strategies for product development and the associated nonclinical safety assessment can still be viewed in terms of broad trends.

The driving truths behind strategies in developing new drugs are:

1. Most molecules will fail. While the true success rate is certainly greater than the often quoted 1 in 10 000, it is clear that only 3–5% of those that enter initial clinical evaluation (i.e., for which an IND “opens”) become marketed drugs. This rate varies depending on therapeutic class (oncology drugs having a success rate as low as 1–2% and CNS therapeutics being only somewhat higher) (Pangalos et al., 2007).
2. The cost of developing drugs is high—while not the currently quoted “average” of \$1.4 billion, just getting to the point of an IND opening will cost a minimum of \$2 million. One can spread out the rate of expenditure over time or shorten the required time by spending money more rapidly, but there are fixed minimums for cost and time.

Costs of development go up sharply with time/progress—subsequent to a plain vanilla first-in-man (FIM) trial, outlays come to be spoken of first in tens of millions, and (frequently) before a marketing approval filing in the hundreds of millions. Once the decision is made to develop a molecule into a drug, the process takes years. Again, one can dispute how many (from 5 to 16 years about covers the extreme range) and at no point up to the end is success (achieving marketing approval and economically successful therapeutic use) assured.

These truths conspire to produce the principal general goals behind drug development strategy:

1. Kill the losers as early as possible before too much money is spent on them.
2. Do all you can to minimize the time spent in developing a drug.

TABLE 1.8 INDs Received and Active at CDER

Calendar Year Received	Original INDs Received	Number of Active INDs at Years End	NDA's
1998	2419	12 723	121
1999	1763	12 584	139
2000	1812	11 838	115
2001	1872	10 873	98
2002	2374	11 544	105
2003	2120 (426 commercial)	12 661 (4 544 commercial)	109
2004	1837 (621 commercial)	12 778 (4 827 commercial)	115
2005	1934 (637 commercial)	13 360 (5 029 commercial)	116
2006	1863 (713 commercial)	14 117 (5 445 commercial)	123
2007	2589 (779 commercial)	14 566 (5 417 commercial)	124
2008	2039 (883 commercial)	15 892 (5 962 commercial)	128
2009	1554 (730 commercial)	9 299 (5 876 commercial)	146
2010	1330 (601 commercial)	9 633 (5 838 commercial)	103
2011	1404 (644 commercial)	9 883 (6 030 commercial)	105
2012	1284 (636 commercial)	9 627 (5 966 commercial)	33 (only recorded for 3 months)
2013	1429 (732 commercial)	10 205 (6 115 commercial)	133
2014	1508 (782 commercial)	10 802 (6 599 commercial)	123
2015	1564 (799 commercial)	10 973 (6 894 commercial)	146
2016	1669 (777 commercial)	11 274 (6 923 commercial)	94
2017	1672 (836 commercial)	11 641 (7 211 commercial)	134
2018	1594 (852 commercial)	11 223 (6 956 commercial)	134
2019	1678 (928 commercial)	12 328 (7 471 commercial)	110

These principles produce a spectrum of strategies in the nonclinical safety assessment of drugs, best illustrated by looking at the two extreme cases.

1.5.1 Do Only What You Must (The Short Game)

Driven by financial limitations and the plan that, at an optimal point in development (most commonly after either FIM/Phase I trials or a “proof of concept” Phase II trial), the candidate therapeutic will be licensed to or partnered with a large company, only the technical and regulatory steps necessary to get a molecule to this point are to be performed. For those pursuing this case, the guidance provided by this book should prove essential (though not generally completely sufficient). This approach is summarized in Figure 1.1 (Table 1.9).

1.5.2 Minimize the Risk of Subsequent Failure

This is considered the traditional big company model. Studies and technical tasks are not limited to the minimum but rather are augmented by additional components. Development proceeds through a series of well-defined and carefully considered “go-no-go” decision points. This approach is summarized in Figure 1.2. Many of the additional components are either limited, non-GLP forms of studies, which will be required later (such as Ames, acute toxicity, hERGs at only one concentration, and 7 days to 4 weeks repeat-dose studies), or studies which are inexpensive and could be done later (CYP inhibitors, induction, metabolic stability, and longer than required repeat-dose toxicity studies before proceeding into Phase II). Exactly which “extra” components are included vary from company to company and frequently reflect past experiences of the organization or individuals involved.

The studies performed to meet regulatory nonclinical safety assessment requirements (which must be considered to include all of the supportive toxicokinetic and metabolism activities and studies) can be thought of as belonging to three major categories:

- a. Those necessary to support the successful filing/opening of an IND, CTA, or equivalent application, and of the subsequent FIM clinical studies.
- b. Those required to support continuation of clinical evaluation and development of a drug, up to and through successful Phase III studies.
- c. Those studies required to support a successful marketing approval application (NDA, BLA, or equivalent) but only required as such. This group is typically exemplified for carcinogenicity studies and the formal reproductive (as opposed to developmental) toxicity studies.

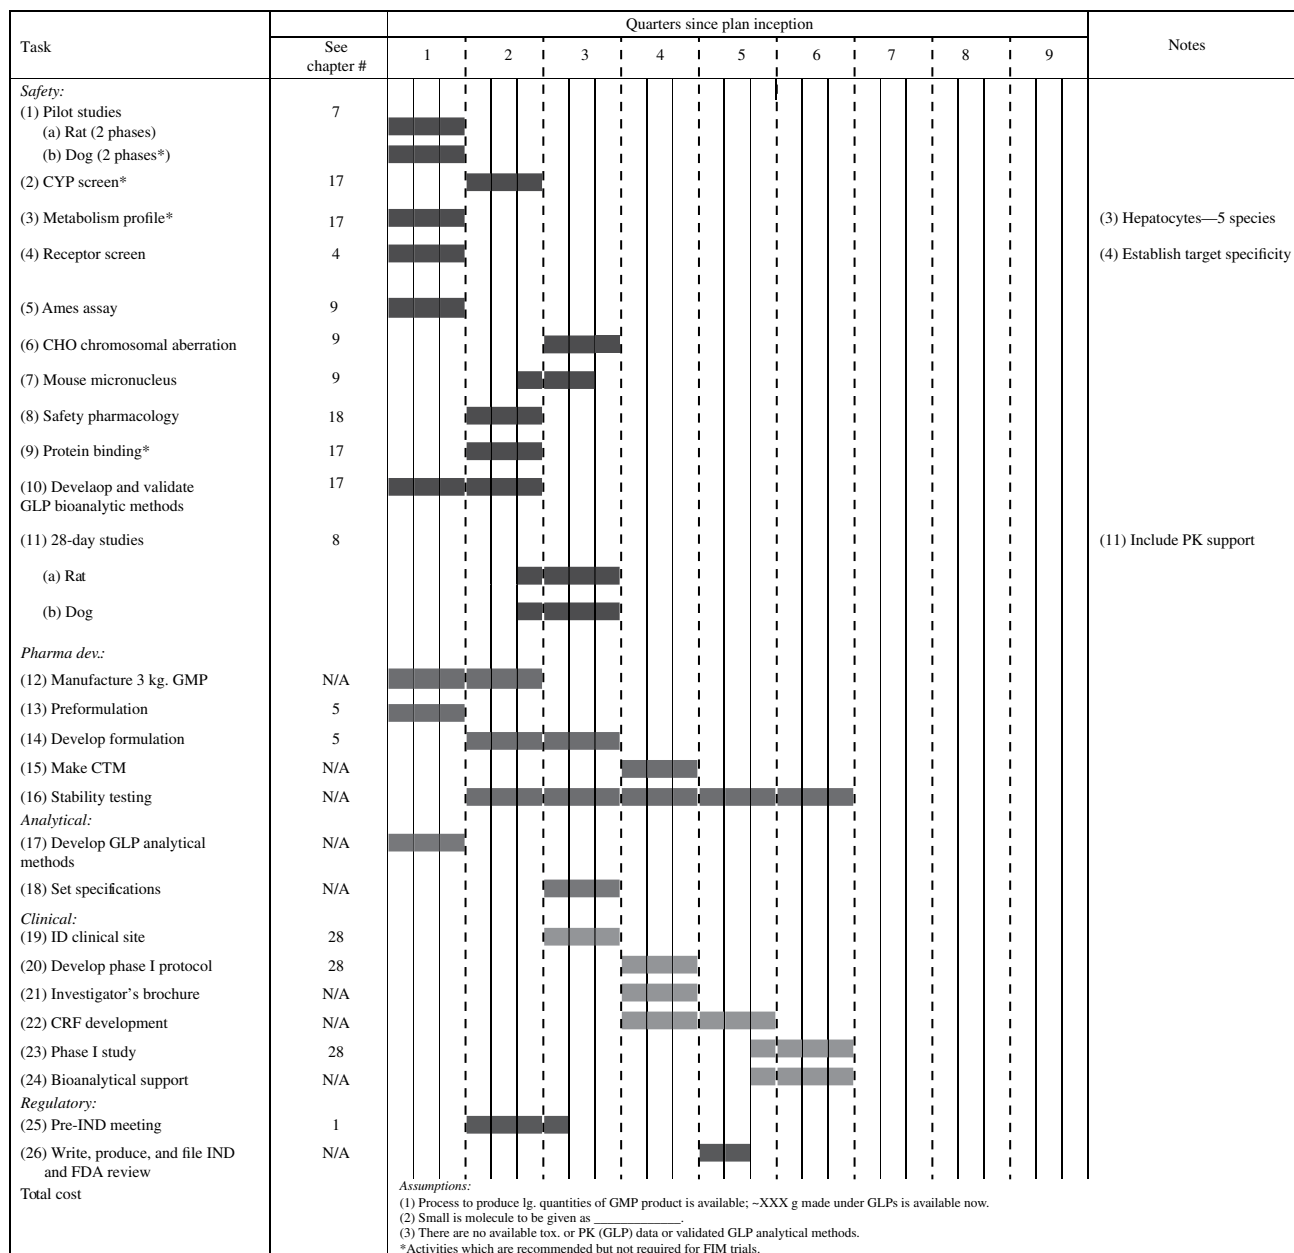

FIGURE 1.1 General case oral drug: lead through Phase I (do only what you must).

Which studies fit into what category is somewhat fluid and influenced by what patient population will be served (therapeutic claim) and the mechanism of action of the drug.

1.6 SAFETY ASSESSMENT AND THE EVOLUTION OF DRUG SAFETY

In the mid-nineteenth century, restrictions on the sale of poisonous substances were imposed in the United States and United Kingdom, but it was not until the early 1900s that any

system of “prescription-only” medicines was introduced, requiring approval of purchase by a licensed medical practitioner. Soon afterwards, restrictions began to be imposed on what “cures” could be claimed in advertisements for pharmaceutical products and what information had to be given on the label; legislation evolved at a leisurely pace. Most of the concern was with controlling frankly poisonous or addictive substances or contaminants, not with the efficacy and possible harmful effects of new drugs.

In 1937, the use of diethylene glycol as a solvent for a sulfonamide preparation caused the deaths of 107 children

TABLE 1.9 The Short Path to Investigational New Drug Application (IND)/Clinical Trials Application (CTA)

12	Make clinical drug product (formulation)	
13	If for IND, prepare clinical Investigator's Brochure (IB)	

in the United States, and a year later, the 1906 Food and Drugs Act was revised, requiring safety to be demonstrated before new products could be marketed, as well as federal inspection of manufacturing facilities. The requirement for proven efficacy, as well as safety, was added in the Kefauver–Harris amendment in 1962 (said amendment being brought about largely by a safety issue—the thalidomide disaster in Europe).

In Europe, preoccupied with the political events in the first half of the century, matters of drug safety and efficacy were a minor concern, and it was not until the mid-1960s, in the wake of the thalidomide disaster—a disaster largely averted in the United States by an officer who used the provisions of the 1938 Food and Drugs Act to delay licensing

approval—that the United Kingdom began to follow the United States' lead in regulatory laws. Until then, the ability of drugs to do harm—short of being frankly poisonous or addictive—was not really appreciated, most of the concern having been about contaminants. In 1959, when thalidomide was first put on the market by the German company Chemie Grünenthal, it was up to the company to decide how much research was needed to satisfy itself that the drug was safe and effective. Grünenthal made a disastrously wrong judgment (see Sjöström and Nilsson (1972) for a full account), which resulted in an estimated 10 000 cases of severe congenital malformation following the company's specific recommendation that the drug was suitable for use by pregnant women. This single event caused an urgent reappraisal on a global scale, leading to the introduction of much tighter government controls.

By the end of the 1960s, the primary planks in the regulatory platform—evidence of safety, efficacy, and chemical purity—were in place in most developed countries. Subsequently, the regulations have been adjusted in various minor ways and adopted with local variations in most countries.

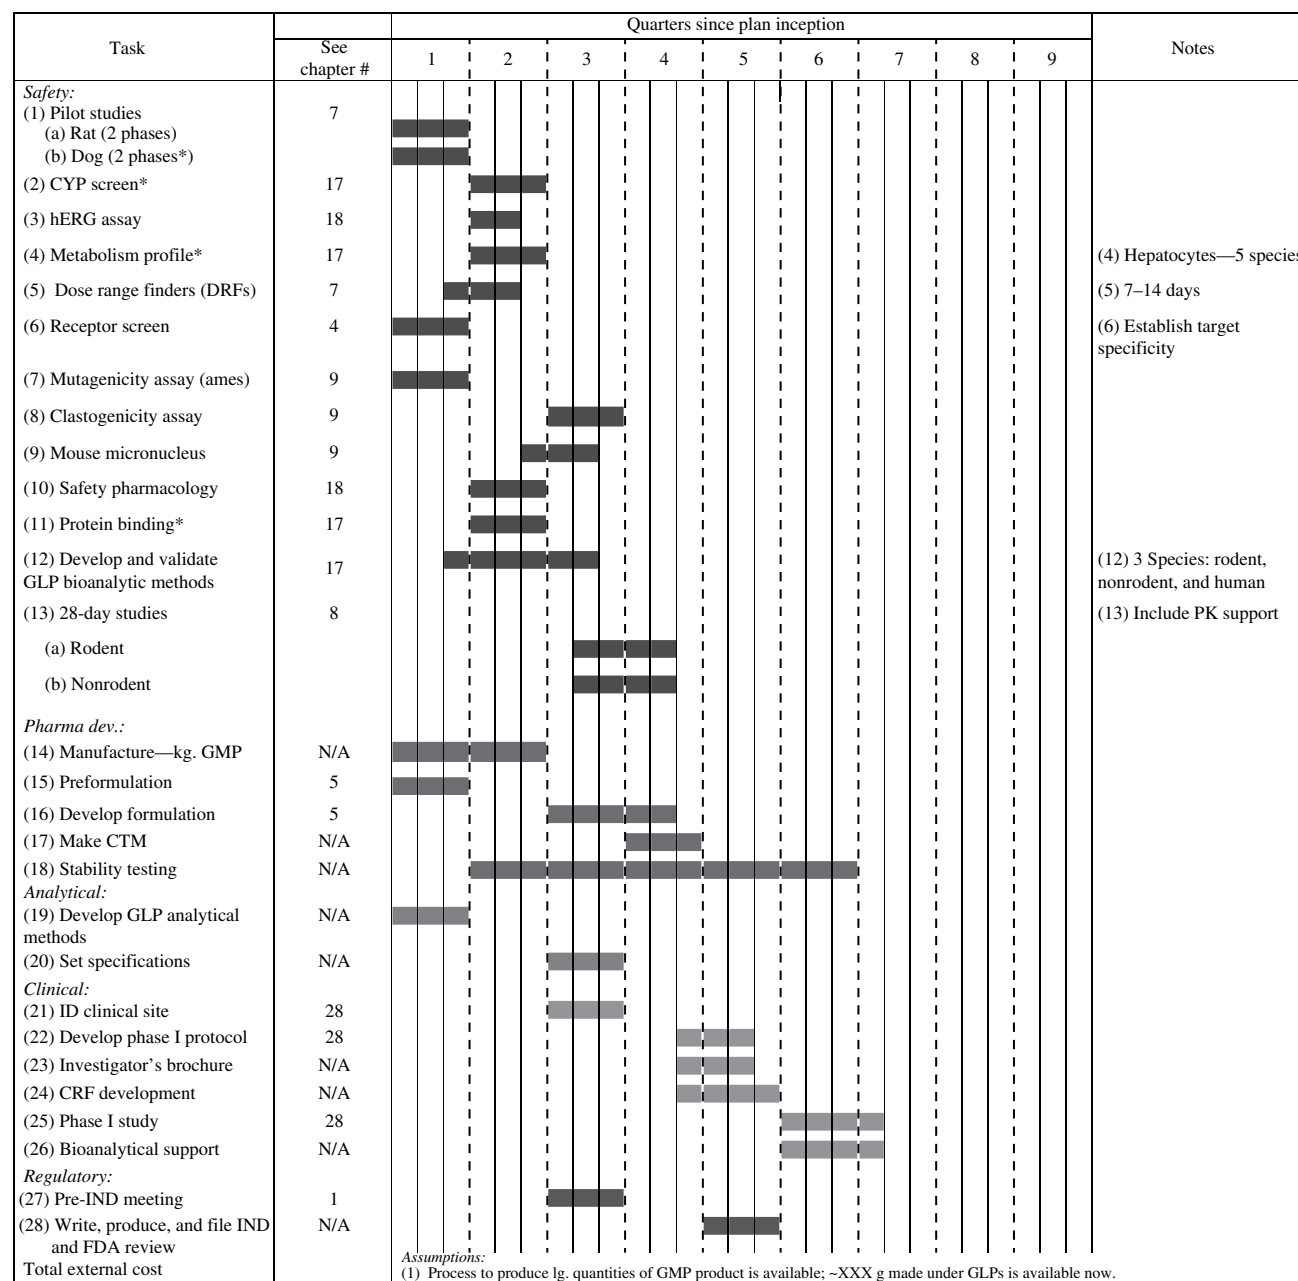

In 1988, Alder and Zbinden published *National and International Drug Safety Guidelines* which set forth the wide differences in safety assessment requirements between the different nations of the world, and at the time global development of a drug required multiple safety assessment programs, with a great number of repetitions of studies and attendant extra costs and increased usage of test animals.

The solution to this was that ICH paradigm which, starting in the late 1980s, sought to have a harmonized set of global requirements for all aspects of drug development (not just assessment). The safety assessment aspects were embodied primarily in the S series ICH guidelines (M4 which sets forth the overall structure of nonclinical requirements being an exception). This did serve to largely standardize ("harmonize") global requirements, with minor differences.

As the rest of this book will make clear, this system is now fraying a bit at the edges.

Recent additions of new guideline topic areas (e.g., immunotoxicology), revisions to existing guidelines (on genotoxicity and biotechnology), regional guideline responses to recent occurrences (the case in point being the failed TGN1412 FIM trial and the resulting two EMA special guidances issued in response to it), as well as differences in requirements for different therapeutic classes have reversed the harmonization trend (Gad, 2011).

Subsequently, also in Europe, a Phase I trial of BIA 10-2474, a fatty acid amide hydrolase (FAAH) inhibitor targeted at the body's endocannabinoid system and intended to treat mood anxiety and movement coordination issues, going drastically wrong. Six males received repeat doses of the

—: fill the number of Kg to be manufactured.

FIGURE 1.2 General case oral drug: lead through Phase I (minimize risk).

drug after 84 others had shown no marked effects. One was first pronounced brain dead but subsequently died, while three of the other five have also shown serious effects, perhaps irreversible.

The oral small-molecule drug was made by the Portuguese company Bial, but clinical tests were performed in a commercial CRO in France (BioTrial). A meta-analysis of noncancer Phase I drug trials, published last year in *The British Medical Journal*, found serious adverse events in only 0.31% of participants and no deaths (Chan, 2016).

1.7 THE THREE STAGES OF DRUG SAFETY EVALUATION IN THE GENERAL CASE

Nonclinical safety assessment studies fall into three categories, as will be examined in detail in the remainder of this book.

These are:

1. IND Enabling (“FIM”): the studies necessary to support the initiation of clinical trials in human beings.

These are generally as specified in ICH M3, and this is the most common and numerous of all the three categories.

2. To support continued clinical development: as clinical development proceeds, longer repeat-dose drug studies must be performed, reproductive and developmental toxicology studies must be done, and other ancillary studies are required.
3. To support filing for marketing approval: the final studies generally required to support marketing of drugs—such as carcinogenicity.

Which studies fall into each of these categories, and exactly what studies must be done to support the development of a drug for a specific therapeutic claim, is extremely variable. The general case—much as specified in ICH M3(R2)—gives us a starting place for understanding what must be done.

At the same time, the image of the pharmaceutical industry in society is problematic (even more so in 2015 with well-publicized incidences of firms buying marketing rights to established small-molecule drugs only to escalate prices 10 to 100-fold). The costs and economics of development are complex and not well understood (Greider, 2003; Angell, 2004; Goozner, 2004; Petersen, 2008), while the role and abilities of regulatory agencies are equally misunderstood (Hawthorne, 2005).

But the general case really applies to the simplest oral drug intended for chronic use, and more often than not, doesn't apply. In fact, it may never fully apply.

REGULATION OF HUMAN PHARMACEUTICAL SAFETY: ROUTES TO HUMAN USE AND MARKET

2.1 INTRODUCTION

The safety of pharmaceutical agents, medical devices, and food additives are the toxicology issues of the most obvious and longest-standing concern to the public. A common factor among the three is that any risk associated with a lack of safety of these agents is likely to affect a very broad part of the population, with those at risk having little or no knowledge as to undertaking this risk. Modern drugs are essential for life in our modern society, yet there is a consistent high level of concern about their safety.

This chapter examines the regulations which establish how the safety of human pharmaceutical products is evaluated and established in the United States and the other major international markets. As a starting place, the history of this regulation will be reviewed, and the current organizational structure of the Food and Drug Administration (FDA) will be briefly reviewed, along with the other quasigovernmental bodies that also influence the regulatory processes. The current structure and context of the regulations in the United States and overseas will also be presented. From this point, the general case of regulatory product development and approval will be presented. Nonclinical safety assessment study designs will be presented. The broad special case of biotechnology-derived therapeutic products and environmental concerns associated with the production of pharmaceuticals will be briefly addressed. The significant changes in regulation brought about by harmonization are also reflected.

As an aid to the reader, appendices are provided at the end of this book: a codex of acronyms that are used in this field, followed by a glossary which defines some key terms.

2.2 BRIEF HISTORY OF US PHARMACEUTICAL LAW

A synopsis of the history of US drug legislation is presented in Table 2.1. Here we will review the history of the three major legislative acts covering pharmaceuticals.

2.2.1 1906: Pure Food and Drug Act

As so eloquently discussed by Temin (1980), the history of health product legislation in the United States largely involves the passage of bills in Congress which was primarily in response to public demand. In 1902, for example, Congress passed the Biologics Act in response to a tragedy in St. Louis where 10 children had died after being given contaminated diphtheria toxins. Interestingly, the background that led to the passage of the first Pure Food and Drug Act in 1906 had more to do with food processing than drugs. The conversion from an agrarian to an urban society fostered the growth of a food-processing industry that was rife with poor practice. Tainted and adulterated food was commonly sold. Practices were sensationalized by the muckraking press, including books such as *The Jungle* by Upton Sinclair.

In the early debates in the US Congress on the Pure Food and Drug Act (passed in 1906), there was little mention of toxicity testing. When Harvey Wiley, chief of the Bureau of Chemistry, Department of Agriculture and driving force in the enactment of this early law, did his pioneering work (beginning in 1904) on the effects of various food preservatives on health, he did so using only human subjects and with no prior experiments in animals (Anderson, 1958). Ironically, work that led to the establishment of the FDA would probably not have been permitted under the current guidelines of the agency. Wiley's

TABLE 2.1 Important Dates in US Federal Drug Law

Year 1902	Event Passage of the Virus Act, regulating therapeutic serums and antitoxins. Enforcement by the Hygienic Laboratory (later to become the National Institutes of Health (NIH)), Treasury Department.
1906	Passage of Pure Food Act, including provisions for the regulations of drugs to prevent the sale of misbranded and adulterated products. Enforcement by the Chemistry Laboratory, Agriculture.
1912	Passage of the Sherley Amendment. Specifically outlawed any false label claims as to curative effect.
1927	Bureau of Chemistry renamed the Food, Drug, and Insecticide Administration.
1931	Renamed again to Food and Drug Administration.
1938	Passage of the Food, Drug, and Cosmetic Act. Superseded the law of 1906. Required evidence of safety, for example, studies in animals. Included coverage of cosmetics and medical devices. Specifically excluded biologics.
1944	Administrative Procedures Act, codifying public health laws: included provision that for a biological license to be granted, a product must meet standards for safety, purity, and potency. NIH also given the responsibility for developing biologics not developed by the private sector.
1945	Amendment to the 1936 Act requiring that the FDA examine and certify for release each batch of penicillin. Subsequently amended to include other antibiotics.
1949	Publication of the first set of criteria for animal safety studies. Following several revisions, guidelines published in 1959 as Appraisals Handbook.
1951	Passage of Durham–Humphrey Amendment. Provided the means for manufacturers to classify drugs as over the counter (not requiring prescription).
1953	Transfer of FDA to the Department of Health, Education, and Welfare (HEW) from Agriculture (now the Department of Health and Human Services).
1962	Passage of major amendments (the Kefauver bill) to the 1938 FDCA, which required proof of safety and effectiveness (efficacy) before granting approval of New Drug Applications. Required affirmative FDA approval.
1968	FDA placed under the Public Health Service of HEW.
1970	Controlled Substance Act and Controlled Substances Import and Export Act. Removed regulation of drug abuse from FDA (transferred to the Drug Enforcement Agency) and provided for stringent regulation of pharmaceuticals with abuse potential.
1972	Transfer of authority to regulate biologics transferred from NIH to FDA. The NIH retained the responsibility of developing biologics.
1973	Consumer Product Safety Act, leading to the formation of separate Consumer Product Safety Commission, which assumes responsibilities once handled by the FDA’s Bureau of Product Safety.
1976	Medical Device Amendment to the FDCA requiring for devices that not only effectiveness be proven but also safety.
1979	Passage of the Good Laboratory Practices Act.
1983	Passage of the first Orphan Drug Amendment to encourage development of drugs for small markets.
1984	Drug Price Competition and Patent Term Restoration Act intended to allow companies to recover some of the useful patent life of a novel drug lost due to the time it takes the FDA to review and approve. Also permits the marketing of generic copies of approved drugs.
1985	The “NDA rewrite” final rule. An administrative action streamlining and clarifying the New Drug Application process. Now embodied in 21 CFR 314.
1986	The US Drug Export Amendment Act of 1986. Permitted the export of drugs outside the United States prior to approval for the US market.
1987	The “IND rewrite” final rule. “to encourage innovation and drug development while continuing to assure the safety of (clinical) test subjects.” Federal Register 52:8798, 1987. Now embodied in 21 CFR 312.
1992	Prescription Drug User Fee Act. Established the payment of fees for the filing of applications (e.g., IND, NDA, PLA).
1994	Orphan Drug Amendment.

(Continued)

TABLE 2.1 (Continued)

Year 1902	Event Passage of the Virus Act, regulating therapeutic serums and antitoxins. Enforcement by the Hygienic Laboratory (later to become the National Institutes of Health (NIH)), Treasury Department.
1997	The Food and Drug Administration Modernization Act: to streamline the drug and device review and approval process.
2002, 2007 and 2012	The Food and Drug Administration Modernization Act Amendments.
2003	Pediatric Research Equity Act (PREA).
2020	Right to Try act—allows eligible patients (those who have been diagnosed with a life-threatening disease or concern) access to experimental therapies that have completed phase I trials but not been approved by the USFDA.
2020	Covid-19: Developing drugs and biological products for treatment or prevention, CDER and CBER, May 2020—a not publicly reviewed guidance formulated because of the urgency of need for means to treat and prevent patients in a global pandemic.

Note: Laws and amendments that have covered other aspects of FDA law, such as those governing food additives (e.g., FQPA), are not included in this table.

studies were not double blinded, so it is also doubtful that his conclusions would have been accepted by the present agency or the modern scientific community. Legislation in place in 1906 consisted strictly of a labeling law prohibiting the sale of processed food or drugs that were misbranded. No approval process was involved, and enforcement relied on postmarketing criminal charges. Efficacy was not a consideration until 1911, when the Sherley Amendment outlawed fraudulent therapeutic claims.

2.2.2 1938: Food, Drug, and Cosmetic Act

The present regulations are largely shaped by the law passed in 1938. It will, therefore, be discussed in some detail. The story of the 1938 Food, Drug, and Cosmetic Act (FDCA) begins in 1933. Franklin D. Roosevelt had just won his first election and installed his first cabinet. Walter Campbell was the chief of the FDA, reporting to Rexford Tugwell, the Undersecretary of Agriculture. The country was in the depths of its greatest economic depression. This was before the therapeutic revolution wrought by antibiotics in the 1940s, and medicine and pharmacy as we know them in the 2010s were not practiced. Most medicines were, in fact, self-prescribed. Only a relatively small number of drugs were sold via physicians' prescription. The use of so-called "patent" (because the ingredients were kept secret) preparations was rife, as was fraudulent advertising. Today, for example, it is difficult to believe that in the early 1930s a preparation such as Radithor (nothing more than a solution of radium) was advertised for treatment of 160 diseases. It is in this environment that one day in the winter of 1933, Campbell delivered a memo to Tugwell on an action level of an insecticide (lead arsenite) used on fruits. Tugwell briskly asked why, if the chemical was so toxic, was it not banned outright. He was amazed to find out from Campbell that the agency had no power to do so.

The 1906 law was designed to control blatantly misbranded and/or adulterated foods and drugs and relied on post facto criminal charges for enforcement. Safety and efficacy were not an issue so long as the product was not misbranded with regard to content. Premarketing review of a drug was an unknown practice. Thus, attempts at rewriting the old 1906 law to include control of bogus therapeutic claims and dangerous preparations proved to be unsatisfactory. Paul Dunbar of the FDA suggested to Campbell that an entirely new law was needed. A committee of FDA professionals and outside academic consultants drafted a new bill, which immediately ran into trouble because no one in Congress was willing to sponsor it. After peddling the bill up and down the halls of Congress, Campbell and Tugwell convinced Senator Royal Copeland of New York to sponsor the bill. Unknowingly at the time, Copeland put himself in the eye of a hurricane that would last for 5 years.

The forces that swirled around Copeland and the Tugwell Bill (Senate bill S.1944) were many. First was the immediate and fierce opposition from the patent medicine lobby. Flyers decried S.1944 as everything from a communist plot to un-American, stating it "would deny the sacred right of self-medication." In opposition to the patent, trade organizations were two separate but unlikely allies: a variety of consumer advocacy and women's groups (such as the American Association of University Women, whose unfaltering support for the bill eventually proved critical to passage) and the mainline professional organizations. Interestingly, many of these organizations at first opposed the bill because it was not stringent enough. There were also the mainline professional pharmacy and medical organizations (such as the American Medical Association (AMA) and the American Association of Colleges of Pharmacy) whose support for the bill ranged from neutral to tepid, but did grow over the years from 1933 to 1938.

Second, there was the basic mistrust on the part of Congress toward Tugwell and other "New Dealers." At the same time,

Roosevelt gave the measure only lukewarm support at best (legend has it that if it had not been for the First Lady, Eleanor, he would have given it no support at all) because of his political differences with Royal Copeland.

Third, there was a considerable bureaucratic turf war over the control of pharmaceutical advertising. Finally, despite all efforts of the various lobbying groups, there was no popular interest or support for the bill. By the end of the congressional period, S.1944 had died for lack of passage.

The following 5 years saw the introduction of new bills, amendments, and competing measures, as well as committee meetings and hearings, lobbying, and House/Senate conferences. The details of this parliamentary infighting make for fascinating history but are outside the scope of this book. The reader is referred to an excellent history of this period, *Food and Drug Legislation in the New Deal* (Jackson, 1970).

The FDA was surprised by the force and depth of the opposition to the bill. The proposed law contained the novel idea that a drug was misbranded if its labeling made any therapeutic claim which was contrary to general medical practice and opinion. The definition of a drug was broadened to include devices used for medical purposes.¹ *Adulteration* was defined as any drug product dangerous to health when used according to label directions. The patent manufacturers charged that the new bill granted too much discretionary power to a federal agency and that no manufacturer could stay in business except by the grace of the Department of Agriculture (there not being a Department of Health and Human Services at the time, and FDA not being an independent agency), a charge that may have been correct. In response to the patent trade lobbying effort, the FDA launched its own educational drive consisting of radio spots, displays (such as the sensationalized Chamber of Horrors exhibition, in which the toxicity of a variety of useless medicines was clearly displayed), mimeographed circulars, speaking engagements, posters, etc.

Ruth Lamb, FDA information officer at the time, was perhaps one of the hardest working and most quotable of the FDA staffers working the street at the time. For example, in reference to one of the counter bills that had language similar to the original Copeland bill, but with extremely complicated enforcement provisions, Ruth Lamb called it “an opus for the relief of indigent and unemployed lawyers.” She once described the Bailey amendment, which would have made proprietary drugs virtually immune to multiple seizures, as permitting the “sale of colored tap water as a cure for cancer . . . unless arsenic was added to each dose making [it] immediately dangerous.” After 1934, however, the educational efforts of the FDA were greatly attenuated by federal laws prohibiting lobbying by federal agencies.

¹The use of a broad definition of what constitutes a drug for regulatory purposes is a precedent that remains in place today. For example, the computer software used in diagnostic systems is considered to be a pharmaceutical for purposes of regulation.

With the autumn of 1937 came the beginnings of the oft-told Elixir of Sulfanilamide incident, which remains one of the nation’s worst drug tragedies. The Massengill Company was not one of the industry giants, but neither was it a “snake oil peddler.” The company’s chief chemist, Harold Watkins, was simply trying to develop a product and, in fact, did so in a manner consistent with the norms of the time. There was a perceived need for a liquid form of sulfanilamide, but it was difficult to dissolve. Then, Watkins hit upon diethylene glycol (at 72%) for use as a solvent. No toxicity tests were performed on the finished product, although the product did pass through the “control lab,” where it was checked for appearance, fragrance, and consistency.

The first reports of human toxicity occurred in October 1937 when Dr. James Stevenson of Tulsa requested some information from the AMA because of six deaths in his area that were attributable to the elixir. At the time, no product of Massengill stood accepted by the Council on Pharmacy and Chemistry, and the Council recognized no solution of sulfanilamide. The AMA telegraphed Massengill, requesting samples of the preparation for testing. Massengill complied. The test revealed diethylene glycol to be a toxic agent, and the AMA issued a general warning to the public on October 18, 1937. In the meantime, the FDA had become aware of the deaths and launched an investigation through its Kansas City station. By October 20, when at least 14 people had died, Massengill wired the AMA to request an antidote for their own product. By the end of October, at least 73 people had died, and another 20 suspicious deaths were linked to the drug. Had it not been for the response of the FDA, more deaths may have occurred. The agency put its full force of field investigators (239 members) on the problem and eventually recovered and accounted for 99.2% of the elixir produced. Massengill fully cooperated with the investigation and in November published a public letter expressing regret over the matter, but further stating that no law had been broken. In fact, the company was eventually convicted on a long list of misbranding charges and fined a total of \$26000 (the largest fine ever levied under the 1906 law).

The Massengill incident made the limits of the 1906 law quite clear. Because there were no provisions against dangerous drugs, the FDA could move only on the technicality of misbranding. The term *elixir* was defined by the US Pharmacopeia (USP) as “a preparation containing alcohol,” which elixir of sulfanilamide was not. It was only this technicality that permitted the FDA to declare the “elixir” misbranded, to seize the inventory, and to stop the sale of this preparation. If it had been called *solution of sulfanilamide*, no charges could have been brought.

The extensive press coverage of the disaster became part of the national dialogue. Letters poured into congressmen demanding action to prevent another such tragedy. Medical and pharmacy groups and journals insisted that a new law was required. Congress was in special session in November 1937

and did not need to be told about the tragedy. Copeland and Representative Chapman (of Kentucky) pressed resolutions calling for a report from the FDA on the tragedy. When issued, the FDA Report stunned Congress not only because of the human disaster but also because it had made apparent the fact that even if the bill had then been presented before the Congress and had been passed as law, the entire tragedy would still have occurred because there were no provisions for toxicity testing before new drugs entered the market. By December 1937, a new bill, S.3037, was introduced which stated that manufacturers seeking to place new drugs on the market would be required to supply records of testing, lists of components, descriptions of each manufacturing process, and sample labels. Drugs would require certification by the FDA before the sale was permitted. A similar bill was introduced in the House by Chapman, although the issues of which agency was to control advertising of drugs still festered in the House. In January 1938, debate started on the Wheeler–Lea Bill, which would ensure that all controls over drug advertising would remain with the Federal Trade Commission (FTC). Despite strong opposition by the FDA, the Wheeler–Lea Bill was signed into law in March 1938. While the loss of advertising control was a blow to the FDA, the Wheeler–Lea Bill did facilitate the passage of the new food and drug law.

With the issue of advertising controls settled, the Copeland–Chapman Bill faced one last hurdle. Section 701, which had been added in the committee, provided for appeal suits that could be entered in any federal district court to enjoin the agency from enforcing new regulations promulgated as a result of the Act. Interestingly, this issue had more to do with foods than drugs, as its major focus was with acceptable tolerance limits for insecticides in food. The new bill defined an *adulterated food* as one containing any poison. However, as the efforts to remove insecticides from fresh fruits and vegetables had never been completely successful, the Secretary of Agriculture needed this power to set tolerance levels. Allies of food producers tried to introduce provisions in the new bill that provided methods for stalling a tolerance regulation with rounds of appeals. The bill was passed by the House despite such provisions (Section 701) and despite the resistance of consumer groups and the FDA and went into joint committee. Roosevelt, in one of his rare efforts to support the FDA, made it clear that he would not accept the bill with such a cumbersome appeals process. The resulting compromise was an appeals process which limited the new evidence that could be introduced into one of the 10 circuit courts. Other provisions regarding labeling were also rectified in joint committee. In May 1938, S.3073 was passed by unanimous vote. Both the chambers ratified the joint committee report, and Franklin Delano Roosevelt signed the new law in June of 1938.

A historical note to this story was that Royal Copeland did not live to see his measure passed. In May 1938, he collapsed on the Senate floor. His death occurred 1 month before President Roosevelt signed his bill into law.

2.2.3 1962: Major Amendment

The 1938 law very much changed the way Americans purchased pharmaceutical agents. In effect, it changed the pharmaceutical industry from a traditional consumer product industry to one in which purchases were made as directed by a third party (the physician). In 1929, ethical pharmaceuticals (prescription drugs) comprised only 32% of all medicines. By 1969, this was up to 83% (Temin, 1980). This led to a peculiar lack of competition in the ethical market. In 1959, Senator Estes Kefauver initiated his now-famous hearings on the drug industry. Interestingly, almost 30 years later, Senator Edward Kennedy had hearings on exactly the same matter. In 1961, Kefauver submitted a proposed legislation to amend the 1938 Act in such a way as to increase FDA's oversight of the drug industry. The proposed amendment contained two novel propositions. The first was compulsory licensing, which would have required, for example, company "A" to license (with a royalty of no greater than 8% of sales) and company "B" to market a drug patented by company "A." Company "A" would have only 3 years' exclusivity with its patent. The second novel provision was that new drugs had to be not only "safe" but also "efficacious." There was not a ground swell of support for this legislation. When it was reported out of committee, it had been rewritten (including the removal of the licensing requirement) to the point that even Kefauver refused to support it. The Kennedy administration wanted new legislation but did not specifically support the Kefauver Bill; rather it introduced its own legislation, sponsored by Representative Orrin Harris of Arkansas, and with little support.

As in 1938, a tragic incident would again intercede in the legislative process: 1961 would see the development of the thalidomide tragedy. An antianxiety agent marketed in Europe, thalidomide, was prescribed for pregnancy-related depression and nausea (or "morning sickness") and taken by countless women. At about the same time, phocomelia, a birth defect marked by the imperfect development of arms and legs, appeared in Europe. Thalidomide was eventually determined to be the causative teratogen in 1961 and was subsequently taken off the European market. The William S. Merrell Company had applied for a New Drug Application (NDA) for thalidomide in the United States in 1960. It was never approved because the FDA examiner, Dr. Frances Kelsey, had returned the application for lack of sufficient information. In accordance with the then-operative law, it was tested clinically in women in the United States, leading to the birth of more than a thousand children with birth defects. Eventually, the company withdrew the application. Senator Kefauver's staff had uncovered the thalidomide story as it was unfolding and had turned its findings over to the *Washington Post*. The *Post* reported the episode under the headline "Heroine of the FDA Keeps Bad Drug off the Market" in July 1962, 3 days after the Kefauver Bill was reported out of committee. Needless to say,

the news created public support for the bill, which was sent back to the committee and reported out again with new language in August 1962. The Kefauver–Harris Bill was signed into law in October 1962. It was demonstrated after the fact that thalidomide was teratogenic in the rabbit; out of the episode grew the current practice of testing new human pharmaceuticals for teratogenicity in two species, one generally being the rabbit.

The 1962 Drug Amendment made three major changes in the manner in which new drugs could be approved (Merrill, 1994). First, and perhaps the most important, was that it introduced the concept of effectiveness into the approval process. An NDA had to contain evidence that the drug was not only safe but also effective. The 1938 law contained no such specification. The effectiveness requirement necessitated that a drug company had to do more extensive clinical trials. The new law required that a company apply to the FDA for approval of its clinical testing plan under an Investigational New Drug Application (INDA). No response from the FDA was deemed to be acceptance. As each level of clinical testing came to require FDA review and approval, the new law made the FDA an active partner in the development of all drugs.

The second major change enacted under the 1962 law was the change in the approval process from premarket notification to a premarket approval system. Under the terms of the 1938 law, an NDA would take effect automatically if the FDA did not respond. For example, the only reason thalidomide was not approved was because Dr. Kelsey returned the application to the sponsor with a request for more information. In contrast, the 1962 law required affirmative FDA action before a drug could be put on the market. Under the terms of the 1962 amendments, the FDA was also empowered to withdraw NDA approval and remove a drug from the market for a variety of reasons, including new evidence that the product was unsafe or that the sponsor had misrepresented or underreported data. The basic nonclinical safety-testing regimen which currently applies was developed and adapted in that time frame (Goldenthal, 1968).

The third major change enlarged the FDA's authority over clinical testing of new drugs. Thus, not only was evidence of effectiveness required, but Section 505(d) of the Act specified the types of studies required. "Substantial evidence consisting of adequate and well-controlled investigations, including clinical investigations by a qualified expert." In meeting the statutory requirement for setting standards of clinical evidence, the FDA has become highly influential in the design of drug testing regimens (Merrill, 1994). Interestingly, discussed in detail by Hutt (1987), the FDA was initially quite unprepared for this new level of responsibility. It was not until 1973 that audited regulations on the determination of safety and effectiveness were put into place (these were, in fact, approved by the Supreme Court). While there have been several procedural changes (e.g., the 1985 Investigational New Drug (IND) rewrite) and additions (e.g., the 1988 IND procedures for life-

threatening disease treatment), there have been no major changes in the law through 1992 with Prescription Drug User Fee Act (PDUFA), 1997 with Food and Drug Administration Modernization Act (FDAMA) (amended in 2002, 2007, and 2012), and 2017 with the Food and Drug Administration Reauthorization Act (FDARA).

We must interject with an interesting historical aside at this point. Despite its reputation, thalidomide made a bit of a comeback in the 1990s (Blakeslee, 1998). Among other properties, thalidomide has been shown to have good anti-inflammatory properties, since it apparently decreases the synthesis and/or release of tissue necrosis factor.

2.2.4 1992, 1997, 2002, 2007, 2012, and 2017: PDUFA, FDAMA, and FDARA

The history of pharmaceutical regulations has been dominated by two oft-opposing schools of thought: the need to provide the citizenry with effective medicaments and the need to protect the consumer from unsafe and misbranded products. The reader is referred to Peter B. Hutt's in-depth reviews (Hutt, 1983a, b) on the subject. For example, the very first federal drug legislation in the United States was the Vaccine Act of 1813, which mandated the provision of the smallpox vaccine to the general public. In the modern era, legislative debate could be further defined as the constant swing back and forth on these two issues (Hutt, 1983a, b), that is, safety versus development costs. In 1963, for example, Senator Hubert Humphrey presided over hearings on the FDA's implementation of the Drug Amendment of 1962. The FDA came under substantial criticism for failure to take strong action to protect the public from dangerous drugs. Eleven years later (1974), Senator Edward Kennedy conducted hearings addressing the same issue. Commissioner Schmidt pressed the point that the FDA is under constant scrutiny regarding the approval of "dangerous" drugs, but no hearing had ever been conducted (up to that time) on the failure of the FDA to approve an important new therapy.

The next decade and a half saw a proliferation of work that analyzed the impact of regulation on competitiveness and the introduction of new therapies (see Hutt (1983b) for a complete review). This included Grabowski and Vernon's work (1983), which concluded that regulation had significant adverse effect on pharmaceutical innovation. This examination of the cost of regulation continued into the 1990s. In a meticulous and well-researched study, DiMasi et al. (1994) reported that throughout the 1980s, the number of INDAs was decreasing and the new drug application success rate was also dropping, while the length of time between discovery and approval was increasing. Clearly, this is a situation that could not go on forever. The reported cost of developing a new drug has risen from \$54 million (US) in 1976 to \$2.558 billion (US, with \$1.395 billion out of pocket and \$1.163 billion in time cost) in 2014 (DiMasi et al., 1991; Tufts, 2014). Members of the pharmaceutical

industry and the biotechnology industry were becoming increasingly alarmed by the negative synergy caused by increased costs and increased time to market. In 1991, Dranove published an editorial examining the increased costs and decreased product flow that resulted from the 1962 amendment. He made the observation that European requirements are less stringent than those of the United States, yet the Europeans did not seem to be afflicted by a greater number of dangerous drugs (see Table 1.2). Yet, if one looks at an analysis of worldwide withdrawals for safety from 1960 to 1999 (Fung et al., 2001), one sees that of 121 products identified 42.1% were withdrawn from European markets alone, then 5% from North America, 3.3% from Asia Pacific, and 49.6% from multiple markets. The top five safety reasons for withdrawal were hepatic (26.2%), hematologic (10.5%), cardiovascular (8.7%), dermatologic (6.3%), and carcinogenic (6.3%) issues.

In an age of decreasing regulatory recourses, the FDA (as well as the Congress) was under increasing pressure to review and release drugs more quickly. In response, the Congress passed the 1992 PDUFA. Under the terms of this Act, companies would pay a fee to the agency to defray costs associated with application review. They would supposedly provide the FDA with the resources available to decrease application review time. In return, companies were guaranteed a more rapid review time. By all accounts, PDUFA has been successful. In 1992 (the year PDUFA was passed), 26 NDAs were approved, requiring on average 29.9 months for data review, while in 1996, 53 new drug (or biological) products were approved, each requiring an average of 17.8 months of review time. PDUFA was successful in decreasing review times but has not really streamlined the procedures.

The acquired immune deficiency syndrome (AIDS) activist community was particularly vocal and effective in demanding more rapid approvals and increased access to therapies. There was also demand for FDA reform on several other fronts (e.g., medical devices, pediatric claims, women and minority considerations, and manufacturing changes). In 1993, the House Commerce Committee on Oversight and Investigations, chaired by John Dingel (D-MI), released a comprehensive investigation and evaluation of the FDA entitled *Less than the Sum of its Parts*. The report was highly critical of the FDA and made several recommendations (Pilot and Waldmann, 1998). The mid-1990s also saw the reinventing government initiatives (RIGO) chaired by Vice President AL Gore. Under RIGO, the FDA sought to identify and implement administrative reforms. The RIGO Report issued was entitled *Reinventing Regulation of Drugs and Medical Devices*. The 104th Congress started hearings on FDA reform again in the winter of 1995. Two bills were introduced that provided the essential outline of what would become FDAMA. Senator Nancy Kassebaum (R-KS), chair of the Senate Committee on Labor and Human Resources, introduced S-1477. The second was H.R.3201, introduced by Rep. Joe Barton (R-TX). Other

bills were introduced by Senator Paul Wellstone (D-MN) and Rep. Ron Weyden (D-OR), which focused more on medical devices, but still paved the way for bipartisan support of FDA reform (Pilot and Waldmann, 1998). Eventually, the 105th Congress passed the FDAMA, which was signed into law by President Clinton in November 1997. The various sections of FDAMA are listed in Table 2.2. By any measure, it was a very broad and complex, if not overly deep, piece of legislation. In 1998, Marwick (1998) observed, “a measure of the extent of the task is that implementation of the Act will require 42 new regulations, . . . 23 new guidance notices, and 45 reports and other tasks.” The FDA has identified these various tasks, regulations, and guidances necessary for the implementation of FDAMA. There is an FDAMA icon on the FDA home page, and both the Center for Biologics Evaluation and Research (CBER) and the Center for Drug Evaluation and Research (CDER) have issued various guidance documents. Some of the more interesting sections of the Act that may be of interest to toxicologists include the following:

- Successive renewals of PDUFA every 5 years.
- Fast track for breakthrough products.
- Changes in the fashion biologicals are regulated (elimination of the Establishment and Product licenses, both replaced with a Biologics License Application [BLA]).
- Changes in the fashion antibiotics are developed and regulated.
- Incentives for the development of pediatric claims.
- Companies will be permitted to disseminate information about approved uses for their products.
- FDAMA requires that the FDA establish a clinical trials database for drugs used to treat serious and life-threatening diseases, other than AIDS and cancers (databases for these diseases had already been established).

The full impact of FDAMA in the pharmaceutical industry in general and on toxicology within this industry remains to be established.

This is a debate that has continued to the present and has been highlighted by demands for anti-HIV chemotherapeutic agents.

While it is not possible to review the history of regulations worldwide, it is possible to point out some differences. We will call attention to specific differences where appropriate throughout the remainder of the text.

The strength of the US regulatory system was emphasized at the BIO-Europe 1993 Conference. David Holtzman stated: “the main subject of the conference was regulation, and the U.S. was perceived to have the superior regulatory agency. It may be more difficult to satisfy but it is more predictable and scientifically based” (Holtzman, 1993). This predictability has not stultified growth in the biotechnology industry in the

United States and has, in fact, made the United States a more inciting target for investment than Europe. It is also a system that, while not perfect, has permitted very few unsafe products on the market.

2.2.5 PREA: The Pediatric Research Equity Act

In response to a long-standing concern that drug efficacy and safety (and optimization of use to ensure both) for children was less rigorous than it should be, PREA was enacted in 2003. Subsequent specific nonclinical (and clinical) requirements for evaluation of drug safety in juveniles must be addressed for new drugs by the end of Phase II, or earlier if juveniles are to be included in the clinical evaluation of a drug.

2.2.6 ICH: International Conference on Harmonization

The International Conference on Harmonization originated at a meeting in Brussels in April 1990. With the complexity and cost of developing new drugs rapidly increasing and distribution and marketing of new therapeutics having become global, the patchwork of different national (or regional) regulations and requirements presents both an avoidable duplication of effort (and cost) and a source of potential gaps in ensuring the safety and efficacy of new drugs. The actual first assembly meeting of the ICH was on October 23, 2015,

in Geneva, Switzerland. Section 2.6 addresses this in further detail.

2.2.7 Electronic Recordings: Electronic Submissions Impact

As of May 5, 2017, most submissions to CDER or CBER are required to be electronic via a portal, eventually all regulatory submissions will have to be made electronically. This requirement starts with requests for pre-IND meetings and then runs through filing of any form of NDA. This requirement hastened the transition of application to the ICH CTD document. Most nonclinical safety data must be provided to the FDA separate from the presentation in a final report. This data format is CDISC Standard for Exchange of Nonclinical Data (SEND). These formatted data tables must be submitted with an IND application, and subsequently concurrent with all other designated GLP Reports, as the drug progresses in development to the marketing application (NDA) stage.

2.2.8 COVID-19

In early 2020, realization came globally that a new viral disease pandemic (COVID 19 SARS) was spreading. It has had immense impact on health, economies, and how we live. The regulatory response has been to promulgate a new guidance in May 2020, which seeks to accelerate development of both

drugs for treatment of the disease and vaccines for protecting against it. There are no reductions proposed in nonclinical or clinical safety testing requirements for COVID-19 Therapeutics, however, use can be approved on emergency basis (called an emergency use authorization by both the US FDA and the EMA) regardless of incomplete evaluation of safety and efficacy. Such approvals are not for general unlimited marketing and can be limited in nature and rescinded if further data fails to support safety or efficacy (CBER, 2020).

2.3 FDAMA SUMMARY: CONSEQUENCES AND OTHER REGULATIONS

In summary, federal regulation of the safety of drugs has had three major objectives:

- Requiring testing to establish safety and efficacy
- Establishing guidelines as to which tests are required and how they are designed
- Promulgating requirements of data recording and reporting

The first of these objectives was served by the 1906 Act, which required that agents be labeled appropriately. This was amended in 1938, in response to the tragedies associated with elixir of sulfanilamide and Lash Lure, to require that drugs and marketed formulations of drugs be shown to be safe when used as intended. In the aftermath of the thalidomide tragedy, the 1962 Kefauver–Harris Amendment significantly tightened requirements for preclinical testing (the INDA) and premarket approval (the NDA) of new drugs. Regulations pertaining to INDAs and NDAs have been modified (most recently in 1988), but essentially remain the backbone of regulations of the toxicity evaluation of new human pharmaceutical agents.

The Good Laboratories Practice (GLP) Act, which specifies standards for study planning, personnel training, data recording, and reporting, came out in 1978 in response to perceived shoddy practices of the operations of laboratories involved in the conduct of preclinical safety studies. It was revised in 1985 and is discussed elsewhere in this book.

The final major regulatory initiative on preclinical evaluation for drug safety arose out of the AIDS crisis. To that point, the process of drug review and approval had very generally been perceived as slowing down, the FDA pursuing a conservative approach to requiring proof of safety and efficacy before allowing new drugs to become generally available. In response to AIDS, in 1988, the Expedited Delivery of Drugs for Life-Threatening Diseases Act established a basis for less rigorous standards (and more rapid drug development) in some limited cases.

In the United Kingdom, the Committee on Safety of Medicines (reporting to the minister of Health) regulates drug

safety and development under the Medicines Act of 1968 (which has replaced the Therapeutic Substances Act of 1925). Details on differences in drug safety regulations in the international marketplace can be found in Alder and Zbinden (1988), but key points are presented in this chapter.

2.4 OVERVIEW OF US REGULATIONS

2.4.1 Regulations: General Considerations

The US federal regulations governing the testing, manufacture, and sale of pharmaceutical agents and medical devices are covered in Chapter 1, Title 21 of the Code of Federal Regulations (21 CFR). These comprise nine 6" × 8" (double sided) volumes which stack 8" high. This title also covers foods, veterinary products, and cosmetics. As these topics will be discussed elsewhere in this book, in this chapter, we will briefly review those parts of 21 CFR that are applicable to human health products and medicinal devices.

Of most interest to a toxicologist working in the pharmaceutical arena would be Chapter 1, Subchapter A (Parts 1–78), which cover general provisions, organization, etc. The GLPs are codified in 21 CFR 58.

General regulations that apply to drugs are in Subchapter C (Parts 200–299). This covers topics such as labeling, advertising, commercial registration, manufacture, and distribution. Of most interest to a toxicologist would be a section on labeling (Part 201, Subparts A–G, which covers Sections 201.1 through 201.317 of the regulations) as much of the toxicological research on a human prescription drug goes toward supporting a label claim. For example, specific requirements on content and format of labeling for human prescription drugs are covered in Section 201.57. Directions for what should be included under the “Precautions” section of a label are listed in 201.57(f). This includes 201.57(f)(6), which covers categorization of pregnancy risk, and the reliance upon animal reproduction studies in making these categorizations is made quite clear. For example, a drug is given a pregnancy category B if “animal reproduction studies have failed to demonstrate a risk to the fetus.” The point here is not to give the impression that the law is most concerned with pregnancy risk. Rather, we wish to emphasize that much basic toxicological information must be summarized on the drug label (or package insert). This section of the law is quite detailed as to what information is to be presented as well as the format of presentation. Toxicologists working in the pharmaceutical arena should be familiar with this section of the CFR.

2.4.2 Regulations: Human Pharmaceuticals

The regulations specifically applicable to human drugs are covered in Subchapter D, Parts 300–399. The definition of a new drug is covered in Part 310(g):

A new drug substance means any substance that when used in the manufacture, processing or packaging of a drug causes that drug to be a new drug but does not include intermediates used in the synthesis of such substances.

The regulation then goes on to discuss “newness with regard to new formulations, indications, or in combinations.” For toxicologists, the meat of the regulations can be found in Section 312 (INDA) and Section 314 (applications for approval to market a new drug or antibiotic drug or NDA). The major focus for a toxicologist working in the pharmaceutical industry is on preparing the correct toxicology “packages” to be included to “support” these two types of applications. (The exact nature of these packages will be covered in the following.)

In a nutshell, the law requires solid scientific evidence of safety and efficacy before a new drug will be permitted into clinical trials or (later) onto the market. The INDA (covered in 21CFR 310) is for permission to proceed with clinical trials on human subjects. Once clinical trials have been completed, the manufacturer or “sponsor” can then proceed to file an NDA (covered in 21 CFR 314) for permission to market the new drug.

As stated in 321.21, “A sponsor shall submit an IND if the sponsor intends to conduct a clinical investigation with a new drug . . . [and] shall not begin a clinical investigation until . . . an IND . . . is in effect.” Similar procedures are in place in other major countries. In the United Kingdom, for example, a Clinical Trials Certificate (CTC) must be filed or a clinical trial exemption (CTX) obtained before clinical trials may proceed. Clinical trials are divided into three phases, as described in 312.21. Phase I trials are initial introductions into healthy volunteers primarily for the purposes of establishing tolerance (side effects), bioavailability, and metabolism. Phase II clinical trials are “controlled studies . . . to evaluate effectiveness of the drug for a particular indication or disease.” The secondary objective is to determine common short-term side effects; hence, the subjects are closely monitored. Phase III studies are expanded clinical trials. It is during this phase that definitive, large-scale, double-blind studies are performed.

The toxicologist’s main responsibilities in the IND process are to design, conduct, and interpret appropriate toxicology studies (or “packages”) to support the initial IND and then design the appropriate studies necessary to support each additional phase of investigation. Exactly what may constitute appropriate studies are covered elsewhere in this chapter. The toxicologist’s second responsibility is to prepare the toxicology summaries for the (clinical) investigator’s brochure (described in 312.23(a)(8)(ii)). This is an integrated summary of the toxicological effects of the drug in animals and *in vitro*. The FDA has prepared numerous guidance documents covering the content and format of INDs. It is of interest that in the Guidance for Industry (CDER and CBER, 1995), an in-depth description of the expected contents of the pharma-

cology and toxicology sections was presented. The document contains the following self-explanatory passage:

Therefore, if final, fully quality-assured individual study reports are not available at the time of IND submission, an integrated summary report of toxicological findings based on the unaudited draft toxicologic reports of the completed animal studies may be submitted.

If audited draft but not yet finalized reports are used in an initial IND, the finalized report must be submitted within 120 days of the start of the clinical trial. The sponsor must also prepare a document identifying any differences between the preliminary and final reports and the impact (if any) on interpretation.

Thus, while the submission of fully audited reports is preferable, the agency does allow for the use of incomplete reports.

Once an IND or CTC/CTX is opened, the toxicologists may have several additional responsibilities: first, to design, conduct, and report the additional tests necessary to support a new clinical protocol or an amendment to the current clinical protocol (Section 312.20). Second, to bring to the sponsor’s attention any finding in an ongoing toxicology study in animals “suggesting a significant risk to human subjects, including any finding of mutagenicity, teratogenicity or carcinogenicity,” as described in 21 CFR 312.32. The sponsor has a legal obligation to report such findings within 10 working days. Third, to prepare a “list of the preclinical studies . . . completed or in progress during the past year” and a summary of the major preclinical findings. The sponsor is required (under Section 312.23) to file an annual report (within 60 days of the IND anniversary date) describing the progress of the investigation. INDs are never “approved” in the strict sense of the word. Once filed, an IND can be opened 30 days after submission, unless the FDA informs the sponsor otherwise. Complete and thorough reports on all pivotal toxicological studies must be provided with the application. The CTD style IND application is outlined in Table 2.3.

If the clinical trials conducted under an IND are successful in demonstrating safety and effectiveness (often established at a pre-NDA meeting, described in 21 CFR 312.47(b)(2)), the sponsor can then submit an NDA. Unlike an IND, the NDA must be specifically approved by the agency. The toxicologist’s responsibility in the NDA/Marketing Authorization Application (MAA) process is to prepare an integrated summary of all the toxicology and/or safety studies performed and be in a position to present and review the toxicology findings to the FDA or its advisory bodies. The approval process can be exhausting, including many meetings, hearings, appeals, etc. The ground rules for all of these are described in Part A of the law. For example, all NDAs are reviewed by an “independent” (persons not connected with either the sponsor or the agency) scientific advisory panel which reviews the findings and makes recommendations as to approval. MAAs must be

TABLE 2.3 Composition of CTD Investigational New Drug Application

reviewed by and reported by an expert recognized by the cognizant regulatory authority. Final statutory approval in the United States lies with the Commissioner of the FDA. It is hoped that few additional studies will be requested during the NDA review and approval process. When an NDA is approved, the agency will send the sponsor an approval letter and will issue a Summary Basis of Approval (SBA)(312.30), which is designed and intended to provide a public record on the agency’s reasoning for approving the NDA while not revealing any proprietary information. The SBA can be obtained through Freedom of Information and can provide insights into the precedents for which types of toxicology studies are used to support specific types of claims.

2.4.3 Regulations: Environmental Impact

Environmental impact statements, while once important only for animal drugs, must now accompany all MDAs. This assessment must also be included in the Drug Master File (DMF). The procedures, formats, and requirements are described in 21 CFR 2531. This requirement has grown in response to the National Environmental Policy Act, the heart of which required that federal agencies evaluate every major action that could affect the quality of the environment. In the INDs, this statement can be a relatively short section claiming that relatively small amounts will post little risk to the environment. The EEC has similar requirements for drug entities in Europe, though data requirements are more stren-

uous. With NDAs, this statement must be more substantial, detailing any manufacturing and/or distribution process that may result in release into the environment. Environmental fate (e.g., photohydrolysis) and toxicity (e.g., fish, daphnia, and algae) studies will be required. While not mammalian toxicology in the tradition of pharmaceutical testing, preparing an environmental impact statement will clearly require toxicological input. The FDA has published a technical bulletin covering the tests it may require (FDA, 1987).

2.4.4 Regulations: Antibiotics

The NDA law (safety and effectiveness) applies to all drugs, but antibiotic drugs were treated differently until the passage of FDAMA in 1997. Antibiotic drugs had been treated differently by the FDA since the development of penicillin revolutionized medicine during World War II. The laws applicable to antibiotic drugs were covered in 21 CFR 430 and 431. Antibiotics such as penicillin or doxorubicin are drugs derived (in whole or in part) from natural sources (such as molds or plants) which have cytotoxic or cytostatic properties. They were treated differently from other drugs as the applicable laws required a batch-to-batch certification process. Originally passed into law in 1945 specifically for penicillin, this certification process was expanded by the 1962 amendment (under Section 507 of the FDCA) to require certification of all antibiotic drugs, meaning that the FDA would assay each lot of antibiotic for purity, potency, and safety. The actual regulations were covered in 21 CFR Subchapter D, Parts 430–460 (over 600 pages), which describes the standards and methods used for certification for all approved antibiotics. Section 507 was repealed by FDAMA (Section 125). As a result of the repeal of Sections 507, the FDA is no longer required to publish antibiotic monographs. In addition, the testing, filing, and reviewing of antibiotic applications are now handled under Section 505 of the Act like any other new therapeutic agent. The FDA has published a guidance document to which the reader is referred for more details (CDER, 1998).

2.4.5 Regulations: Biologics

Biological product, including vaccines, are covered in Subchapter F, Parts 600–680. As described in 21 CFR 600.3(h), “biological product means any virus, therapeutic serum, toxin, antitoxin or analogous product applicable to the prevention, treatment or cure of diseases or injuries of man.” In other words, these are vaccines and other protein products derived from animal sources. Clearly, the toxicological concerns with such products are vastly different than those involved with low molecular weight synthetic molecules. There is little rational basis, for example, for conducting

a repeated-dose toxicity study with more than a month duration with a vaccine or a human blood product. The FDA definition for safety with regard to these products is found in 21 CFR 603.1(p): “Relative freedom from harmful effect to persons affected, directly or indirectly, by a product when prudently administered.” Such safety consideration has more to do with purity, sterility, and adherence to good manufacturing standards than with the toxicity of the therapeutic molecule itself. The testing required to show safety is stated in licensing procedures 21 CFR 601.25(d)(1): “Proof of safety shall consist of adequate test methods reasonably applicable to show the biological product is safe under the prescribed conditions.” Once a license is granted, each batch or lot of biological product must be tested for safety, and the methods of doing so are written into the law. A general test for safety (i.e., required in addition to other safety tests) is prescribed using guinea pigs as described in 610.11. Additional tests are often applied to specific products. For example, 21 CFR 630.35 describes the safety tests required for measles vaccines, which includes tests in mice and *in vitro* assays with tissue culture. Many new therapeutic entities produced by biotechnology are seeking approval as biologics with the results being FDA approval of a Product License Application (PLA). Table 2.4 presents general guidance for the basis of deciding if an individual entity falls under CDER or CBER authority for review.

The International Conference on Harmonization (ICH) has published its document S6 Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals. The FDA (both CDER and CBER jointly) has published the document as a Guidance for Industry (FDA, 1997).

A current list of regulatory documents (including the most recent points to consider (PTCs)) can be found on the FDA website by accessing the FDA home page at www.fda.gov, scrolling down and finding the “Regulatory Information” tab with applicable links near the bottom left. The Regulatory Information site can also be directly accessed using the following web address: <http://www.fda.gov/RegulatoryInformation/default.htm>.

2.4.6 Regulations Versus Law

A note of caution must be inserted here. The law (document passed by Congress) and the regulations (documents written by regulatory authorities to enforce laws) are separate documents. Sections in the law do not necessarily have numerical correspondence with those of the regulations. For example, the regulations on the NDA process are described in 21 CFR 312, but the law describing the requirement for an NDA process is in Section 505 of the FDCA. Because regulations rather than laws themselves have a greater impact on toxicological practice, greater emphasis is placed on regulation in this chapter. For a complete review of FDA law, the reader is

2.5 ORGANIZATIONS REGULATING DRUG AND DEVICE SAFETY IN THE UNITED STATES

The agency formally charged with overseeing the safety of drugs in the United States is the FDA. The FDA is headed by a commissioner who reports to the Secretary of the Department of Health and Human Services (DHHS) and has a tremendous range of responsibilities. Drugs are overseen primarily by the CDER (though some therapeutic or health-care entities are considered biologics and are overseen by the corresponding CBER). Figure 2.1 presents the organization of CDER, and that of CBER is shown in Figure 2.2.

Most of the regulatory interactions of toxicologists take place with these two offices of Drug Evaluation, which have under them a set of groups focused on areas of therapeutic claim (cardiorenal, neuropharmacological, gastrointestinal and coagulation, oncology and pulmonary, metabolism and endocrine, and anti-infective and antiviral). Within each of these are chemists, pharmacologists/toxicologists, statisticians, and clinicians. When an INDA is submitted to the offices of Drug Evaluation, it is assigned to one of the therapeutic groups based on its area of therapeutic claim. Generally, it will remain with that group throughout its regulatory approval “life.” INDs, when allowed, grant investigators the ability to go forward into

clinical (human) trials with their drug candidate in a predefined manner, advancing through various steps of evaluation in human (and in additional preclinical or animal studies) until an NDA can be supported, developed, and submitted. Likewise, for biological products, the PLA or other applications (INDA, IND) are handled by the offices of Biological Products Review within the CBER.

For drugs, there is at least one nongovernmental (NGO) body which must review and approve various aspects—the USP (established in 1820)—which maintains (and revises) the compendia of the same name, as well as the National Formulary which sets drug composition standards (Ember, 2001). This volume sets forth standards for purity of products in which residues may be present and tests for determining various characteristics of drugs, devices, and biologics. The USP also contains significant “guidance” for the evaluation process (USP, 2020).

2.6 PROCESS OF PHARMACEUTICAL PRODUCT DEVELOPMENT AND APPROVAL

Except for a very few special cases (treatments for life-threatening diseases such as cancer or AIDS), the safety

June 2020

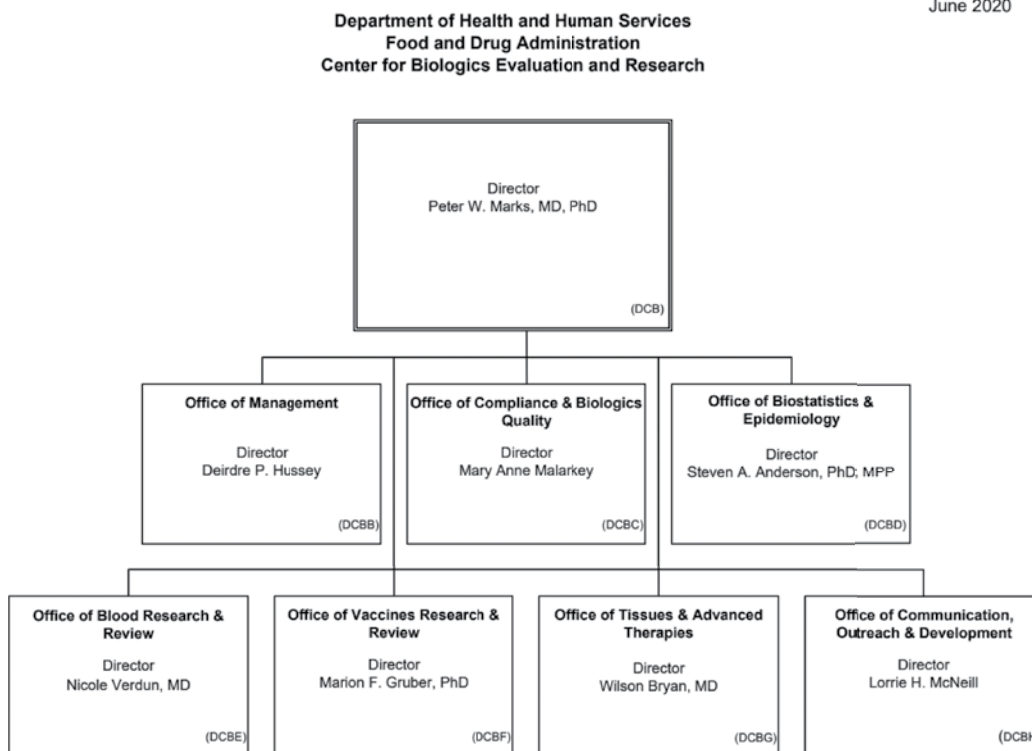

FIGURE 2.2 Center for Biologics Evaluation and Research (CBER). *Source:* <https://www.fda.gov/about-fda/fda-organization-charts/center-biologics-evaluation-and-research-organization-chart>.

assessment of new drugs is mandated by regulations which seemingly proceed in a rather fixed manner. The IND is filed to support (or enable) clinical testing and development of the drug. An initial set of studies (typically, studies of appropriate length by the route intended for humans are performed in both a rodent (typically rat) and a nonrodent (usually a dog or a primate)) are required to support phase I clinical testing. Such phase I testing is intended to evaluate the safety (“tolerance” in clinical subjects), pharmacokinetics, and general biological effects of a new drug and is conducted in normal volunteers (almost always males).

Successful completion of phase I testing allows, with the approval of the FDA, progression into phase II clinical testing. Here, selected patients are enrolled to evaluate therapeutic efficacy, dose ranging, and more details about the pharmacokinetics and metabolism. Longer-term systemic toxicity studies must be in conformity with the guidelines that are presented in the next section. Once a sufficient understanding of the actions, therapeutic dose–response, and potential risk-to-benefit ratio of a drug is in hand (once again, with FDA approval), trials move into phase III testing.

Phase III tests are large, long, and expensive. They are conducted using large samples of selected patients and are intended to produce proof of safety and efficacy of a drug. Two studies providing statistically significant proof of the

claimed therapeutic benefit must be provided. All resulting data from preclinical and clinical animal studies are organized in a specified format in the form of an NDA, which is then submitted to the FDA.

By the time phase III testing is completed, some additional preclinical safety tests must also generally be in hand. These include the three separate reproductive and developmental toxicity studies (segments I and III in the rat and segment II in the rat and rabbit) and carcinogenicity studies in both rats and mice (unless the period of therapeutic usage is intended to be very short). Some assessment of genetic toxicity will also be expected.

The ultimate product of the pharmaceutical toxicologist will thus generally be the toxicology summaries of the IND and NDA (or PLA). For medical devices, the equivalents are the Investigational Device Exemption (IDE) and Product Development Notification (PDN). Data required to support each of these documents is specified in a series of guidelines, as will be discussed in the following.

Acceptance of these applications is contingent not only upon adherence to guidelines and good science but also adherence to GLPs.

There are currently a range of potential expedited routes for approval of a therapeutic entity once an IND is opened. See Table 2.10 for a summary of these.

2.7 TESTING GUIDELINES

2.7.1 Toxicity Testing: Traditional Pharmaceuticals

Although the 1938 Act required safety assessment studies, no consistent guidelines were available. Guidelines were first proposed in 1949 and published in the *Food, Drug, and Cosmetic Law Journal* that year (Burns, 1983). Following several revisions, these guidelines were issued as the Appraisal Handbook in 1959. While never formally called a guideline, it set the standard for preclinical toxicity test design for several years. The current basic guidelines for testing required for safety assessment in support of the phases of clinical development of drugs were first outlined by Goldenthal (1968) and later incorporated into a 1971 FDA publication entitled *FDA Introduction to Total Drug Quality*.

All general case pharmaceuticals need to address four major aspects of toxicology before going into humans. These are systemic toxicity, potential genetic toxicity, safety pharmacology, and (if any route of administration other than oral) local tissue tolerance issues.

2.7.2 General or Systematic Toxicity Assessment

Table 2.6 presents an overview of the current FDA toxicity testing guidelines for human drugs. Table 2.7 presents the parallel ICH guidance (ICH, 2009) which now largely supplants the FDA guidelines. They are misleading in their apparent simplicity, however. First, each of the systemic toxicity studies in these guidelines must be designed and executed in a satisfactory manner. Sufficient animals must be used to have confidence in finding and characterizing any adverse drug actions that may be present. In practice, as the duration of the study increases, small doses are administered, and larger numbers of animals must be employed per group. These two features—dosage level and group size—are critical to study designs. Table 2.8 presents general guidance on the number of animals to be used in systemic studies. These and other technical considerations for the safety assessment of pharmaceuticals are present in detail in this book.

The protocols discussed thus far have focused on general or systemic toxicity assessment. The agency and, indeed, the lay public have a special set of concerns with reproductive toxicity, fetal/embryo toxicity, and developmental toxicity (also called *teratogenicity*). Collectively, these concerns often go by the acronyms *DART* (developmental and reproductive toxicity) or *RTF* (reproduction, teratogenicity, fertility). Segment II studies are more designed to detect developmental toxicity. Only pregnant females are dosed during critical period of organogenesis. Generally, the first protocol DART test (exclusive of range-finding studies) is a segment I study of rats in fertility and general reproductive performance. This is generally done while the drug is in phase II clinical trials.

Alternatively, many companies are now performing the segment II teratology study in rats before the segment I study because the former is less time and resource-intensive. One or both should be completed before including women of child-bearing potential in clinical trials. The FDA requires teratogenicity testing in two species—a rodent (rat or mouse) and the rabbit. Use of the rabbit was instituted as a result of the finding that thalidomide was a positive teratogen in the rabbit but not in the rat. On occasion, when a test article is not compatible with the rabbit, teratogenicity data in the mouse may be substituted. There are also some specific classes of therapeutics (e.g., quinolone antibiotics) where segment II studies in primates are effectively required prior to product approval. Both should be completed before entering phase III clinical trials. The most complicated of the DART protocols—segment III—is generally commenced during phase III trials and should be part of the NDA. There are differences in the different national guidelines (as discussed later with international considerations) regarding the conduct of these studies. The large multinational drug companies try to design their protocols to be in compliance with as many guidelines as possible to avoid duplication of testing while allowing the broadest possible approval and marketing of therapeutics.

2.7.3 Genetic Toxicity Assessment

Genetic toxicity testing generally focuses on the potential of a new drug to cause mutations (in single-cell systems) or other forms of genetic damage. The tests, generally short in duration, often rely on *in vitro* systems and generally have a single end point of effect (point mutations, chromosomal damage, etc.). For a complete review of protocols, technology, etc., the reader is referred to Brusick (1987). It is of interest that the FDA had no standard or statutory requirement for genetic toxicity testing but generally expects to see at least some such tests performed and will ask for them if the issue is not addressed. If one performs such a study, any data collected, of course, must be sent to the agency as part of any IND, PLA, or NDA (CDER, 2006). These studies have yet to gain favor with the FDA (or other national regulatory agencies) as substitutes for *in vivo* carcinogenicity testing. However, even with completed negative carcinogenicity tests, at least some genetic toxicity assays are generally required. Generally, pharmaceuticals in the United States are evaluated for mutagenic potential (e.g., the Ames assay) or for chromosomal damage (e.g., the *in vivo* mouse micronucleus test). In general, in the United States, pharmaceutical companies apply genetic toxicity testing in the following fashion:

- *As a screen:* An agent that is positive in one or more genetic toxicity tests may be more likely than one that is negative to be carcinogenic and, therefore, may not warrant further development.

TABLE 2.6 Synopsis of General Guidelines for Animal Toxicity Studies for Drugs

Category	Duration of Human Administration	Clinical Phase	Subacute or Chronic Toxicity	Special Studies
Oral or parenteral	Several days	I, II, III, NDA	Two species; 2 weeks	For parentally administered drugs
	Up to 2 weeks	I	Two species; 4 weeks	
		II	Two species; up to 4 weeks	
		III, NDA	Two species; up to 3 months	Compatibility with blood where applicable
	Up to 3 months	I, II	Two species; 4 weeks	
		III	Two species; 3 months	
		NDA	Two species; up to 6 months	
	6 months to unlimited	I, II	Two species; 3 months	
		III	Two species; 6 months or longer	
		NDA	Two species; 9 months (nonrodent) and 12 months (rodent)	
+2 rodent species for CA; 18 months (mouse); 24 months (rat). Mouse may be replaced with an allowable transgenic mouse study				
Inhalation (general anesthetics)	I, II, III, NDA	Four species; 5 days (3 h day ⁻¹)		
Dermal	Single application	I	One species; single 24 h exposure followed by 2-week observation	Sensitization
	Single or short-term application	II	One species; 20-day repeated exposure (intact and abraded skin)	
	Short-term application	III	As aforementioned	
	Unlimited application	NDA	As aforementioned, but intact skin study extended up to 6 months	
Ophthalmic	Single application	I		Eye irritation tests with graded doses
	Multiple application	I, II, III	One species; 3-week daily applications, as in clinical use	
		NDA	One species; duration commensurate with period of drug administration	
Vaginal or rectal	Single application	I		Local and systematic toxicity after vaginal or rectal application in two species
	Multiple application	I, II, III, NDA	Two species; duration and number of applications determined by proposed use	
Drug combinations		I, II, III, NDA	Two species; up to 3 months	Lethality by appropriate route, compared to components run concurrently in one species

TABLE 2.7 Duration of Repeated-Dose Toxicity Studies to Support Clinical Trials and Marketing^a

Duration of Clinical Trials	Minimum Repeated Duration of -Dose Toxicity Studies ^b		Duration of Clinical Trials	Minimum Duration of Repeated-Dose Toxicity Studies ^c	
	Rodents	Nonrodents		Rodents	Nonrodents
Single dose	2 weeks ^d	2 weeks	Up to 2 weeks	1 month	1 month
Up to 2 weeks	2 weeks ^d	2 weeks	Up to 1 month	3 months	3 months
Up to 1 month	1 month	1 month	Up to 3 months	6 months	3 months
Up to 6 months	6 months	6 months ^e	>3 months	6 months	Chronic ^d
>6 months	6 months	Chronic ^e			

^a In Japan, if there are no phase II clinical trials of equivalent duration to the planned phase III trials, conduct of longer duration toxicity studies is recommended as given earlier.

^b Data from 6 months of administration in nonrodents should be available before the initiation of clinical trials longer than 3 months. Alternatively, if applicable, data from a 9-month nonrodent study should be available before the treatment duration exceeds that which is supported by the available toxicity studies.

^c The table also reflects the marketing recommendations in the three regions except that a chronic nonrodent study is recommended for clinical use >1 month.

^d In the United States, as an alternative to 2-week studies, single-dose toxicity studies with extended examinations can support single-dose human trials (4).

^e To support phase I and II trials in the EU and phase I, II, and III trials in the United States and Japan.

TABLE 2.8 Numbers of Animals per Dosage Group in Systemic Toxicity Studies (OECD Guidances)

Study Duration (per Sex)	Rodents (per Sex)	Nonrodents
2–4 weeks	5	3
13 weeks	20 ^a	6
26 weeks	30	8
Chronic	50	10
Carcinogenicity	60 ^b	Applies only to contraceptives
Bioassays		Applies only to contraceptives

^a Starting with 13-week studies, one should consider adding animals (particularly to the high dose) to allow evaluation of reversal of effects.

^b In recent years, there have been decreasing levels of survival in rats on 2-year studies. What is required is that at least 20–25 animals/sex/group survive at the end of the study. Accordingly, practice is beginning to use 70 or 75 animals per sex, per group.

- *As an adjunct:* An agent that is negative in carcinogenicity testing in two species and also negative in a genetic toxicity battery is more likely than not to be noncarcinogenic in human beings.
- *To provide mechanistic insight* For example, if an agent is negative in a wide range of genetic toxicity screens but still produces tumors in animals, then one could hypothesize that an epigenetic mechanism was involved.

While not officially required, the FDA does have the authority to request, on a case-by-case basis, specific tests it feels may be necessary to address a point of concern. A genetic toxicity test could be part of such a request. In general, therefore, companies deal with genetic toxicity (after “screening”) on a case-by-case basis, dictated by good science. If more than a single administration is intended, common practice is to perform the tests prior to submitting an IND.

2.7.4 Safety Pharmacology

Midway through 2001 ICH and the related regional regulatory authorities (such as FDA, EMA, and MHW) implemented a new set of preclinical (to be completed before initiation of human clinical trials) safety assessment requirements focused on reversible organ function alterations that could have rapid fatal effects before reversal. The general case core set of these is the freestanding GLP evaluations of cardiovascular, respiratory, pulmonary, and central nervous system (CNS) functions; ICH S7a and S7b are the relevant guidelines. There are exceptions for the “requirements” in some structural class cases. This is discussed in detail in Chapter 18 and in Gad (2012).

2.7.5 Local Tissue Tolerance

Not called out in ICH guidances, but rather in the USP and other pharmacopoeia are the requirements to assess local tissue effects of drugs as they potentially can occur at or

around the site of drug application or administration. These effects include irritation, pyrogenicity, hemolysis, and others. There are specific requirements for all routes except oral.

2.7.6 Reproductive and Developmental

The assessment of potential reproductive and developmental toxicity of drugs continues to be an evolving area. ICH S5(R3) (2017) is the principal technical guideline and applies to small molecules, biotechnology-derived pharmaceuticals, vaccines for infectious diseases, and novel excipients. It does not apply to cellular tissue or gene therapies.

The FDA has more recently issued a guidance on reproductive toxicity testing and labeling requirements for oncologic drugs, and in the cases where a drug may be given only to men or to postmenopausal women.

2.7.7 Carcinogenicity

The FDA adopted versions of ICH S1A, S1B, and S1C(R2) (all released in 2020) provide the current guidance for the need for assessing the potential for carcinogenicity of new drugs, how such testing should be conducted, how doses should be selected, and how to handle reporting on the results of such testing. Closely related, the FDA has a guidance on integration of genetic toxicity results into the evaluation of potential carcinogenicity of drugs (FDA, 2006).

Additionally, currently the expectation is that proposed testing plans (including requests for waivers from some or all the requirements) and doses to be used should be submitted for review to the carcinogenicity assessment committee (CAC).

2.7.8 Toxicity Testing: Biotechnology Products

As mentioned, the regulation of traditional pharmaceuticals (small molecules such as aspirin or digitalis) and biologicals (proteins such as vaccines and antitoxins derived from animal sources) has very different histories. See the discussion on biologics earlier in this chapter. Until 1972, the NIH (or its forerunning agency, the Hygienic Laboratory of the Department of the Treasury) was charged with the responsibility of administering the Virus Act of 1902. With the passage of the food and drug laws of 1906, 1938, and 1962, there was a recurring debate regarding whether these laws applied or should apply to biologicals (Pendergast, 1984). This debate was resolved when the authority for the regulation of biologics was transferred to the FDA's new Bureau of Biologics (now the CBER) in 1972. Since then, there appears to have been little difference in the matter of regulation for biologics and pharmaceuticals. The FDA essentially regulates biologics as described under the 1902 Act but then uses the rule-making authority granted under the Food and Drug Act to "fill in the gaps."

The Bureau of Biologics was once a relatively "sleepy" agency, primarily concerned with the regulation of human blood products and vaccines used for mass immunization programs. The authors of the 1902 law could hardly have foreseen the explosion in biotechnology that occurred in the 1980s. New technology created a welter of new biological products, such as recombinant DNA (rDNA)-produced proteins (e.g., tissue plasminogen activator), biological response modifiers (cytokinins and colony-stimulating factors), monoclonal antibodies, antisense oligonucleotides, and self-directed vaccines (raising an immune response to self-proteins such as gastrin for therapeutic reasons). The new products raised a variety of new questions on the appropriateness of traditional methods for evaluating drug toxicity that generated several PTC documents. For the sake of brevity, this discussion will focus on the rDNA proteins. Some of the safety issues that have been raised over the years:

- The appropriateness of testing a human-specific peptide hormone in nonhuman species.
- The potential that the peptide could break down due to nonspecific metabolism, resulting in products that had no therapeutic value or even a toxic fragment.
- The potential sequelae to an immune response (formation of neutralizing antibodies, provoking an autoimmune or a hypersensitivity response), pathology due to immune precipitation, etc.
- The presence of contamination with oncogenic virus DNA (depending on whether a bacterial or mammalian system was used on the synthesizing agent) or endotoxins.
- The difficulty interpreting the scientific relevance of response to supraphysiological systemic doses of potent biological response modifiers.

The last few intervening years have shown some of these concerns to have been more relevant than others. The "toxic peptide fragment" concern, for example, has been shown to be without merit. The presence of potentially oncogenic virus DNA and endotoxins is a quality assurance concern and is not truly a toxicological problem. Regardless of the type of synthetic pathway, all proteins must be synthesized in compliance with Good Manufacturing Practices (GMPs). Products must be as pure as possible not only free of rDNA but also free of other types of cell debris (endotoxin). Batch-to-batch consistency with regard to molecular structure must also be demonstrated using appropriate methods (e.g., amino acid). The regulatory thinking and experience over the last 15 years has come together in the document "S6 Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals" prepared by the ICH. The FDA (both CDER and CBER jointly) has published the document as a Guidance for Industry (FDA, 1997; CDER, 1998). The document intended to

provide basic guidance for the preclinical evaluation of biotechnology-derived products, including proteins and peptides, either produced by cell culture using rDNA technology, but did not cover antibiotics, allergenic extracts, heparin, vitamins, cellular drug products vaccines, or other products regulated as biologics. Items covered are summarized as follows:

- *Test-article specifications* In general, the product that is used in the definitive pharmacology and toxicology studies should be comparable to the product proposed for the initial clinical studies.
- *Animal species/model selection* Safety evaluation should include the use of relevant species, in which the test article is pharmacologically active due, for example, to the expression of the appropriate receptor molecule. These can be screened with *in vitro* receptor binding assays. Safety evaluation should normally include two appropriate species, if possible and/or feasible. The potential utility of gene knockout and/or transgenic animals in safety assessment is discussed.
- *Group size* No specific numbers are given, but it does state that a small sample size may lead to failure to observe toxic events.
- *Administration* The route and frequency should be as close as possible to that proposed for clinical use. Other routes can be used when scientifically warranted.
- *Immunogenicity* It has also been clearly demonstrated in the testing of rDNA protein products that animals will develop antibodies to foreign proteins. This response has been shown to neutralize (rapidly remove from circulation) the protein, but no pathological conditions have been shown to occur as a sequelae to the immune response. Bear in mind, however, that interleukins have powerful effects on immune response, but these are due to their physiological activity and not due to an antigen–antibody response. The first has to do with “neutralizing antibodies”; that is, is the immune response so great that the test article is being removed from circulation as fast as it is being added? If this is the case, does long-term testing of such a chemical make sense? In many cases, it does not. The safety testing of any large molecule should include the appropriate assays for determining whether the test system has developed a neutralizing antibody response. Depending on the species, route of administration, intended therapeutic use, and development of neutralizing antibodies (which generally takes about 2 weeks), it is rare for a toxicity test on an rDNA protein to be of a duration longer than 4 weeks. However, if the course of therapy in humans is to be longer than 2 weeks, formation of neutralizing antibodies must be demonstrated, or longer-term testing performed. The second antigen–antibody formation concern is that a hypersen-

sitivity response will be elicited. Traditional preclinical safety assays are generally adequate to guard against this if they are 2 weeks or longer in duration and the relevant end points are evaluated.

- *Safety pharmacology* It is important to investigate the potential for unwanted pharmacological activity in appropriate animal models and to incorporate monitoring for these activities in toxicity studies.
- *Exposure assessment* Single- and multiple-dose pharmacokinetics, toxicokinetics, and tissue distribution studies in relevant species are useful. Proteins are not given orally, demonstrating absorption and mass balance are not typically primary considerations. Rather, this segment of the test should be designed to determine half-life (and other appropriate pharmacokinetic (PK) descriptor parameters), the plasma concentration associated with biological effects, and potential changes due to the development of neutralizing antibodies.
- *Reproductive performance and developmental toxicity studies* These will be dictated by the product, clinical indication, and intended patient population.
- *Genotoxicity studies* The S6 document states that the battery of genotoxicity studies routinely conducted for traditional pharmaceuticals are not appropriate for biotechnology-derived pharmaceuticals. In contrast to small molecules, genotoxicity testing with a battery of *in vitro* and *in vivo* techniques of protein molecules has not become common US industry practice. Such tests are not formally required by the FDA but, if performed, must be reported. They are, however, required by European and Japanese regulatory authorities. This has sparked a debate as to whether or not genotoxicity testing is necessary or appropriate for rDNA protein molecules. It is the authors’ opinion that such testing is, scientifically, of little value. First, large protein molecules will not easily penetrate the cell wall of bacteria or yeast, and (depending on size, charge, lipophilicity, etc.) penetration across the plasma lemma of mammalian cells will be highly variable. Second, if one considers the well-established mechanism(s) of genotoxicity of small molecules, it is difficult to conceive of how a protein might act in the same fashion. For example, proteins will not be metabolized to be electrophilic active intermediates that will cross-link guanine residues. In general, therefore, genotoxicity testing with rDNA proteins is wasteful of resources. It is conceivable, however, that some proteins, because of their biological mechanism of action, may stimulate the proliferation of transformed cells. For example, it is a feasible hypothesis that a colony-stimulating factor could stimulate the proliferation of leukemic cells (it should be emphasized that this is a hypothetical

situation, presented here for illustrative purposes). Again, this is a question of a specific pharmacological property, and such considerations should be tested on a case-by-case basis.

- *Carcinogenicity studies* These are generally inappropriate for biotechnology-derived pharmaceuticals; however, some products may have the potential to support or induce proliferation of transformed cells—possibly leading to neoplasia. When this concern is present, further studies in relevant animal models may be needed.

These items are covered in greater detail in the S6 guidance document and in a review by Hayes and Ryffel (1997).

So, given the previous discussion, what should the toxicology testing package of a typical rDNA protein resemble? Based on the products that have successfully wended their way through the regulatory process, the following generalizations can be drawn:

- The safety tests look remarkably similar to those for traditional tests. Most have been done on three species: the rat, the dog, or the monkey. The great difference has to do with test length. It is rare for a safety test on a protein to be more than 13 weeks long.
- The dosing regimens can be quite variable and at times very technique intensive. These chemicals are almost always administered by a parenteral route of administration, normally intravenously or subcutaneously. Dosing regimens have run the range from once every 2 weeks for an antihormone “vaccine” to continuous infusion for a short-lived protein.
- As reviewed by Ryffel (1996), most side effects in man of a therapy with rDNA therapy may be predicted by data from experimental toxicology studies, but there are exceptions. IL-6, for example, induced a sustained increase in blood platelets and acute-phase proteins, with no increase in body temperature. In human trials, however, there were increases in temperature.
- The S6 document also mentions monoclonal antibody products. Indeed, many of the considerations for rDNA products are also applicable to monoclonal antibodies (including hybridized antibodies). With monoclonal antibodies, there is the additional concern of cross reactivity with nontarget molecules.

As mentioned, the rapid development in the biotechnology industry has created some confusion as to what arm of the FDA is responsible for such products. In October 1992, the two major reviewing groups, CBER and CDER, reached a series of agreements to explain and organize the FDA’s position on products that did not easily fall into its traditional classification schemes. CDER would continue to have

responsibility for traditional chemically synthesized molecules as well as those purified from mineral or plant sources (except allergens), antibiotics, hormones (including insulin, growth hormone, etc.), most fungal or bacterial products (disaccharidase inhibitors), and most products from animal or solid human tissue sources. CBER would have responsibility for products subject to licensure (BLA), including all vaccines, human blood or blood-derived products (as well as drugs used for blood banking and transfusion), immunoglobulin products, products containing intact cells, fungi, viruses, proteins produced by cell culture or transgenic animals, and synthetic allergenic products. This situation was further simplified by the introduction of the concept of “well-characterized biologics.” When introduced during the debate on FDA reform in 1996, the proposed section of S.1447 stated that “Biological products that the secretary determines to be well-characterized shall be regulated solely under the Federal Food, Drug and Cosmetic Act.” Under this concept, highly purified, well-characterized therapeutic rDNA proteins would be regulated by CDER, regardless of therapeutic target (Anonymous, 1996).

2.8 TOXICITY/SAFETY TESTING: CELLULAR AND GENE THERAPY PRODUCTS

Human clinical trials of cellular and gene therapies involve administration to patients of materials considered investigational biological, drug, or device products. Somatic cell therapy refers to the administration to humans of autologous, allogenic, or xenogenic cells which have been manipulated or processed *ex vivo*. Gene therapy refers to the introduction into the human body of genes or cells containing genes foreign to the body for the purposes of prevention, treatment, diagnosing, or curing disease.

Sponsors of cellular or gene therapy clinical trials must file an IND or in certain cases an IDE with the FDA before initiation of studies in humans. It is the responsibility of the CBER to review the application and determine if the submitted data and the investigational product meet applicable standards. The critical parameters of identity, purity, potency, stability, consistency, safety, and efficacy relevant to biological products are also relevant to cellular and gene therapy products.

In 1991, FDA first published “Points to Consider in Human Somatic Cell Therapy and Gene Therapy” (Anonymous, 1991). At the time, virtually all gene therapies were retroviral and were prepared as *ex vivo* somatic cell therapies. This was subsequently reviewed by Kessler et al. (1993). While the data for certain categories of information such as that regarding molecular biology were defined in previous guidance documents relating to rDNA products, the standards for preclinical and clinical development were less well defined. The field has advanced to include not only new

vectors but also novel routes of administration. "Points to Consider in Human Somatic Cell Therapy and Gene Therapy" was thus amended in 1996 (Leibert, 1996) to reflect both advancements in product development and more importantly the accumulation of safety information.

FDA regulations state that the sponsor must submit, in the IND, adequate information about pharmacological and toxicological studies of the drug including laboratory animals or *in vitro* studies on the basis of which the sponsor has considered that it is reasonably safe to conduct the proposed clinical investigation. For cellular and gene therapies, designing and conducting relevant preclinical safety testing has been a challenge to both the FDA and to the sponsors. For genes delivered using viral vectors, the safety of the vector system *per se* must be considered and evaluated.

The preclinical knowledge base is initially developed by designing studies to answer fundamental questions. The development of this knowledge base is generally applicable to most pharmaceuticals as well as biopharmaceuticals and includes data to support (i) the relationship of the dose to biological activity, (ii) the relationship of the dose to toxicity, (iii) the effect of route and/or schedule on activity or toxicity, and (iv) identification of the potential risks for subsequent clinical studies. These questions are considered in the context of indication and/or disease state. In addition, there are often unique concerns in relation to the specific category or product class.

For cellular therapies, safety concerns may include development of a database from studies specifically designed to answer questions relating to growth factor dependence, tumorigenicity, local and systemic toxicity, and effects on host immune responses including immune activation and altered susceptibility to disease. For viral-mediated gene therapies, specific questions may relate to the potential for overexpression of the transduced gene, transduction of normal cells/tissues, genetic transfer to germ cells and subsequent alterations to the genome, recombination/rescue with endogenous virus, reconstitutions of replication competence, potential for insertional mutagenesis/malignant transformation, altered susceptibility to disease, and/or potential risk(s) to the environment.

To date cellular and gene therapy, products submitted to FDA have included clinical studies indicated for bone marrow marking, cancer, cystic fibrosis, AIDS, and inborn errors of metabolism, and infectious diseases. Of the current active INDs, approximately 78% have been sponsored by individual investigators or academic institutions and 22% have also been industry sponsored. In addition to the variety of clinical indications, the cell types have also been varied. Examples include tumor-infiltrating lymphocytes (TIL) and lymphocyte-activated killer (LAK) cells, selected cells from bone marrow and peripheral blood lymphocytes (e.g., stem cells), myoblasts, tumor cells, and encapsulated cells (e.g., islet cells and adrenal chromaffin cells).

2.8.1 Cellular Therapies

Since 1984, CBER has reviewed close to 300 somatic cell therapy protocols. Examples of the specific categories include manipulation, selection, mobilization, tumor vaccines, and other.

Manipulation: Autologous, allogenic, or xenogenic cells which have been expanded, propagated, or manipulated or had their biological characteristics altered *ex vivo* (e.g., TIL or LAK cells; islet cells housed in a membrane).

Selection: Products designed for positive or negative selection of autologous or allogenic cells intended for therapy (e.g., purging of tumor from bone marrow, selection of CD34+ cells).

Mobilization in vivo: mobilization of autologous stem cells intended for transplantation.

Tumor vaccines: Autologous or allogenic tumor cells which are administered as vaccines (e.g., tumor cell lines, tumor cell lysates, primary explant. See FDA (1993)). This group also includes autologous antigen-presenting cells pulsed with tumor-specific peptides or tumor cell lysates.

Other: Autologous, allogenic, and xenogenic cells which do not specifically fit above. This group includes cellular therapies such as extracorporeal liver assist devices.

2.8.2 Gene Therapies

The types of vectors that have been used, or proposed, for gene transduction include retrovirus, adenovirus, adeno-associated viruses, other viruses (e.g., herpes, vaccinia), and plasmid DNA. Methods for gene introduction include *ex vivo* replacement, drug delivery, marker studies, and others and *in vivo* viral vectors, plasmid vectors, and vector producer cells.

2.8.3 *ex vivo*

Replacement cells transduced with a vector expressing a normal gene in order to correct or replace the function of a defective gene.

Drug delivery cells transduced with a vector expressing a gene encoding a therapeutic molecule which can be novel or native to the host.

Marker studies cells (e.g., bone marrow, stem cells) transduced with a vector expressing a marker or a reporter gene used to distinguish it from other similar host tissues.

Other products which do not specifically fit under above (e.g., tumor vaccines in which cells are cultured or transduced *ex vivo* with a vector).

2.8.4 *in vivo*

Viral vectors The direct administration of a viral vector (e.g., retrovirus, adenovirus, adeno-associated virus, herpes, and vaccinia) to patients.

Plasmid vectors The direct administration of plasmid vectors with or without other vehicles (e.g., lipids) to patients.

Vector producer cells The direct administration of retroviral vector producer cells (e.g., murine cells producing HTK vector) to patients.

2.8.5 Preclinical Safety Evaluation

The goal of preclinical safety evaluation includes recommendation of an initial safe starting dose and safe dose-escalation scheme in humans, identification of potential target organ(s) of toxicity, identification of appropriate parameters for clinical monitoring, and identification of “at-risk” patient population(s); therefore, when feasible, toxicity studies should be performed in relevant species to assess a dose-limiting toxicity. General considerations in study design include selection of the model (e.g., species, alternative model, and animal model of disease), dose (e.g., route, frequency, and duration), and study end point (e.g., activity and/or toxicity).

The approach to preclinical safety evaluation of biotechnology-derived products, including novel cellular and gene therapies, has been referred to as the “case-by-case” approach. This approach is science-based, data driven, and flexible. The major distinction from past practices from traditional pharmaceuticals is that the focus is directed at asking specific questions across various product categories. Additionally, there is a consistent reevaluation of the knowledge base to reassess real or theoretical safety concerns and hence reevaluation of the need to answer the same questions across all product categories. In some cases, there may even be conditions which may not need specific toxicity studies, for example, when there is a strong efficacy model which is rationally designed to answer specific questions and/or there is previous human experience with a similar product with respect to dose and regimen.

2.8.6 Basic Principles for Preclinical Safety Evaluation of Cellular and Gene Therapies

Biotechnology-derived products in general:

- Use of product in animal studies that is comparable or the same as the product proposed for clinical trial(s).
- Adherence to basic principles of GLP to ensure quality of the study including a detailed protocol prepared prospectively.
- Use of the same or similar route and method of administration as proposed for clinical trials (whenever possible).
- Determination of appropriate doses delivered based upon preliminary activity obtained from both *in vitro* and *in vivo* studies (i.e., finding a dose likely to be

effective and not dangerous, a no-observed-adverse-effect level, and a dose causing dose-limiting toxicity).

- Selection of one or more species sensitive to the end point being measured, for example, infections or pathologic sequelae and/or biological activity or receptor binding.
- Consideration of animal model(s) of disease that may be better to assess the contribution of changes in physiologic or underlying physiology to safety and efficacy.
- Determination of effect on host immune response.
- Localization/distribution studies—evaluation of target tissue, normal surrounding tissue, and distal tissue sites and any alteration in normal or expected distribution.
 - Local reactogenicity.

2.8.7 Additional Considerations for Cellular Therapies

- Evaluation of cytopathogenicity.
- Evaluation of signs of cell transformation/growth factor dependence effect on animal cells, normal human cells, and cells prone to transform easily.
- Determination of alteration in cell phenotype, altered cell products, and/or function.
- Tumorigenicity.

2.8.8 Additional Considerations for Gene Therapies

- Determination of phenotype/activation state of effector cells.
- Determination of vector/transgene toxicity.
- Determination of potential transfer to germline.
- *in vitro* challenge studies—evaluation of recombination or complementation, potential for “rescue” for subsequent infection with wild-type virus.
- Determination of persistence of cells/vector.
- Determination of potential for insertional mutagenesis (malignant transformation).
- Determination of environmental spread (e.g., viral shedding).

2.9 TOXICITY TESTING: SPECIAL CASES

On paper, the general case guidelines for the evaluation of the safety of drugs are relatively straightforward and well understood. However, there are also a number of special case situations under which either special rules apply, or some additional requirements are relevant. The more common of these are summarized as follows.

2.9.1 Oral Contraceptives

Oral contraceptives are subject to special testing requirements. These have recently been modified so that in addition to those preclinical safety tests generally required, the following are also required (Berliner, 1974):

- A 3-year carcinogenicity study in beagles (this is a 1987 modification in practice from earlier FDA requirements and the 1974 publication).
- A rat reproductive (segment I) study including a demonstration of return to fertility.

2.9.2 Life-Threatening Diseases (Compassionate Use)

Drugs to treat life-threatening diseases are not strictly held to the sequence of testing requirements as put forth in Table 2.3 because the potential benefit on any effective therapy in these situations is so high. In the early 1990s, this situation applied to AIDS-associated diseases and cancer. The development of more effective HIV therapies (protease inhibitors) has now made cancer therapy more the focus of these considerations. Though the requirements for safety testing prior to initial human trials are unchanged, subsequent requirements are flexible and subject to negotiation and close consultation with FDA's Division of Oncology (within CDER) (FDA, 1988). The more recent thinking on anticancer agents has been reviewed by DeGeorge et al. (1998). The preclinical studies that will be required to support clinical trials and marketing of new anticancer agents will depend on the mechanism of action and the target clinical population. Toxicity studies in animals will be required to support initial clinical trials. These studies have multiple goals:

- Determine a starting dose for clinical trials
- Identify target organ toxicity and assess recovery
- Assist in the design of clinical dosing regimens

The studies should generally conform to the protocols recommended by the National Cancer Institute, as discussed by Greishaber (1991). In general, it can be assumed that most antineoplastic cytotoxic agents will be highly toxic. Two studies are essential to support initial clinical trials (IND phase) in patients with advanced disease. These are studies of 5–14 days in length, but with longer recovery periods. A study in rodents is required that identifies those doses that produce either life-threatening or nonlife-threatening toxicity. Using the information from this first study, a second study in nonrodents (generally the dog) is conducted to determine if the tolerable dose in rodents produces life-threatening toxicity. Doses are compared on a milligram-per-square-meter basis. The starting dose in initial clinical trials is generally one-tenth of that required to produce severe toxicity in rodents (STD10) or one-tenth the highest dose in nonrodents that does not cause

severe irreversible toxicity. While not required, information on PK parameters, especially data comparing the plasma concentration associated with toxicity in both species, is very highly regarded. Special attention is paid to organs with high cell division rates, bone marrow, testes, lymphoid tissue testing, and gastrointestinal (GI) tract. As these agents are almost always given intravenously, special attention needs to be given relatively early in development to intravenous irritation and blood compatibility study. Subsequent studies to support the NDA will be highly tailored, depending on the following:

- Therapeutic indication and mechanism of action
- The results of the initial clinical trials
- The nature of the toxicity
- Proposed clinical regimen

Even at the NDA stage, toxicity studies with more than 28 days of dosing are rarely required. While not required for the IND, assessment of genotoxicity and developmental toxicity will need to be addressed. For genotoxicity, it will be important to establish the ratio between cytotoxicity and mutagenicity. *in vivo* models, for example, the mouse micronucleus test, can be particularly important in demonstrating the lack of genotoxicity at otherwise subtoxic doses. For developmental toxicity, ICH stage C–D studies (traditionally known as segment II studies for teratogenicity in rat and rabbits) will also be necessary.

The emphasis of this discussion has been on purely cytotoxic neoplastic agents. Additional considerations must be given to cytotoxic agents that are administered under special circumstances: those that are photoactivated, delivered as liposomal emulsions, or delivered as antibody conjugates. These types of agents will require additional studies. For example, a liposomal agent will need to be compared to the free agent and a blank liposomal preparation. There are also studies that may be required for a particular class of agents. For example, anthracyclines are known to be cardiotoxic, so comparison of a new anthracycline agent to previously marketed anthracyclines will be expected.

In addition to antineoplastic, cytotoxic agents, there are cancer therapeutic or preventative drugs that are intended to be given on a chronic basis. This includes chemopreventatives, hormonal agents, immunomodulators, etc. The toxicity assessment studies on these will more closely resemble those of more traditional pharmaceutical agents. Chronic toxicity, carcinogenicity, and full developmental toxicity (ICH A–B, C–D, E–F) assessments will be required. For a more complete review, the reader is referred to DeGeorge et al. (1998).

2.9.3 Vaccines

The arrival of the COVID-19 pandemic (following on other SARS respiratory diseases) as well as the development of both

a new technology and class of vaccine as well as a significant anti-vaccination movement have sharpened focus on establishing safety of new vaccines. There is a specific COVID-19 vaccine guidance (FDA, 2020) layered on top of the 2011 FDA guidance (CBER, 2011) for developing vaccines against global infectious diseases. Added to the emerging ranks of vaccines for use in preventing cancer, singles, and (in 2022) monkey-pox, this has made the development/safety evaluation process much more complicated. The number of inoculations, the timing of these, the adjuvants used, and the intended target population must all be factored in. Pressure to meet demand paired with the number of deaths has also added to the complications for everyday use sort of approvals.

2.9.4 Oncology Drugs and Imaging Agents

After years of the specific requirements for evaluating the nonclinical safety of oncology drugs being understood but not published, FDA issued the final form of the ICH S9 guidance (2018) on the subject. Its utilization is somewhat complicated by the subsequent reorganization of the office of oncology drugs to the office of oncologic diseases (OOD) with six separate divisions.

- Division of Oncology 1 (DO1)
- Division of Oncology 2 (DO2)
- Division of Oncology 3 (DO3)
- Division of Hematologic Malignancies 1 (DHM1)
- Division of Hematologic Malignancies 2 (DHM2)
- Division of Hematology Oncology Toxicology (DHOT)

The complication comes when a potential drug may have potential efficacy in more than one tissue; therefore, requiring the filing and upkeep of multiple INDs.

Imaging agents have always been somewhat of an outlier, as they do not alter tissue or act by chemically/biochemically interacting with a patient's body, they do not list the general definition of a drug. But they are regulated by CDER, not by CDRH (CDER and CBER, 2004; FDA, 2004). Most broadly, they are classified as being one of two classes of contrast agents or diagnostic radio pharmaceuticals.

2.9.5 Optical Isomers

The FDA (and like regulatory agencies, as reviewed by Daniels et al. (1997)) has become increasingly concerned with the safety of stereoisomeric or chiral drugs. Stereoisomers are molecules that are identical to one another in terms of atomic formula and covalent bonding but differ in the three-dimensional projections of the atoms. Within this class are those molecules that are nonsuperimposable mirror images of one another. These are called enantiomers (normally designated as R- or S-). Enantiomeric pairs of a molecule

have identical physical and chemical characteristics except for the rotation of polarized light. Drugs have generally been mixtures of optical isomers (enantiomers), because of the difficulties in separating the isomers. It has become apparent in recent years, however, that these different isomers may have different degrees of both desirable therapeutic and undesirable toxicological effects. Technology has also improved to the extent that it is now possible to perform chiral specific syntheses, separations, and/or analyses. It is now highly desirable from a regulatory (FDA, 1988; De Camp, 1989; Anonymous, 1992/2015; FDA, 2015) basis to develop a single isomer unless all isomers have equivalent pharmacological and toxicological activity. The FDA has divided enantiomeric mixtures in the following categories:

- Both isomers have similar pharmacologic activity, which could be identical, or they could differ in the degrees of efficacy.
- One isomer is pharmacologically active, while the other is inactive.
- Each isomer has completely different activity.

During preclinical assessment of an enantiomeric mixture, it may be important to determine to which of these three classes it belongs. The pharmacological and toxicological properties of the individual isomers should be characterized. The PK profile of each isomer should be characterized in animal models with regard to disposition and interconversion. It is not at all unusual for each enantiomer to have a completely different PK behavior.

If the test article is an enantiomer isolated from a mixture that is already well characterized (e.g., already on the market), then appropriate bridging guides need to be performed which compare the toxicity of the isomer to that of the racemic mixture. The most common approach would be to conduct a sub-chronic (3 months) and a segment II type teratology study with an appropriate "positive" control group which received the racemate. In most instances, no additional studies would be required if the enantiomer and the racemate did not differ in toxicity profile. If, on the other hand, differences are identified, the reasons for this difference need to be investigated and the potential implications for human subjects need to be considered.

2.9.6 Special Populations: Pediatric and Geriatric Claims

Relatively few drugs marketed in the United States (~20%) have pediatric dosing information available. Clinical trials had rarely been done specifically on pediatric patients. Traditionally, dosing regimens for children have been derived empirically by extrapolating on the basis of body weight or surface area. This approach assumes that the

pediatric patient is a young adult, which simply may not be the case. There are many examples of how adults and children differ qualitatively in metabolic and/or pharmacodynamic responses to pharmaceutical agents. In their review, Shacter and DeSantis (1998) state, “The benefit of having appropriate usage information in the product label is that health care practitioners are given the information necessary to administer drugs and biologics in a manner that maximizes safety, minimizes unexpected adverse events, and optimizes treatment efficacy. Without specific knowledge of potential drug effects, children may be placed at risk. In addition, the absence of appropriate proscribing information, drugs and biologics that represent new therapeutic advances may not be administered to the pediatric population in a timely manner.” In response to the need for pediatric information, the FDA had developed a pediatric plan. This two-phase plan called first for the development of pediatric information on marketed drugs. The second phase focused on new drugs. The implementation of the plan was to be coordinated by the Pediatric Subcommittee of the Medical Policy Coordinating Committee of CDER. The Pediatric Use Labeling Rule was a direct result of phase I in 1994 (PhRMA, 1998). Phase II resulted in 1997 from a proposed rule entitled “Pediatric Patients: Regulations Requiring Manufacturers to Assess the Safety and Effectiveness of New Drugs and Biologics.” Soon after this rule was proposed, the FDAMA of 1997 was passed. FDAMA contained provisions that specifically addressed the needs and requirements for the development of drugs for the pediatric population.

The FDAMA bill essentially codified and expanded several regulatory actions initiated by the FDA during the 1990s. Among the incentives offered by the bill, companies will be offered an additional 6 months of patent protection for performing pediatric studies (clinical trials) on already approved products. In fact, the FDA was mandated by the FDAMA to develop a list of over 500 drugs for which additional information would produce benefits for pediatric patients. The FDA is supposed to provide a written request for pediatric studies to the manufacturers (Hart, 1999).

In response to the pediatric initiatives, the FDA has published policies and guidelines and conducted a variety of meetings. CDER has established a website (<http://www.fda.gov/cder/pediatric>) which lists three pages of such information. Interestingly, the focus has been on clinical trials, and almost

no attention has been given to the preclinical toxicology studies that may be necessary to support such trials. There are three pages of documents on the pediatric website. None appears to address the issue of appropriate testing. This is a situation that is just now being addressed and is in a great deal of flux.

In the absence of any guidelines from the agency for testing drugs in young or “pediatric” animals, one must fall back on the maxim of designing a program that makes the most scientific sense. As a guide, the FDA-designated levels of postnatal human development and the approximate equivalent ages (in the author’s considered opinion) in various animal models are given in Table 2.9. The table is somewhat inaccurate, however, because of difference in the stages of development at birth. A rat is born quite underdeveloped when compared to a human being. A 1-day-old rat is not equivalent to a 1-day-old full-term human infant. A 4-day-old rat would be more appropriate. In terms of development, the pig may be the best model of those listed; however, one should bear in mind that different organs have different developmental schedules in different species.

Table 2.9 can be used as a rough guide in designing toxicity assessment experiments in developing animals. In designing of the treatment period, one needs to consider not only the dose and the proposed course of clinical treatment but also the proposed age of the patient and whether or not an equivalent dosing period in the selected animal model covers more than one developmental stage. For example, if the proposed patient population is human infants, initiating a toxicity study of the new pharmaceutical agent in 3-day-old rats is not appropriate. Furthermore, if the proposed course of treatment in adult children is 2 weeks, it is unlikely that this would cross over into a different developmental stage. A 2-week treatment initiated in puppies, however, might easily span two developmental stages. Thus, in designing an experiment in young animals, one must carefully consider the length of the treatment period balancing the developmental age of the animal model and the proposed length of clinical treatment. Where appropriate (infant animals), one needs to also assess changes in standard developmental landmarks (e.g., eye opening, pinnae eruption, external genitalia development) as well as the more standard indicators of target organ toxicity. The need for maintaining the experimental animals past the dosing period, perhaps into sexual maturity, to assess recovery or delayed effects needs also to be carefully considered.

TABLE 2.9 Comparison of Postnatal Development Stages

Stage	Human	Rat	Dog	Pig
Neonate	Birth to 1 month	Birth to 1 week	Birth to 3 weeks	Birth to 2 weeks
Infant	1 month–2 years	1–3 weeks	3–6 weeks	2–4 weeks
Child	2–12 years	3–9 weeks	6 weeks–5 months	4 weeks–4 months
Adolescent	12–16 years	9–13 weeks	5–9 months	4–7 months
Adult	Over 16 years	Over 13 weeks	Over 9 months	Over 7 months

To summarize, the current status of assessment of toxicity in postnatal mammals, in response to the pediatric initiatives covered in FDAMA, is an extremely fluid situation. One needs to carefully consider a variety of factors in designing the study and should discuss proposed testing programs with the appropriate office at CDER.

Drugs intended for use in the elderly, like those intended for the very young, may also have special requirements for safety evaluation, but geriatric issues were not addressed in the FDAMA of 1997. The FDA has published a separate guidance document for geriatric labeling (CDER and CBER, 2001). As was the case with pediatric guidance, this document does not address preclinical testing. With the elderly, the toxicological concerns are quite different than the developmental concerns associated with pediatric patients. With the elderly, one must be concerned with the possible interactions between the test article and compromised organ function. The FDA had previously issued a guidance for clinically examining clinical safety of new pharmaceutical agents in patients with compromised renal and/or hepatic function (CDER, 1989). The equivalent ICH guideline (S5A) was issued in 1994. Whether this type of emphasis will require toxicity testing in animal models with specifically induced organ insufficiency remains to be seen. In the interim, we must realize that there is tacit evaluation of test-article-related toxicity in geriatric rodents for those agents that undergo 2-year carcinogenicity testing. As the graying of America continues, labeling for geriatric use may become more of an issue in the future.

As presented in Table 2.10, there are four special case INDs that lead to earlier approval of drugs for special cases. The prototype for these would be the orphan drug route.

2.9.7 Orphan Drugs

The development of sophisticated technologies, coupled with the rigors and time required for clinical and preclinical testing, has made pharmaceutical development very expensive. To recoup such expenses, pharmaceutical companies have tended to focus on therapeutic agents with large potential markets. Treatments for rare but life-threatening diseases have been “orphaned” as a result. An orphan product is defined as one targeted at a disease which affects 200 000 or fewer individuals in the United States. Alternatively, the therapy may be targeted for more than 200 000, but the developer would have no hope of recovering the initial investment without exclusivity. The Orphan Drug Act (ODA) of 1983 was passed in an attempt to address this state of affairs. Currently applicable regulations were put in place in 1992 and amended in 2013 (Anonymous, 2013). In 1994, there was an attempt in Congress to amend the Act, but it failed to be passed into law. The current regulations are administered by the Office of Orphan Products Development (OOPD). The Act offers the following incen-

tives to encourage the development of products to treat rare diseases:

- Seven-year exclusive market following the approval of a product for an orphan disease.
- Written protocol assistance from the FDA.
- Tax credits for up to 50% of qualified clinical research expenses.
- Available grant to support pivotal clinical trials.

As reviewed by Haffner (1998), other developed countries have similar regulations.

There are significant misconceptions about the orphan drug process (Tambuyzer, 2010). The ODA did not change the requirements of testing drug products. The nonclinical testing programs are similar to those used for more conventional products. They will undergo the same FDA review process. A major difference, however, is the involvement of the OPD. A sponsor must request OPD review. Once OPD determines that a drug meets the criteria for orphan drug status, it will work with the sponsor to provide the assistance required under the Act. The ODA does not review a product for approval. The IND/NDA process is still handled by the appropriate reviewing division (e.g., cardiovascular) for formal review. The Act does not waive the necessity for submission of an IND, not for the responsibility of toxicological assessment. As always, in cases where there is ambiguity, a sponsor may be well served to request a pre-IND meeting at the appropriate division to discuss the acceptability of a toxicology assessment plan.

2.9.8 Expedited and Augmented Routes to Approval (Once you have an IND)

As summarized in Table 2.10, once an IND has opened and there is some clinical data, a range of potentially expedited routes to product approval may be available for a drug in addition to the four possible listed in the table (note that orphan drug designation is not an expedited route to approval and thus is not listed, in 2017 (under section 529 of the Food, Drug, and Cosmetic Act), the FDA may grant designation of a drug as suitable for use in treating a rare pediatric disease (RPD). Such designation then provides a voucher for priority review, which may then be transferred for use with another drug.

2.9.9 Botanical Drug Products

There is an old saying, “What goes around comes around,” and so it is with botanicals. At the beginning of the twentieth century, most marketed pharmaceutical agents were botanical in origin. For example, aspirin was first isolated from willow bark. These led the way in the middle part of the century, for reasons having to do with patentability, manufacturing costs, standardization, selectivity, and potency. The dawning of the

^a Title VIII of FDASIA, "Generating Antibiotic Incentives Now (GAIN)," provides incentives for the development of antibacterial and antifungal drugs for human use intended to treat serious and life-threatening infections. Under GAIN, a drug may be designated as a qualified infectious disease product (QIDP) if it meets the criteria outlined in the statute. A drug that receives QIDP designation is eligible under the statute for fast-track designation and priority review. However, QIDP designation is beyond the scope of this guidance.

^b Any supplement to an application under Section 505 of the FD&C Act that proposes a labeling change pursuant to a report on a pediatric study under this section shall be considered a priority review supplement per Section 505A of the FD&C Act as amended by Section 5(b) of the Best Pharmaceuticals for Children Act.

^c See footnote a above.

^d Any application or supplement that is submitted with a priority review voucher will be assigned a priority review. Priority review vouchers will be granted to applicants of applications for drugs for the treatment or prevention of certain tropical diseases, as defined in Section 524(a)(3) and (a)(4) of the FD&C Act and for treatment of rare pediatric diseases as defined in Section 529(a)(3) of the FD&C Act.

^e As part of its commitments in PDUFA V, the FDA has established a review model, the Program. The Program applies to all new molecular entity NDAs and original BLAs, including applications that are resubmitted following a refuse-to-file action, received from October 1, 2012, through September 30, 2017. For applications filed by FDA under the Program, the PDUFA review clock will begin at the conclusion of the 60-calendar day filing review period that begins on the date of FDA receipt of the original submission.

^f A sponsor may also withdraw fast-track designation if the designation is no longer supported by emerging data or the drug development program is no longer being pursued (see Section A.5).

^g A sponsor may also withdraw breakthrough therapy designation if the designation is no longer supported by emerging data or the drug development program is no longer being pursued (see Section B.5).

twenty-first century has seen a grassroots return to botanical preparations (also sold as herbals or dietary supplements). These preparations are being marketed to the lay public as “natural” supplements to the nasty synthetic chemicals now proscribed as pharmaceutical products. In 1994, the Dietary Supplement Health and Education Act was passed which permitted the marketing of dietary supplements (including botanicals) with limited submissions to the FDA (Wu et al., 2000). If a producer makes a claim that an herbal preparation is beneficial to a specific part of the body (e.g., enhanced memory), then it may be marketed after a 75-day period of FDA review but without formal approval. On the other hand, if any curative properties are claimed, then the botanical will be regulated as a drug and producers will be required to follow the IND/NDA process. In 1997 and 1998 combined, some 26 INDs were filed for botanical products (Wu et al., 2000).

The weakness in the current regulation has to do with its ambiguity. The line between a beneficial claim and a curative claim is sometimes difficult to draw. What is the difference, for example, between an agent that enhances memory and one that prevents memory loss? Given the number of products and claims hitting the shelves every day, this situation will probably demand increased regulatory scrutiny in the future.

2.9.10 Types of New Drug Applications (NDAs)

Actual product approvals for drugs (including biologics) are one form or another of NDA. While in this volume we focus on the traditional (505(b)(1)), there are two others for small molecules—505(b)(2) Applications and Abbreviated New Drug Application (ANDA) (for generic drug applications). These have minimal if any nonclinical safety requirements. While these are US FDA terms for the non-NME drug approvals, equivalents exist in other major regulatory paradigms (see, e.g., EOC Directive 2001/83/EC, amended in July of 2008).

2.10 INTERNATIONAL PHARMACEUTICAL REGULATION AND REGISTRATION

Prior to ICH, the requirements for evaluating the safety and then gaining product approval varied significantly between

companies. Different studies might be required, and the details of testing (as well as days of dosing and number of animals required) varied between companies, leading to significant duplication of studies and misuse of time, money, and animals. ICH has served to harmonize requirements for testing and documentation, though there is still a degree of variation between countries and regions, which are minimal.

2.10.1 International Council for Harmonization

The ICH was established to make the drug regulatory process more efficient in the United States, Europe, and Japan. The US involvement grew out of the fact that the United States is party to the General Agreement on Tariffs and Trade, which included the Agreement on Technical Barriers to Trade, negotiated in the 1970s, to encourage reduction of nontariff barriers to trade (Barton, 1998). The main purpose of ICH is, through harmonization, to make new medicines available to patients with a minimum of delay. More recently, the need to harmonize regulation has been driven, according to ICH, by the escalation of the cost of R&D. The regulatory systems in all countries have the same fundamental concerns about safety, efficacy, and quality, yet sponsors had to repeat many time-consuming and expensive technical tests to meet country-specific requirements. Secondarily, there was a legitimate concern over the unnecessary use of animals. Conference participants include representatives from the drug regulatory bodies and research-based pharmaceutical industrial organizations of three regions: the European Union (EU), the United States, and Japan were over 90% of world’s pharmaceutical industry. Representation is summarized in Table 2.11. The biennial conference met regularly beginning in 1991, rotating between sites in the United States, Europe, and Japan.

The ICH meets its objectives by issuing guidelines for the manufacturing, development, and testing of new pharmaceutical agents that are acceptable to all three major parties. For each new guideline, the ICH Steering Committee establishes an expert working group with representation from each of the six major participatory ICH bodies. Each new draft guideline goes through the five various steps of review and revision summarized in Table 2.12. So far, ICH has proposed or

TABLE 2.11 ICH Representation

Country/Region	Regulatory	Industry
European Union	European Commission (2)	European Federation of Pharmaceutical Industries and Associations (2)
Japan	Ministry of Health and Welfare (2)	Japan Pharmaceutical Manufacturers Association (2)
United States	Food and Drug Administration (2)	Pharmaceutical Research and Manufacturers of America (2)
Observing organizations	World Health Organization, European Free Trade Association, Canadian Health Protection Branch	International Federation of Pharmaceutical Manufactures & Associations (2): also provides the secretariat

Numbers in parentheses are number of representatives on the ICH Steering Committee.

TABLE 2.12 Steps in ICH Guideline Development and Implementation

1. Building scientific consensus in joint regulatory/industry expert working groups
2. Agreement by the steering committee to release the draft consensus text for wider consultation
3. Regulatory consultation in the three regions. Consolidation of the comments
4. Agreement on a harmonized ICH guideline; adopted by the regulators^a
5. Implementation in the three ICH regions^a

^a ICH (1997).

adopted over 40 safety, efficacy, and quality guidelines (listed in Table 2.13) for use by the drug regulatory agencies in the United States, Europe, and Japan. Those guidelines specifically applying to nonclinical drug safety evaluation, in their most current state, are listed in Table 2.14.

The guidelines are organized under broad categories: the “E” series having to do with clinical trials, the “Q” series having to do with quality (including chemical manufacturing and control as well as traditional GLP issues), and the “S” series having to do with safety. Guidelines may be obtained from the ICH secretariat, c/o of IFPMA, 30 rue de St.-Jean, PO Box 9, 1211 Geneva 18, Switzerland, or may be downloaded directly from the ICH website (<http://www.ich.org/products/guidelines.html>). They are also published in the Federal Register. It is the guidelines of the “S” series that will have the most impact on toxicologists. The biggest changes having to do with toxicological assessment are summarized as follows.

2.10.1.1 Carcinogenicity Studies Carcinogenicity studies are covered in Guidelines S1A, S1B, and S1C. The guidelines are almost more philosophical than they are technical. In comparison to the EPA guidelines, for example, the ICH guidelines contain little in the way on concrete study criteria (e.g., the number of animals, the necessity for clinical chemistry). There is discussion on when carcinogenicity studies should be done, whether two species are more appropriate than one, and how to set dosages on the basis of human clinical PK data. The major changes being wrought by these guidelines are the following:

- Only one 2-year carcinogenicity study should be generally required. Ideally, the species chosen should be the one most like man in terms of metabolic transformations of the test article.
- The traditional second long-term carcinogenicity study can be replaced by a shorter-term alternative model. In practical terms, this guideline is beginning to result in sponsors conducting a 2-year study in the rat and a 6-month study in an alternative mouse model, such as the P53 or the TG.AC genetically manipulated mouse strains.

- In the absence of target organ toxicity with which to set the high dose at the maximally tolerated dose, the high dose can be set at the dose that produces an area under the curve (AUC). This is 25-fold higher than that obtained in human subjects.
- A new carcinogenicity guidance (S1B(R1) issued in the second half of 2022) has clarified paths to obtain a complete or partial waiver of carcinogenicity testing.

2.10.1.2 Chronic Toxicity Traditionally, chronic toxicity of new pharmaceuticals in the United States was assessed in studies of 1-year duration in both the rodent and the nonrodent species of choice. The European view was that studies of 6 months are generally sufficient. The resulting guideline (S4A) was a compromise. Studies of 6-month duration were recommended for the rodent, as rodents would also be examined in 2-year studies. For the nonrodent (dog, nonhuman primate, and pig), studies of 9-month duration were recommended.

2.10.1.3 Developmental and Reproductive Toxicity This was an area in which there was considerable international disagreement and the area in which ICH has promulgated the most technically detailed guidelines (S5A and S5B). Some of the major changes include the following:

- The traditional segment I, II, and III nomenclature has been replaced with different nomenclature, as summarized in Table 2.15.
- The dosing period of the pregnant animals during studies on embryonic development (traditional segment II) studies has been standardized.
- New guidelines for fertility assessment (traditional segment I) studies that have shortened the pre-mating dosing schedule (e.g., in male rats from 10 to 4 weeks). There has been an increased interest in assessment of spermatogenesis and sperm function.
- The new guidelines allow for a combination of studies in which the end point typically assessed in the traditional segment II and segment III studies is now examined under a single protocol.

For a more complete review of the various study designs, the reader is referred to the review by Manson (1994).

While they were not quite as sweeping in approach as the aforementioned guidelines, a toxicologist working in pharmaceutical safety assessment should become familiar with the all the other ICH guidelines in the S series.

In an interesting article, Ohno (1999) discussed not only the harmonization of nonclinical guidelines but also the need to harmonize the timing of nonclinical tests in relation to the conduct of clinical trials. For example, there are regional differences in the inclusion of women of childbearing potential

in clinical trials. In the United States, including woman in such trials is becoming more important, and therefore evaluation of embryo-fetal development will occur earlier in the drug development process than in Japan. Whether or not such timing or staging of nonclinical tests becomes part of an ICH guideline in the near future remains to be established.

2.10.2 Other International Considerations

The United States is the single largest pharmaceutical market in the world. But the rest of the world (particularly, but not limited to the second and third largest markets, Japan and the EU) represents in aggregate a much larger market, so no one develops a new pharmaceutical for marketing in just the United States. The effort at harmonization (exemplified by the ICH) has significantly reduced differences in requirements for these other countries, but certainly not obliterated them. Though a detailed understanding of their regulatory schemes is beyond this volume, the bare bones and differences in toxicology requirements are not.

2.10.2.1 European Union The standard EU toxicology and pharmacologic data requirements for a pharmaceutical include the following:

- Single-dose toxicity
- Repeat-dose toxicity (subacute and chronic trials)
- Reproduction studies (fertility and general reproductive performance, embryotoxicity, and peri-/post-natal toxicity)
- Mutagenic potential (*in vitro* and *in vivo*)
- Carcinogenicity
- Pharmacodynamics
 - Effects related to proposed drug indication
 - General pharmacodynamics
 - Drug interactions
- Pharmacokinetics
 - Single dose
 - Repeat dose

TABLE 2.15 Comparison of Traditional and ICH Guidelines for Reproductive and Developmental Toxicology

Traditional Protocol	Stages Covered	ICH Protocol	Dosing Regimen
Segment I (rats)	A. Premating to conception	Fertility and early embryonic development, including implantation	Males: 4 weeks premating, mating (1–3 weeks) plus 3 weeks postmating
	B. Conception to implantation		Females: 2 weeks premating, mating through day 7 of gestation
Segment II (rabbits)	C. Implantation to closure of hard palate	Embryo-fetal development	Females: day 6–20 of pregnancy
	D. Closure of hard palate to the end of pregnancy		
Study Title	Termination	Endpoints: In-Life	Endpoints: Postmortem
Fertility and early embryonic development, including implantation	Females: day 13–15 of pregnancy	Clinical signs and mortality	Macroscopic examination plus histology on gross lesions
	Males: day after completion of dosing	Body weights and feed intake Vaginal cytology	Collection of reproductive organs for possible histology Quantitation of corpora lutea and implantation sites Seminology (count, motility and morphology)
Embryo-fetal development		Clinical signs and mortality	Macroscopic examination plus histology on gross lesions
		Body weights and changes	Quantitation of corpora lutea and implantation sites
		Feed intake	Fetal body weights Fetal abnormalities
Pre- and postnatal development, including maternal function		Clinical signs and mortality	Macroscopic examination plus histology on gross lesions
		Body weights and changes	Implantation
		Feed intake	Abnormalities (including terata)
		Duration of pregnancy	Live/dead offspring at birth
		Parturition	Pre- and postweaning survival and growth (F ₁) Physical development (F ₁) Sensory functions and reflexes (F ₁) Behavior (F ₁)

These are mostly identical with requirements in the United States.

In January 2020, the United Kingdom (England, Scotland, and Wales) left the European Union. We are currently in a two-year transition period, but it is not clear how testing and documentation requirements may change.

- Distribution in normal and pregnant animals
- Biotransformation
 - Local tissue tolerance
 - Environmental toxicity

In general, the registration process in the EU allows one to either apply to an overall medicines' authority or to an individual national authority. Either of these steps is supposed to lead to mutual recognition by all the individual members.

2.10.2.2 Japan In Japan, the Koseisho is the national regulatory body for new drugs. The standard LD₅₀ test is no longer a regulatory requirement for new medicines in the United States, the EU, or Japan. The Japanese guidelines were the first to be amended in accordance with this agreement, with the revised guidelines becoming effective in August 1993. The Japanese may still anticipate that single-dose (acute) toxicity studies should be conducted in at least two species, one rodent and one nonrodent (the rabbit is not accepted as a nonrodent). Both males and females should be included from at least one of the species selected: if the rodent, then a minimum of five per sex and if the nonrodent, at least two per sex. In nonrodents, both the oral and parenteral routes should be used, and normally the clinical route of administration should be employed. In nonrodents, only the intended route of administration needs to be employed; if

the intended route of administration in humans is intravenous, then use of this route in both species is acceptable. An appropriate number of doses should be employed to obtain a complete toxicity profile and to establish any dose–response relationship. The severity, onset, progression, and reversibility of toxicity should be studied during a 14-day follow-up period, with all animals being necropsied. When macroscopic changes are noted, the tissue must be subjected to histological examination.

Chronic and subchronic toxicity studies are conducted to define the dose level, when given repeatedly, that cause toxicity and the dose level that does not lead to toxic findings. In Japan, such studies are referred to as repeated-dose toxicity studies. As with single-dose studies, at least two animal species should be used, one rodent and one nonrodent (rabbit not acceptable). In rodent studies, each group should consist of at least 10 males and 10 females; in nonrodent species, three of each sex are deemed adequate. Where interim examinations are planned, however, the numbers of animals employed should be increased accordingly. The planned route of administration in human subjects is normally explored. The duration of the study will be dictated by the planned duration of clinical use (Table 2.16).

At least three different dose groups should be included, with the goals of demonstrating an overtly toxic dose and a no-effect dose and establishing any dose–response relationship. The establishment of a nontoxic dose within the framework of these studies is more rigorously adhered to in Japan than elsewhere in the world. All surviving animals should also be necropsied, either at the completion of the study or during its extension recovery period, to assess reversal of toxicity and the possible appearance of delayed toxicity. Full histological examination is mandated on all nonrodent animals used in a chronic toxicity study; at a minimum, the highest-dose and control groups of rodents must be submitted to a full histological examination.

TABLE 2.16 Required Duration of Dosing in Nonclinical Study to Support Clinical Dosing

Duration of Dosing in Toxicity Study (months)	Duration of Human Exposure
1	Single dose or repeated dosage not exceeding 1 week
3	Repeated dosing exceeding 1 week and to a maximum of 4 weeks
6	Repeated dosing exceeding 4 weeks and to a maximum of 6 months
12 ^a	Repeated dosing exceeding 6 months or where this is deemed to be appropriate

Source: New Drugs Division Notification No. 43, June 1992. CDER and CBER (2014), ICH (1997).

^a Where carcinogenicity studies are to be conducted, the Koseisho had agreed to forego chronic dosage beyond 6 months.

While the value of repeated-dose testing beyond 6 months has been questioned (Lumley et al., 1992), such testing is a regulatory requirement for several agencies, including the US FDA and the Koseisho. In Japan, repeated-dose testing for 12 months is required only for new medicines expected to be administered to humans for periods in excess of 6 months (Yakuji Nippo, 1994). At the first ICH held in Brussels, the consensus was that 12-month toxicity studies in rodents could be reduced to 6 months where carcinogenicity studies are required. While not yet adopted in the Japanese guidelines, 6-month repeated-dose toxicity studies have been accepted by the agencies of all three regions. Japan—like the EU—accepts a 6-month duration if accompanied by a carcinogenicity study. The United States still requires a 9-month nonrodent study.

With regard to reproductive toxicology, as a consequence of the first ICH, the United States, the EU, and Japan agreed to recommend mutual recognition of their respective current guidelines. A tripartite harmonized guideline on reproductive toxicology has achieved ICH step 4 status and should be incorporated into the local regulations of all three regions soon. This agreement represents a very significant achievement that should eliminate many obstacles to drug registration.

Preclinical male fertility studies Before conducting a single-dose male volunteer study in Japan, it is usually necessary to have completed a preclinical male fertility study (segment 1) that has an in-life phase of 10 or more weeks (i.e., 10 weeks of dosing, plus follow-up). Although government guidelines do not require this study to be completed before phase I trials begin, the responsible institutional review board, or the investigator usually imposes this condition. Japanese regulatory authorities are aware that the segment 1 male fertility study is of poor predictive value. The rat, which is used in this study, produces a marked excess of sperm. Many scientists therefore believe that the test is less sensitive than the evaluation of testicular weight and histology that constitute part of the routine toxicology assessment.

Female reproductive studies Before entering a female into a clinical study, it is necessary to have completed the entire reproductive toxicology program, which consists of the following studies:

- Segment 1: Fertility studies in the rat or mouse species used in the segment 2 program
- Segment 2: Teratology studies in the rat or mouse and the rabbit
- Segment 3: Late gestation and lactation studies in a species used in the segment 2 studies

Such studies usually take approximately 2 years. Although the US regulations state the need for completion of segments 1 and 2 and the demonstration of efficacy in male patients, where appropriate, before entering females into a clinical program, the current trend in the United States is toward relaxation of the requirements to encourage investigation of the

drug both earlier and in a larger number of females during product development. Growing pressure for the earlier inclusion of women in drug testing may encourage selection of this issue as a future ICH topic. The trend in the United States and the EU toward including women earlier in the critical program has not yet been embraced in Japan, however.

The three tests required in Japan for genotoxicity evaluation are a bacterial gene mutation test, *in vitro* cytogenetics, and *in vivo* tests for genetic damage. The Japanese regulations state these tests to be the minimum requirement and encourage additional tests. Currently, Japanese guidelines do not require a mammalian cell gene mutation assay. Harmonization will likely be achieved by the Koseisho recommending all four tests, which will match requirements in the United States and the EU; at present, this topic is at step 1 in the ICH harmonization process. The mutagenicity studies should be completed before the commencement of phase II clinical studies.

Guidelines presented at the second ICH are likely to alter the preclinical requirements for registration in Japan; they cover toxicokinetics and when to conduct repeated-dose tissue distribution studies. The former document may improve the ability of animal toxicology studies to predict possible adverse events in humans; currently, there are no toxicokinetic requirements in Japan, and their relevance is questioned by many there. Although there is a general agreement on the registration requirement for single-dose tissue distribution studies, implementation of the repeated dose study requirement has been inconsistent across the three ICH parties.

2.10.2.3 China The Chinese equivalent of the FDA is the New Medical Product Authority (NMPA). It generally adheres to ICH requirements, but current requirements for a New Drug Clinical Research Application (NDRA) are not available in English, only in Mandarin. There are several additional requirements to open an “IND” in China. These include acute toxicity studies in two species, and free-standing pharmacokinetic studies in one or two species.

2.10.3 Safety Pharmacology

Japan was the first major country to require extensive pharmacological profiling on all new pharmaceutical agents as part of the safety assessment profile. Prior to commencement of initial clinical studies, the drug’s pharmacology must be characterized in animal models. In the United States and Europe, these studies have been collectively called safety pharmacology studies. For a good general review of the issues surrounding safety pharmacology, the reader is referred to Hite (1997). The Japanese guidelines for such characterizations were published in 1991. They include

- Effects on general activity and behavior
- Effects on the CNS

- Effects on the autonomic nervous system and smooth muscle
- Effects on the respiratory and cardiovascular systems
- Effects on the digestive system
- Effects on water and electrolyte metabolism
- Other important pharmacological effects

Source: New Drugs Division Notification No. 4, January 1991.

In the United States, pharmacological studies in demonstration of efficacy have always been required, but specific safety pharmacological studies have never been required. Special situational or mechanistic data would be requested on a case-by-case basis. This is a situation that is changing. In the United States the activities of the Safety Pharmacology Discussion Group, for example, have helped bring attention to the utility and issues surrounding safety pharmacology data. In 1999 and 2000, the major toxicological and pharmacological societal meetings had symposia on safety pharmacological testing. Many major US pharmaceutical companies are in the process of implementing programs in safety pharmacology. The issue has been taken up by ICH and the draft guideline is currently at the initial stages of review. This initial draft (Guideline S7) includes core tests in the assessment of CNS, cardiovascular, and respiratory function. Studies will be expected to be performed under GLP guidelines.

Even with harmonization as per ICH, there remain significant variations over the length of the entire process that takes a drug through to market (Hirako et al., 2007; Gad, 2012; Brock et al., 2013). These require guidance from a knowledgeable team of experts over the course of the process. This is especially true for emerging markets such as China (Deng and Kaitin, 2004). But the promulgation and near-complete acceptance of a single format (the Common Technical Document—CTD) for worldwide regulatory submissions (see Table 2.17 for an outline of components) has been a huge step for global harmonization.

2.11 COMBINATION PRODUCTS

Recent years have seen a vast increase in the number of new therapeutic products which are not purely drug, device, or biologic, but rather a combination of two or more of these. This leads to a problem of deciding which of the three centers shall have ultimate jurisdiction.

The Center for Devices and Radiological Health (CDRH) is designated the center for major policy development and for the promulgation and interpretation of procedural regulations for medical devices under the Act. The CDRH regulates all medical devices inclusive of radiation-related devices that are not assigned categorically or specifically to CDER. In addition, the CDRH will independently administer the

TABLE 2.17 Composition of the Common Technical Document (ICH Format)

Nonclinical summary
Clinical overview
Clinical summary
3. Quality data
4. Nonclinical study reports
5. Clinical study reports

following activities (references to “Sections” are the provisions of the Act):

- A. Small business assistance programs under Section 10 of the amendments (See PL 94-295). Both CDER and CDRH will identify any unique problems relating to medical device regulation for small business.
- B. Registration and listing under Section 510 including some CDER-administered device applications. CDER will receive printouts and other assistance, as requested.
- C. Color additives under Section 706, with review by CDER, as appropriate.
- D. GMPs Advisory Committee. Under Section 520(f) (3), CDER will regularly receive notices of all meetings, with participation by CDER, as appropriate.
- E. Medical Device Reporting. The manufacturers, distributors, importers, and users of all devices, including those regulated by CDER, shall report to CDRH under Section 519 of the Act as required. The CDRH will provide monthly reports and special reports as needed to CDER for investigation and follow-up of those medical devices regulated by CDER.

2.11.1 Device Programs That Are CDER and CBRH Each Will Administer

Both CDER and CDRH will administer and, as appropriate, enforce the following activities for medical devices assigned to their respective centers (references to “Sections” are the provisions of the Act):

- A. Surveillance and compliance actions involving general controls violations, such as misbranded or adulterated devices under Section 301, 501, and 502
- B. Warning letters, seizures, injunctions, and prosecutions under Section 302, 303, and 304
- C. Civil penalties under Section 303(f) and administrative restraint under Section 304(g)

- D. Nonregulatory activities, such as educational programs directed at users, participation in voluntary standards organizations, etc.
- E. Promulgation of performance standards and applications of special controls under Section 514
- F. Premarket notification; investigational device exemptions including humanitarian exemptions; premarket approval; product development protocols; classification; device tracking; petitions for reclassification; postmarket surveillance under Sections 510(k), 513, 515, 519, 520(g) & (m), and 522; and the advisory committees necessary to support these activities
- G. Banned devices under Section 516
- H. FDA-requested and firm-initiated recalls whether under Section 518 or another authority and other Section 518 remedies such as recall orders
- I. Exemptions, variances, and applications of CGMP regulations under Section 520(f)
- J. Governmentwide quality assurance program
- K. Requests for export approval under Sections 801(e) and 802

2.11.2 Coordination

The centers will coordinate their activities in order to assure that manufacturers do not have to independently secure authorization to market their product from both centers unless this requirement is specified in Section VII.

2.11.3 Submissions

All submissions should be made to the appropriate center or project manager electronically. If paper copies are requested, they should be delivered to the appropriate document center as listed:

Central Document Room
 Center for Drug Evaluation and Research
 Food and Drug Administration
 5901-B Ammendale Road
 Beltsville, MD 20705-1266
 or
 Central Document Room
 Center for Devices and Radiological Health
 Food and Drug Administration
 5901-B Ammendale Road
 Beltsville, MD 20705-1266

For submissions involving medical devices and/or drugs that are not clearly addressed in this agreement, sponsors are referred to the product jurisdiction regulations (21 CFR Part 3). These regulations have been promulgated to facilitate the

determination of regulatory jurisdiction but do not exclude the possibility for a collaborative review between the centers.

2.11.3.1 Center Jurisdiction The following subsections provide details concerning status, market approval authority, special label/regulatory considerations, investigational options, and intercenter consultations for the categories of products specified. Section VII provides the general criteria that CDRH and CDER will apply in reaching decisions as to which center will regulate a product.

- A. 1.a. Device with primary purpose of delivering or aiding in the delivery of a drug that is distributed without a drug (i.e., unfilled)

Examples

Devices that calculate drug dosages

Drug delivery pump and/or catheter infusion pump for implantation
Iontophoresis device
Medical or surgical kit (e.g., tray) with reference in instructions for use with specific drug (e.g., local anesthetic)
Nebulizer
Small particle aerosol generator (SPAG) for administering drug to ventilated patient
Splitter block for mixing nitrous oxide and oxygen
Syringe, jet injector, and storage and dispensing equipment
Status Device and drug, as separate entities.

Market approval authority CDRH and CDER, respectively, unless the intended use of the two products, through labeling, creates a combination product.

Special label/regulatory considerations The following specific procedures will apply depending on the status of the drug delivery device and drugs that will be delivered with the device:

- (i) It may be determined during the design or conduct of clinical trials for a new drug that it is not possible to develop adequate performance specifications data on those characteristics of the device that is required for the safe and effective use of the drug. If this is the case, then drug labeling cannot be written to contain information that makes it possible for the user to substitute a generic, marketed device for the device used during developments to use with the marketed drug. In these situations, CDER will be the lead center for regulation of the device under the device authorities.
- (ii) For a device intended for use with a category of drugs that are on the market, CDRH will be the lead center for regulation for the device under

the device authorities. The effects of the device use on drug stability must be addressed in the device submission, when relevant. An additional showing of clinical effectiveness of the drug when delivered by the specific device will generally not be required. The device and drug labeling must be mutually conforming with respect to indication, general mode of delivery (e.g., topical, IV), and drug dosage/schedule equivalents.

- (iii) For a drug delivery device and drug that are developed for marketing to be used together as a system, a lead center will be designated to be the contact point with the manufacturer(s). If a drug has been developed and marketed and the development and studying of device technology predominate, the principal mode of action will be deemed to be that of the device, and CDRH would have the lead. If a device has been developed and marketed and the development and studying of drug predominate, then, correspondingly, CDER would have the lead. If neither the drug nor the device is on the market, the lead center will be determined on a case-by-case basis.

Investigation options IDE or IND, as appropriate.

Intercenter consultation CDER, when lead center, will consult with CDRH if CDER determines that a specific device is required as part of the NDA process. CDRH as lead center will consult with CDER if the device is intended for use with a marketed drug and the device creates a significant change in the intended use, mode of delivery (e.g., topical, IV), or dose/schedule of the drug.

- H. Device with primary purpose of delivering or aiding in the delivery of a drug and distributed containing a drug (i.e., “prefilled delivery system”)

Examples

Nebulizer
Oxygen tank for therapy and OTC emergency use
Prefilled syringe
Transdermal patch
Status Combination product.

Market approval authority CDER using drug authorities and device authorities, as necessary.

Special label/regulatory considerations None.

Investigation options IND.

Intercenter consultations Optional.

- 2. Device incorporating a drug component with the combination product having the primary intended purpose of fulfilling a device function:

Examples

- Bone cement containing antimicrobial agent
 - Cardiac pacemaker lead with steroid-coated tip
 - Condom, diaphragm, or cervical cap with contraceptive or antimicrobial agent (including virucidal) agent
 - Dental device with fluoride
 - Dental wood wedge with hemostatic agent
 - Percutaneous cuff (e.g., for a catheter or orthopedic pin) coated/impregnated with antimicrobial agent
 - Skin closure or bandage with antimicrobial agent
 - Surgical or barrier drape with antimicrobial agent
 - Tissue graft with antimicrobial or other drug agent
 - Urinary and vascular catheter coated/impregnated with antimicrobial agent
 - Wound dressing with antimicrobial agent
 - Status Combination product.
 - Market approval authority CDRH using device authorities.
 - Special label/regulatory considerations These products have a drug component that is present to augment the safety and/or efficacy of the device.
 - Investigation options IDE.
 - Intercenter consultation Required if a drug or the chemical form of the drug has not been legally marketed in the United States as a human drug for the intended effect.
3. Drug incorporating a device component with the combination product having the primary intended purpose of fulfilling a drug function:

Examples

- Skin-prep pads with antimicrobial agent
 - Surgical scrub brush with antimicrobial agent
 - Status Combination product.
 - Market approval authority CDER using drug authorities and, as necessary, device authorities.
 - Special label/regulatory considerations Marketing of such a device requires a submission of an NDA with safety and efficacy data on the drug component or it meets monograph specifications as generally recognized as safe (GRAS) and generally recognized as effective (GRAE). Drug requirements, for example, CGMPs, registration and listing, and experience reporting, apply to products.
 - Investigation options IND.
 - Intercenter consultation Optional.
4. a. Device used in the production of a drug either to deliver directly to a patient or for the use in the pro-

ducing medical facility (excluding use in a registered drug manufacturing facility)

Examples

- Oxygen concentrators (home or hospital)
 - Oxygen generator (chemical)
 - Ozone generator
 - Status Device
 - Market approval authority CDER, applying both drug and device authorities.
 - Special label/regulatory consideration May also require and NDA if the drug produced is a new drug. Device requirements (e.g., CGMPs, registration and listing, and experience reporting) will apply to products.
 - Investigation options IDA, or NDA, as appropriate.
 - Intercenter consultation Optional.
- b. Drug/device combination product intended to process a drug into a finished package form

Examples

- Device that uses drug concentrates to prepare large-volume parenterals
 - Oxygen concentrator (hospital) output used to fill oxygen tanks for use within that medical facility
 - Status Combination product.
 - Market approval authority CDER, applying both drug and device authorities.
 - Special label/regulatory considerations Respective drug and device requirements (e.g., CGMPs, registration and listing, experience reporting) will apply.
 - Investigation options IDE or NDA, as appropriate.
 - Intercenter consultation Optional, but will be routinely obtained.
- B. 1. Device used concomitantly with a drug to directly activate or to augment drug effectiveness

Examples

- Biliary lithotripter used in conjunction with dissolution agent
- Cancer hyperthermia used in conjunction with chemotherapy
- Current generator used in conjunction with an implanted silver electrode (drug) that produces silver ions for an antimicrobial purpose
- Materials for blocking blood flow temporarily to restrict chemotherapy drug to the intended site of action
- UV and/or laser activation of oxsoresalen for psoriasis or cutaneous T-cell lymphoma

Status Device and drug, as separate entities.

Market approval authority CDRH and CDER, respectively.

Special label/regulatory considerations The device and drug labeling must be mutually conforming with respect to indications, general mode of delivery (e.g., topical, IV), and drug dosage/schedule equivalence. A lead center will be designated to be the contact point with the manufacturer. If a drug has been developed and approved for another use and the development and studying of device technology predominate, then CDRH would have lead. If a device has been developed and marketed for another use and the development and studying of drug action predominate, then CDER would have the lead. If neither the drug nor the device is on the market, the lead center will be determined on a case-by-case basis. If the labeling of the drug and device creates a combination product, as defined in the combination product regulations, then the designation of the lead center for both applications will be based upon a determination of the product's primary mode of action.

Investigation options IDE or IND, as appropriate.

Intercenter consultations Required.

2. Device kits labeled for use with drugs that include both device(s) and drug(s) as separate entities in one package with the overall primary intended purpose of the kit fulfilling a device function

Examples

Medical or surgical kit (e.g., tray) with drug component

Status Combination product.

Market approval authority CDRH, using device authorities, is responsible for the kit if the manufacturer is repackaging a market drug. Responsibility for overall packaging resides with CDRH. CDER will be consulted as necessary on the use of drug authorities for the repackaged drug component.

Special label/regulatory consideration Device requirements (e.g., CGMPs, registration and listing, and experience reporting) apply to kits. Device manufacturers must assure that manufacturing steps do not adversely affect drug components of the kit. If the manufacturing steps do affect the marketed drug (e.g., the kit is sterilized by irradiation), ANDA or NDA would also be required with CDRH as a lead center.

Investigation options IDA or IND, as appropriate.

Intercenter consultation Optional if ANDA or NDA not required.

- C. Liquids, gases, or solids intended for use as devices (e.g., implanted, or components, parts, or accessories to devices)

Examples

Dye for tissues used in conjunction with laser surgery to enhance absorption of laser light in target tissue

Gas mixtures for pulmonary function testing devices

Gases used to provide "physical effects"

Hemodialysis fluids

Hemostatic devices and dressings

Injectable silicon, collagen, and Teflon

Liquids functioning through physical action applied to the body to cool or freeze tissues for therapeutic purposes

Liquids intended to inflate, flush, or moisten (lubricate) indwelling device (in or on the body)

Lubricants and lubricating jellies

Ophthalmic solutions for contact lenses

Organ/tissue transport and/or perfusion fluid with antimicrobial or other drug agent, that is, preservation solutions

Powders for lubricating surgical gloves

Sodium hyaluronate or hyaluronic acid for use as a surgical aid

Solution for use with dental "chemical drill"

Spray on dressings not containing a drug component

Status Device

Market approval authority CDRH

Special label/regulatory considerations None

Investigation options IDE

Intercenter consultation Required if the device has direct contact with the body and the drug or the chemical form of the drug has not been legally marketed as a human drug

- D. Products regulated as drugs

Examples

Irrigation solutions

Purified water or saline in prefilled nebulizers for use in inhalation therapy

Skin protectants (intended for use on intact skin)

Sun screens

Topical/internal analgesic-antipyretic

Status Drug

Market approval authority CDER
 Special label/regulatory considerations None
 Investigation options IND
 Intercenter consultations Optional

E. Ad Hoc Jurisdictional Decisions

Examples	Status	Center
Motility marker constructed of radiopaque plastic	Device	CDRH
Brachytherapy capsules, needles, etc., that are radioactive and may be removed from the body after radiation therapy has been administered	Device	CDRH
Skin markers	Device	CDRH

Status Device or drug
 Market approval authority CDRH or CDER as indicated
 Special label/regulatory considerations None
 Investigation options IDE or IND, as appropriate
 Intercenter consultation Required to assure agreement on drug/device status

2.11.3.2 General Criteria Affecting Drug/Device Determination The following represent the general criteria that will apply in making device/drug determinations:

A. Device criteria

1. A liquid, powder, or other similar formulation intended only to serve as a component, part, or accessory to a device with a primary mode of action that is physical in nature will be regulated as a device by CDRH.
2. A product that has the physical attributes described in 201(h) (e.g., instrument, apparatus) of the Act and does not achieve its primary intended purpose through chemical action within or on the body, or by being metabolized, will be regulated as a device by CDRH.
3. The phrase “within or on the body” as used in 201(h) of the Act does not include extracorporeal systems or the solutions used in conjunction with such equipment. Such equipment and solutions will be regulated as devices by CDRH.
4. An implant, including an injectable material, placed in the body for primarily a structural purpose even though such an implant may be absorbed or metabolized by the body after it has achieved its primary purpose will be regulated as a device by CDRH.
5. A device containing a drug substance as a component with the primary purpose of the combination

being to fulfill a device function is a combination product and will be regulated as a device by CDRH.

6. A device (e.g., machine or equipment) marketed to the user, pharmacy, or licensed practitioner that produces a drug will be regulated as a device or combination product by CDER. This does not include equipment marketed to a registered drug manufacturer.
7. A device whose labeling or promotional materials make reference to a specific drug or generic class of drugs unless it is prefilled with a drug ordinarily remains a device regulated by CDRH. It may, however, also be subject to the combination products regulation.

B. Drug criteria

1. A liquid, powder, tablet, or other similar formulation that achieves its primary intended purpose through chemical action within or on the body, or by being metabolized, unless it meets one of the specified device criteria, will be regulated as a drug by CDER.
2. A device that serves as a container for a drug or a device that is a drug delivery system attached to the drug container where the drug is present in the container is a combination product that will be regulated as a drug by CDER.
3. A device containing a drug substance as a component with the primary purpose of the combination product being to fulfill a drug purpose is a combination product and will be regulated as a drug by CDER.
4. A drug whose labeling or promotional materials make reference to a specific device or generic class of devices ordinarily remains a drug regulated by CDER. It may, however, also be subject to the combination products regulation.

2.12 MEETINGS AND SUBMISSIONS TO FDA TOXICOLOGISTS

While there are a variety of meetings that may be requested and held with FDA concerning the development of a new drug, the most common are

- Pre-IND meeting: held prior to submitting an IND, this meeting seeks to gain clarity on the questions or the points relating to the route sought and technical works proposed or needed.
- End of Phase 2 (EOP 2) meeting. This meeting seeks to achieve agreement on the plans for looking forward into phase 3 trials for a drug.

2.13 CONCLUSION

In summary, we have touched upon the regulations that currently control the types of preclinical toxicity testing done on potential human pharmaceuticals and medical device products. We have reviewed the history, the law, the regulations themselves, the guidelines, and common practices employed to meet regulatory standards. Types of toxicity testing were discussed, as were the special cases pertaining to, for example, biotechnology products.

DATA MINING: SOURCES OF INFORMATION FOR CONSIDERATION IN STUDY AND PROGRAM DESIGN AND IN SAFETY EVALUATION

3.1 INTRODUCTION

The appropriate starting place for the safety assessment of any new chemical entity (NCE), particularly a potential new drug, is to first determine what is already known about the molecule, its structural and therapeutics or functional class analogs (pharmacological analogs being agents with assumed similar pharmacological mechanisms), and the disease one seeks to treat. Such a determination requires the fullest possible access and review of the available literature. Here we try to provide a fundamental overview of the current range of approaches to gathering such data (Table 3.1). In using this information, one must keep in mind that there is both an initial requirement to build a data file or database and a continuing need to update such a database or files on a regular basis, serving as part of the project record. Updating a database requires not only merely adding to what is already there but also discarding out-of-date (i.e., now known to be incorrect) information and reviewing the entire structure for connections and organization.

Such data are first used in selecting which possible compounds should be carried forward in development as a possible new drug (as illustrated in Figure 3.1 and explored in detail in Gad (2005)). A multitude of reasons for collecting and for uses of data should be recognized and considered.

3.1.1 Claims

Claims are what is said in labeling and advertising and may be either of a positive (therapeutic or beneficial) or negative (lack of an adverse effect) nature. The positive or efficacy claims are not usually the direct concern of the toxicologist, though it must be kept in mind that such claims both must be proven and can easily exceed the limits of the statutory defi-

nition of a device, turning the product into a drug or combination product.

Negative claims such as “nonirritating” or “hypoallergenic” also must be proven and are generally the responsibility of the product safety professional to substantiate. There are special tests for such claims.

3.1.2 Time and Economics

The final factors of influence or arbitrator of test conduct and timing are the requirements of the marketplace, the resources of the organization, and the economic worth of the product.

Plans for filings with regulatory agencies and for market launches are typically set before actual testing (or final stage development) is undertaken, as the need to be in the marketplace within a certain time frame is critical. Such timing and economic issues are beyond the scope of this volume but must be considered.

3.1.3 Prior Knowledge

The appropriate starting place for the safety assessment of any NCE, particularly a potential new material for a medical device, is to first determine what is already known about the material and whether there are any close structural or pharmacological analogs (pharmacological analogs being agents with assumed similar pharmacological mechanisms). Such a determination requires complete access to the available literature. In using this information, one must keep in mind that there is both an initial requirement to build a data file or database and a need to update such a store on a regular basis. Updating a database requires not only merely adding to what is already there but also discarding out-of-date

(i.e., now known to be incorrect) information and reviewing the entire structure for connections and organization.

The first step in any new literature review is to obtain as much of the following information as possible:

- Correct chemical identity including molecular formula, Chemical Abstracts Service (CAS) Registry Number, common synonyms, trade names, and a structural diagram. Gosselin et al. (1984), Ash and Ash (2007, 2008), and the USP (2020) (and ongoing) are excellent sources of information on existing commercial products and their components and uses. Limited by being print sources but still relevant.
- Chemical composition (if a mixture) and major impurities.
- Production and use information.
- Chemical and physical properties (physical state, vapor pressure, pH, solubility, chemical reactivity, etc.).
- Any structurally related chemical substances that are already on the market or in production.
- Known or presumed pharmacological properties.

Collection of the previous information is not only important for hazard assessment (high-vapor pressure would indicate high inhalation potential, just as high and low pH would indicate high irritation potential) but also the prior identification of all intended use and exposure patterns may provide leads to alternative information sources; for example drugs to be used

as antineoplastics or antibiotics may already have extensive toxicology data obtainable from government or private sources. A great deal of the existing toxicity information (particularly information on acute toxicity) is not available in the published or electronic literature because of concerns about the proprietary nature of this information and the widespread opinion that it does not have enough intrinsic scholarly value to merit publication. This unavailability is unfortunate, as it leads to a lot of replication of effort and expenditure of resources that could be better used elsewhere. It also means that an experienced toxicologist must use an informal search of the unpublished literature and the knowledge of their colleagues as a supplement to searches of the published and electronic literature.

There are now numerous published texts that should be considered for use in literature-reviewing activities. An alphabetic listing of 36 of the more commonly used hard copy sources for safety assessment data is presented in Table 3.2 and included in the reference section of this chapter. Obviously, this is not a complete listing and consists of only the general multipurpose texts that have a wider range of applicability for toxicology. Texts dealing with specialized classes of agents (e.g., disinfectants, excipients, and pharmaceutical salts) or with specific target organ toxicity (neurotoxins and teratogens) are generally beyond the scope of this text. Parker (1988) should be consulted for details on the use of these texts. Wexler (2014), Parker (1988), and Sidhu et al. (1989) should be consulted for more extensive listings of the literature and computerized databases. Such sources can be of direct (free) Internet sources (where one must beware of garbage in, garbage out (GIGO)), commercial databases, and package products, to mention just the major categories. Appendix C provides addresses for major free Internet sources.

3.1.4 Miscellaneous Reference Sources

There are some excellent published information sources covering some specific classes of chemicals, for example heavy metals, plastics, resins, or petroleum hydrocarbons. The National Academy of Science series *Medical and Biologic Effects of Environment Pollutants* covers 10–15 substances considered to be environmental pollutants. *Scientific American Medicine* presents a current (and consistently updated) summary of knowledge of diseases and treatments. *CRC Critical Reviews in Toxicology* is a well-known scientific journal that over the years has compiled over 26 volumes of extensive literature reviews of a wide variety of chemical substances. A photocopy of this journal's topical index will prevent one from overlooking information that may be contained in this important source. Trade organizations such as the Fragrance Industry Manufacturers Association and the Chemical Manufacturers Association

have extensive toxicology databases from their research programs that are readily available to toxicologists of member companies. Texts that deal with specific target organ toxicity—neurotoxicity, hepatotoxicity, or hematotoxicity—often contain detailed information on a wide range of chemical structures. Published information sources like the *Target of Organ Toxicity* series (Taylor & Francis, now partway through a third set of revisions) are examples of the types of publications that often contain important information on many industrial chemicals that may be useful either directly or by analogy. Upon discovery that the material one

is evaluating may possess target organ toxicity, a cursory review of these types of texts is warranted.

In the last decade, for most toxicologists, the online literature search has changed from an occasional, sporadic activity to a semicontinuous need. Usually, in many companies, nontoxicology-related search capabilities are already in place. Therefore, all that is needed is to expand the information source to include some of the databases that cover the types of toxicology information one desires. However, if no capabilities exist within an organization (increasingly the case), one can approach a university, consultant, or a private contract

laboratory and utilize their online system at a reasonable rate. It is of course possible to access almost all of these sources from home (or home office) using a personal computer. The major available online databases are as follows:

A. *National Library of Medicine*. The National Library of Medicine (NLM) information retrieval service contains several well-known databases commonly used by toxicologists for acute data. Beginning in 2020, these databases have been consolidated and can be found on either PubMed or PubChem:

1. TOXLINE (now part of PubMed) is a bibliographic database covering the pharmacological, biochemical, physiological, environmental, and toxicological effects of drugs, and other chemicals. It contains approximately 1.7 million citations, most of which are complete with abstract, index terms, and CAS Registry Numbers. TOXLINE citations have publication dates of 1981 to the present. Older information is on TOXLINE 65 (pre-1965 through 1980).
2. MEDLINE (now part of PubMed) is a database containing approximately 7 million references to biomedical journal articles published since 1966. These articles, usually with an English abstract, are from over 3000 journals. Coverage of previous years (back to 1966) is provided by back files, searchable online, that total some 3.5 million references.
3. Hazardous Substances Data Bank (HSDB) (now part of PubChem) is a scientifically reviewed and edited data bank containing toxicological information enhanced with additional data related to the environment, emergency situations, and regulatory issues. Data are derived from a variety of sources including government documents and special reports. This database contains records for over 4100 chemical substances.
4. Chemical Carcinogenesis Research Information System (CCRIS) (now part of PubChem) is a National Cancer Institute sponsored database derived from both short- and long-term bioassays on 2379 chemical substances. Studies cover carcinogenicity, mutagenicity, promotion, and cocarcinogenicity.
5. Registry of Toxic Effects of Chemical Substances (RTECS) is the NLM's online version of the National Institute for Occupational Safety and Health's (NIOSH) annual compilation of substances with toxic activity. The original collection of data was derived from the 1971 Toxic Substances Lists. RTECS data contains threshold limit values, aquatic toxicity ratings, air standards, National Toxicology Program carcinogenesis bioassay

information, and toxicological/carcinogenic review information. The NIOSH is responsible for the file content in RTECS and for providing quarterly updates to NLM: RTECS currently covers toxicity data on more than 106 000 substances.

B. *The Merck Index*. *The Merck Index* is now available online for up-to-the-minute access to new chemical entities.

3.1.5 Search Procedure

As mentioned in Section 3.1, chemical composition and identification information should already have been obtained before the chemical is to be searched. With most information retrieval systems, this is a relatively straightforward procedure. Citations on a given subject may be retrieved by entering the desired free-text terms as they appear in titles, keywords, and abstracts of articles. The search is then initiated by entering the chemical CAS number and/or synonyms. If you are only interested in a specific target organ effect—for instance, carcinogenicity—or specific publication years, searches can be limited to a finite number of abstracts before requesting the printout.

Often, it is unnecessary to request a full printout (author, title, abstract). You may choose to review just the author and title listing before selecting out the abstracts of interest. In the long run, this approach may save your computer time, especially if the number of citations being searched is large.

Once you have reviewed the abstracts, the last step is to request photocopies of the articles of interest. Extreme caution should be used in making any final health hazard determination based solely on an abstract or nonprimary literature source.

3.1.6 Monitoring Published Literature and Other Research in Progress

Although there are a few other publications offering similar services, the *Life Sciences* edition of *Current Contents* is the publication most widely used by toxicologists for monitoring the published literature. *Current Contents* monitors over 1180 major journals and provides a weekly listing by title and author. Selecting out those journals you wish to monitor is one means of selectively monitoring the major toxicology journals.

Aids available to the toxicologist for monitoring research in progress are quite variable. Ongoing research include monitoring research in progress by reviewing abstracts presented at the annual meetings of professional societies such as the Society of Toxicology, Teratology Society, Environmental Mutagen Society, and American College of Toxicology. These societies usually have their abstracts prepared in printed form; for example, the most recent (2015) *Toxicologist* contains over 2600 abstracts presented at the annual meeting.

Copies of the titles and authors of these abstracts are usually listed in the societies' respective journals, which, in many cases, would be reproduced and could be reviewed through *Current Contents*.

3.1.7 Kinds of Information

The kinds of information described here are found on two types of physical PC media—CD-ROM and laser disks. The gradual emergence of this technology during the past decade blossomed with the introduction of several CD-ROM products that deal with safety issues surrounding the toxicology and safety of chemicals. CD-ROM media with such information can generally be characterized by two major advantages: they are relatively easy to use and are amazingly quick in retrieving data of interest. The products run the gamut of allowing one to assess current developments on a weekly basis, as well as carry out more traditional reviews of historical information. The general types of information one can cover include basic pharmacology, preclinical toxicology, competitive products, and clinical safety.

The specific products discussed are as follows: CD-ROM products called *Current Contents*, *Toxic Release Inventory (TRI)*, *Material Safety Data Sheets (MSDS)*, *CCINFODisc*, *Pollution/Toxicology*, and *MEDLINE Ondisc* and a laser disk product entitled the *Veterinary Pathology Slide Bank*. We provide a brief synopsis of the major features of each as well as a description of their integration into a functional, PC-based *Toxicology Information Center (TIC)*. It must be noted, however, that all of these are being replaced to a large extent by online resources.

When such a TIC is established, one will find that some unusual benefits accrue. One now has immediate and uninterrupted access to libraries of valuable and comprehensive scientific data. This access is free of "online" constraints and designed to be user friendly, with readily retrievable information available 24 h a day, 7 days a week. The retrieved information can also usually be manipulated in an electronic form, so one can use it in reports and/or store it in machine-readable form as ASCII files.

The minimal hardware requirements, which are certainly adequate for all items discussed here, are a current Windows or Mac OS operating a single CD-ROM drive, at least a 1 GB system hard disk drive, a CD-ROM drive, a VGA color monitor, and a printer. The basic point here is that hardware requirements are minimal and readily available. In the case of the laser disk products, a laser disk drive and high-resolution (VGA) monitor are also required.

3.1.8 Toxic Release Inventory (TRI)

Before embarking on a discussion of products describing health, toxicology, and safety issues, it is well to be aware of

a new, pilot CD-ROM version of the Environmental Protection Agency's (EPA) 1987 Toxic Chemical Release Inventory and Hazardous Substances Fact Sheets. This TRI resource, which contains information regarding the annual inventory of hundreds of named toxic chemicals from certain facilities (since 1987), as well as the toxicological and ecological effects of chemicals, is available from the National Technical Information Service (NTIS), US Department of Commerce, Springfield, Virginia, 22161.

The list of toxic chemicals subject to reporting was originally derived from those designed for similar purposes by the states of Maryland and New Jersey. As such, over 300 chemicals and categories are noted. (After appropriate rule-making, modifications to the list can be made by the EPA.) The inventory is designed to inform the public and government officials about routine and accidental releases of toxic chemicals to the environment.

The CD-ROM version of the database can be efficiently searched with a menu-driven type of software called *SearchExpress*. It allows one to search with Boolean expressions as well as individual words and/or frequency of "hits" as a function of the number of documents retrieved on a given topic. Numerous searchable fields have been included, allowing one to retrieve information by a variety of means—for example, the compound name; the chemical registry number; the amount of material released into the air, water, or land; the location of the site of release; and the SIC code of the releasing party. One can also employ ranging methods with available numeric fields and sorting of output.

It is hoped that this shared information will help to increase the awareness, concern, and action by individuals to ensure a clean and safe environment. The TRI database is a significant contribution to that effort, and the CD-ROM version is a superb medium with which to widely publicize and make accessible the findings.

3.1.9 Material Safety Data Sheets (MSDS)

The MSDS CD-ROM is a useful resource that contains over 33 000 MSDS on chemicals submitted to the Occupational Safety and Health Administration (OSHA) by chemical manufacturers. This resource contains complete MSDS information as well as other important information such as the chemical formula, structure, physical properties, synonyms, registry number, and safety information.

Users can easily search the CD-ROM by employing the Aldrich catalog number, CAS number, chemical name, or molecular formula. One can also export the chemical structures to some supported software for subsequent inclusion into work processing programs. The product is available from Aldrich Chemical Company, Inc., 940 West Street, Paul Avenue, Milwaukee, Wisconsin, 54233.

3.1.10 Canadian Centre for Occupational Health and Safety (CCINFO)

This set of four CD-ROM disks contains several valuable databases of information that are updated on a quarterly basis: MSDS, CHEM Data, Occupational Health and Safety (OHS) Source, and OHS Data. The MSDS component currently contains over 60 000 MSDS supplied by chemical manufacturers and distributors. It also contains several other databases (RIPP, RIPA, Pest Management Research Information System (PRIS)), one of which (PRIS) even includes information on pest management products, including their presence and allowable limits in food.

A second disk in the series (CHEM Data) contains comprehensive information from the CHEMINFO, RTECS, and Chemical Evaluation Search and Retrieval System (CESARS) databases, as well as recommendations on Transport of Dangerous Goods (TDG)/Hazardous Materials (49CFR).

The third and fourth disks include OHS information. These disks contain databases on resource organizations, resource people, case law, jurisprudence, fatalities, mining incidents, and ADISCAN. Furthermore, information on noise levels, NIOSH nonionizing radiation levels, and a document information directory system is readily retrievable. These CD-ROM materials are available from the Canadian Centre for Occupational Health and Safety, 250 Main Street East, Hamilton, Ontario, L8N 1H6.

3.1.11 Pollution and Toxicology (POLTOX)

This CD-ROM library also focuses our attention on environmental health and safety concerns. Scientists working in any industry or capacity that deals with toxic or potentially toxic chemicals will find it very useful. It allows one access to seven major databases in this field in a single search through its use of “linking” features in its software. The distributors of this product have provided us with a spectrum of information dealing with toxic substances and environmental health.

The collection of these databases include five that are available exclusively from Cambridge Scientific Abstracts (CSA)—Pollution Abstracts, Toxicology Abstracts, Ecology Abstracts, Health and Safety Science Abstracts, and Aquatic Pollution and Environmental Quality. The abstracts come from journals or digests published by CSA on important issues including environmental pollution, toxicological studies of industrial chemicals, ecological impacts of biologically active chemicals, as well as health, safety, and risk management in occupational situations. The POLTOX CD-ROM contains over 200 000 records from these sources since 1981.

POLTOX also contains two other useful databases—TOXLINE (described earlier) and the Food Science and Technology Abstracts (FSTA) libraries. The FSTA component is a reasonably comprehensive collection of information

regarding toxicological aspects of compounds found in food, including contamination, poison, and carcinogenic properties. The CD-ROM product is available from Compact Cambridge, 7200 Wisconsin Avenue, Bethesda, Maryland, 20814.

3.1.12 MEDLINE

The MEDLINE database, which comes from the NLM, is a superb, indispensable reference library that is particularly strong in its wide coverage of research activities in the biomedical literature. It also encompasses the areas of clinical medicine, health policy, and healthcare services. Each year, over 300 000 articles are reviewed and indexed into the database. The full bibliographic citations of these articles, usually including the abstract of the published work, are available from numerous vendors in CE-ROM form, and are usually updated on a monthly basis.

Information can be accessed from MEDLINE in a variety of ways: by author, title, subject, CAS Registration Number, keyword, publication year, and journal title. MEDLINE Ondisc is the CD-ROM product we employ (from Dialog Information Services, Inc., 3460 Hillview Avenue, Palo Alto, California, 94304). It allows one access to the full MEDLINE files back to 1984. Each year from that time until 1988 is covered on a single CD-ROM disk; starting in 1989, each disk covers only a 6-month time period. The information is accessed through either an easily employed “menu-driven” system or a more standard online type of “command language.”

Gower Publishing (Brookfield, VT) has published a series of “electronic handbooks” providing approved ingredient information on materials used in cosmetics, personal care additives, food additives, and pharmaceuticals. Academic Press, through its Sci-Vision branch, has just (2000) launched an ambitious service of CD-ROM-based toxicity database products which are structure and substructure searchable.

It is worth noting that the CD-ROM-based system has been seamlessly integrated with (proprietary) both record-keeping and communications software so that one can optionally monitor the use of the online services and easily continue searching in the dialog “online” environment after using the CD-ROM-based MEDLINE library. Another very useful feature includes the storage of one’s search logic so that repetitive types of searches, over time, for example, can be done very easily.

3.2 PC-BASED INFORMATION PRODUCTS: LASER DISC

3.2.1 International Veterinary Pathology Slide Bank (IVPSB)

This application represents an important complementary approach toward training and awareness using laser disk

technology. The International Veterinary Pathology Slide Bank (IVPSB) provides a quality collection of transparencies, laser videodisks, and interactive computer/videodisk training programs. In particular, the videodisk contains over 21 000 slides from over 60 contributors representing 37 institutions from 6 countries. These slides are accessible almost instantaneously because of the tremendous storage capacity and rapid random search capabilities of the videodisk through the interactive flexibility of the computer. The information available is of particular interest to toxicologists and pathologists because the visuals illustrate examples of gross lesions of infectious diseases, regional diseases, clinical signs or external microscopy, histopathology, normal histology, cytology and hematology, and parasitology.

The laser disk, a catalog of the entries, a computer database, and selected interactive programs can be obtained from Dr. Wayne Crowell, Department of Veterinary Pathology, University of Georgia, Athens, Georgia, 30602.

3.3 CONCLUSION

This brief overview of some of the readily available PC-based information resources will, hopefully, encourage more widespread use of this type of technology. Toxicologists and pathologists, in particular, can avail themselves of these useful resources in a way that was simply not possible just a few years ago. The information one needs to make decisions is now far more accessible to many more of us for relatively reasonable expenditures of money for software and hardware.

An effective approach to provide maximal access to these resources is to set up a "TIC," which consists of the earlier-noted PC hardware and single, centrally available copies of the noted CD-ROM-based and laser disk products. By employing a menu-based system (available commercially or by shareware) to access the respective products, one can usually provide entry into each of the products discussed here with a single keystroke.

As time goes on, one can grow with the system by considering networking the CD-ROM-based resources and/or setting up other strategically located TICs on one's campus. The important concept here is that we wish to make the superb "new" PC-based information products as available as we can to interested scientists.

A critical part of the strategy for delivery of information to the end user is that one can anticipate marked increased usage of the more traditional hard copy-based resources of the centralized library. The tools described here are frequently complementary to the pivotal library-based information center. What one can anticipate, however, is a much more focused use of hard copy-based information.

ELECTRONIC RECORDS, REPORTING, AND SUBMISSION: eCTD AND SEND

4.1 INTRODUCTION

The world of drug safety assessment and development has as a central component that data and regulatory interactions involving such data must be clearly and securely captured and transmitted. How this is done has gone from being entirely on paper to entirely via electronic media over the course of my (SCG) time working in this field which began in the 1970s. Good Laboratory Practice (GLP) regulations first came into force on December 22, 1978, setting the initial standards for how data should be recorded, stored, and reported. In 1977, data recording was by hand, and reports were prepared on electronic typewriters. Word processors (initially the size of refrigerators) came into use using large floppy diskettes as media to enable storage. Statistical analysis used data entered and stored on punch cards and processed on mainframes (Gad and Taulbee, 1996).

One must submit suitable data to the appropriate regulatory agency, such as the FDA in the United States, in order to market a drug or biological product; this data establish that the product is safe and effective. The FDA no longer accepts paper or nonelectronic copies of reports or Common Technical Document submissions for product submissions. The electronic Common Technical Document (eCTD) is currently the standard format for submission of regulatory applications, amendments, data, and reports to the FDA. The FDA is also requiring that electronic data from some nonclinical studies be submitted with applications. The data submission must be in the Standard for Exchange of Nonclinical Data (SEND) format. As the Sponsor is responsible for ensuring the accuracy of any regulatory submission, the Sponsor needs to make sure that any outsourced work is performed according to all applicable regulations and guidelines in a stipulated format.

The Federal Food, Drug, and Cosmetic Act was enacted in 1938 and provided much-needed standards for ensuring the quality of foods, pharmaceuticals, and cosmetics; the act was amended in 1962. Part of the amendment contains grounds for refusing an application if the Applicant does not provide proof that a product is both efficacious and safe before receiving FDA approval (Public Law, 1962). This Amendment forged the way for regulatory submissions, including Investigative New Drugs (IND), New Drug Applications (NDA), and Center for Biologics Evaluation and Research (BLA). These regulatory submissions were historically paper-based and voluminous (sometimes as much as 30–60 volumes of summaries, data, and reports), difficult to organize and maintain, and challenging to store and then deliver the three required copies to the appropriate document control offices.

The FDA determined that multiple guidance documents were needed to describe and implement all of the submissions and details needed to cover electronic formatting. These documents will be discussed throughout this chapter. Even when released as drafts, the FDA tends to treat these guidances as having the force of law.

On December 17, 2014, the operative guidance “Providing Regulatory Submissions in Electronic Format—Submissions under Section 745A(a) of the Federal Food, Drug, and Cosmetic Act” was published. This guidance describes how FDA interprets and plans to implement the requirements of Section 745A(a), by implementing additional statutory electronic submission requirements, describing the submission types that must be submitted electronically, exemptions from and criteria for waivers of the electronic submission requirements, and the timetable and process for implementing the requirements. As a result, all Commercial INDs (as of December 17, 2017), NDAs, and BLAs (as of December 17,

2016) must be organized electronically and submitted online in eCTD format through an official portal.

The standardized format used for eCTDs in the USA is in the same format that is required for other countries, primarily countries that are Organization for Economic Cooperation and Development (OECD) members. The eCTD is arranged in five modules (although Module 1 is not technically part of the eCTD), with each containing an explicit type of material:

- Module 1: region-specific administrative information
- Module 2: chemistry, manufacturing, controls (CMC), nonclinical and clinical overviews and summaries
- Module 3: detailed manufacturing information
- Module 4: nonclinical study reports
- Module 5: clinical study reports

Additional Guidances were published while individual guidances (e.g., “Providing Regulatory Submissions in Electronic Format—Standardized Study Data,” and “Providing Regulatory Submissions in Electronic Format—Human Pharmaceutical Product Applications and Related Submissions Using the eCTD Specifications”) will be developed to specify the formats for specific submissions and corresponding timetables for implementation. In December 2014, the FDA issued “Providing Regulatory Submissions in Electronic Format—Standardized Study Data: Guidance for Industry.” According to the Food, Drug, and Cosmetic Act Section 745A(a), applications must utilize specific standards as defined in the FDA Data Standards Catalog starting 24 months after the final guidance is announced for NDAs and BLAs, and 36 months after the final guidance is announced for INDs.

It is also a required to supply the FDA with electronic data from all nonclinical studies intended to support the safety of candidate drugs. For submission of study data, all Commercial INDs (December 17, 2017), and all NDAs and BLAs (December 17, 2016) must include reports accompanied by SEND electronic format records for specified studies. Submissions may not be filed and will be rejected if they do not adhere to the eCTD Guidance.

Likewise, as soon as a therapeutic drug entity is determined to be a viable candidate drug, an IND number should be requested from the FDA, and there is no charge for this. It is also suggested to start obtaining FDA Electronic Submissions Gateway (Gateway) access as soon as practical. The Gateway is the software system that the FDA uses to accept the submissions. Currently, all submissions ten gigabytes or smaller must be submitted via the Gateway. Guy (2019) provides an excellent guidance to organizations of CTD submissions.

Sponsors and consultants are directed to International Conference on Harmonization (ICH) M4 Safety (M4S)—Common Technical Document for the Registration of Pharmaceuticals for Human Use—Safety (EMA 2003a), which details the nonclinical overview and nonclinical sum-

maries of Module 2 and the organization of Module 4. It states that section headings should be maintained in the eCTD document; however, if a study has not been performed in a certain category, a brief explanation should be provided as to why these studies were not conducted (EMA 2003b). In addition, the Sponsor needs to review ICH M4 Quality (M4Q), Module 2 Quality Overall Summary, and also Module 3 Format of the Quality Section of the eCTD. Nonclinical sections of the eCTD are mainly found in Modules 2.4, 2.6, and 4.

Module 2.4 is the Nonclinical Overview where the main work of a toxicologist is summarized and discussed. The Nonclinical Overview provides an integrated analysis of the overall information in the eCTD. In general, the Nonclinical Overview should not exceed about 30 pages. It should contain appropriate references and links to the Tabulated Summaries, in the following format: (Table X.X, Study/Report Number). The Nonclinical Overview should be presented in the following order:

- Overview of the nonclinical testing strategy
- Pharmacology
- Pharmacokinetics
- Toxicology
- Integrated overview and conclusions
- List of literature references

It is not an uncommon problem for by-products between sections to be inadvertently severed. Careful observation while editing these is recommended.

Module 6.6 is where the written and tabulated summaries are inserted in the document. Generally, the Sponsor will prepare these sections, but often, the clinical research organization (CRO) will prepare the tabulated summaries and present them in an appendix to the report. This would need to be discussed in the contract between the CRO and the Sponsor, or it may be added to the items listed in the protocol that will be prepared for the study report.

4.2 SUBMISSION OF SEND DATA IN MODULE 4 OF THE ECTD

SEND is an acronym for Standard for Exchange of Nonclinical Data. Study data and supporting information (metadata) will have electronic files appropriately placed in the eCTD in a predetermined location in Module 4. This is a mandatory part of each eCTD application.

4.3 SEND BACKGROUND

SEND is a data exchange standard developed and maintained by Clinical Data Interchange Standards Consortium

(CDISC), a nonprofit organization that develops data standards to streamline clinical research and enable connections to healthcare. It assists the FDA reviewer as it standardizes data and since the data are all electronic also assists with streamlining the review process.

SEND organizes a nonclinical study, including the study protocol, dosing information, and collected test results and observations, and metadata—into a series of machine-readable files, called datasets. Each dataset has a specific purpose, naming convention and organization, with certain datasets that contain similar information having a similar organization. A detailed description of each dataset's organization and examples of how common study data are represented and is published in a SEND Implementation Guide (SENDIG). As the standard changes, there is a public review, then new versions of the SENDIG are published on the CDISC website. Currently, SENDIG version 3.0 and 3.1 are available.

4.4 SEND REGULATORY

When the guidance “Providing Regulatory Submissions in Electronic Format—Submissions Under Section 745A(a) of the Federal Food, Drug, and Cosmetic Act” was published in December 2014, an offshoot of the guidance “Providing Regulatory Submissions in Electronic Format—Standardized Study Data” was published. This guidance describes the requirements for an electronic submission of standardized clinical and nonclinical study data as per the 745A(a) of the Federal Food, Drug and Cosmetic Act.

A technical specification document, the “Study Data Technical Conformance Guide,” is also published by the US FDA. This document contains nonbinding guidance for submission of both clinical and nonclinical electronic study data. The objective of this document is to communicate best industry practices that enable effective agency review of electronic data in a document that is regularly updated based on industry feedback and agency experiences. The original guidance was published in January 2014; however, this document is updated more frequently than the binding guidance and contains information that is useful to companies creating or verifying SEND datasets. The current version (version 4.8.1) was published in October 2021.

As with all submissions to the FDA, the SEND study submission package must follow specific rules. These rules are defined and published by both the Clinical Data Interchange Standards Consortium CDISC and by the FDA. CDISC, as the standards development organization, defines the rules that SEND datasets must follow to be considered in conformance with a specific version of a standard, as the standards are updated often. The FDA publishes business rules, which focus on content that enables the FDA reviewers to use the FDA review software. In addition, the FDA publishes a “Technical

Rejection for Study Data” as part of the eCTD validation criteria which would assist in automating a review of an eCTD-based submission for the presence of required electronic study data.

For details of the contents and layout of electronic submissions, the FDA requires the inclusion of the nonclinical Study Data Reviewers Guide (nSDRG) associated with study SEND datasets. The nSDRG will be discussed later in this chapter. The nSDRG is submitted as a PDF document. Any PDF documents that are included as part of an electronic submission must adhere to the FDA technical specification, that is, “Portable Document Format (PDF) Specifications.” Following this specification ensures that PDFs submitted to the Agency are in a format that the receiving center currently supports (the receiving FDA Center has established processes and technology to support the receipt, processing, reviewing, and archiving files in the specified standard format).

In addition, the FDA currently has an active website with information on eCTD submission standards which may be accessed at <https://www.fda.gov/drugs/electronic-regulatory-submission-and-review/electronic-common-technical-document-ectd>. This webpage also includes current versions and hyperlinks for eCTD submissions to both Center for Drug Evaluation and Research (CDER) and Center for Biologics Evaluation and Research (CBER).

It is important to remember that the guidance states that a study starting after December 17, 2016, that is included in an NDA, Abbreviated New Drug Application (ANDA), or BLA, and a study starting after December 17, 2017, that is included in an IND, must be submitted with electronic study data.

4.5 SEND FEATURES

All SEND datasets are organized into a simple table with rows and column, where one row is a record of information from the study, and each column contains some distinct detail related to that information. Body weights, for example, are reported in a SEND dataset named BW. Each live-phase and terminal body weight collected on the study for each animal is reported in a separate row, and each column represents information about the collected body weight. The columns include identifiers for the study and the animal weighed, whether the weight is a live-phase or terminal body weight, the study day and date that the weighing was performed, as well as the weight collected and units of measure. The information included in this SEND BW dataset is equivalent to an individual animal body weight table included in an appendix to the study report. Table 4.1 shows SEND body weight dataset rows for one study animal.

Other numeric results, including feed consumption, clinical pathology parameter values, etc., that are collected during a study, are similarly reported in other SEND datasets with

STUDYID	DO- MAIN	USUBJID	BW- SEQ	BW- TESTCD	BWTEST	BW- ORRES	BW- ORRESU	BW- STRESC	BW- STRESN	BW- STRESU	BW- STAT	BW- REASND	BW- BLFL	VIS- ITDY	BWDTC	BWDY
ABC123	BW	ABC123-0193	1	BW	Body Weight	274	g	274	274	g				-4	2007-06- 08T08:48:52	-4
ABC123	BW	ABC123-0193	2	BW	Body Weight	299	g	299	299	g				-1	2007-06- 11T08:10:06	-1
ABC123	BW	ABC123-0193	3	BW	Body Weight	307	g	307	307	g		y	1	2007-08- 12T07:17:53	1	
ABC123	BW	ABC123-0193	4	BW	Body Weight	348	g	348	348	g			8	2007-06- 19T07:37:34	8	
ABC123	BW	ABC123-0193	5	BW	Body Weight	377	g	377	377	g			15	2007-06- 26T07:31:58	15

ABC123	BW	ABC123-0193	7	TERMBW	Terminal Body Weight	378	g	378	378	g			29	2007-07- 10T11:32:14	29	

TABLE 4.1 Example SEND Body Weights.

additional information reported as needed for a clear and complete representation of the collected data.

Complex, nonnumerical observational data such as clinical signs, gross observations, and histopathology findings are also included in SEND.

The files are organized so that they are fairly easy to understand. Columns in different datasets that contain the same type of information will either have the same column heading or will have a column header with the dataset name as a prefix to a common “stub” column name. For example, across all files for a study, the column STUDYID will contain the study ID, and the column USUBJID will contain the unique identifier for the animal. The data will be reported in BWORRES column for the body weight file BW, in LBORRES column for the laboratory tests file LB, and in the MIORRES column for the microscopic observations file MI.

SENDIG will have descriptive labels for each dataset’s column names. An abbreviated/short or full column header, or both, may be visible depending on how the files are displayed. Table 4.3 illustrates the first eight columns headers of the SEND body weight file showing both the short column name and the descriptive label when viewed using the Statistical Analysis System (SAS) Viewer. A full description and examples of each file header can be found in the SEND Implementation Guide.

Study protocol information is separated from the study data and may be found in a collection of datasets called Trial Design datasets.

SEND datasets also will contain data from individual animal dosing. Dosing information is typically not reported in the Study Report. These are found in a dataset called Exposure (EX). Exposure is intended to report the dose administered per animal, with either one row per animal dose, or one row to represent all doses administered over a defined period.

Table 4.2 shows the list of SEND datasets that can be created for a study using SEND Implementation Guide Version 3.1 from CDISC. This version is intended to support data typically found in single-dose general toxicology, repeat-dose general toxicology, and carcinogenicity studies, as well as respiratory and cardiovascular testing done during safety pharmacology studies.

As mentioned above, the documentation of clinical observations is more complex than documentation of numerical values. A helpful component of SEND is the use of controlled terminology. To fully take advantage of what SEND has to offer, including for uses like data mining, observational data must be aligned into a standard format, and the terminology

TABLE 4.2 Order of Presentation Within a Section

- 3.2.1 in vitro studies before in vivo studies
- 3.2.2 Ordered by species, by route, and then by duration (shortest duration first)
- 3.2.3 Order of species:
 - Mouse
 - Rat
 - Hamster
 - Other rodent
 - Rabbit
 - Dog
 - Nonhuman primate
 - Other nonrodent mammal
 - Nonmammals
- 3.2.4 Routes of administration should be ordered as follows:
 - The intended route for human use
 - Oral
 - Intravenous
 - Intramuscular
 - Intraperitoneal
 - Subcutaneous
 - Inhalation
 - Topical
 - Other

Source: Adapted from EMA (2003b).

utilized must, therefore, also be standardized, so that the same concept is represented by the same term within a nonclinical study, across nonclinical studies, and across clinical and non-clinical studies. For example, for body weights (BWs) “g” is used to represent grams as a unit of measure; any other representation such as “grams” or “G” cannot be used. Urinalysis test codes and names, as well as units of “mL” are standardized. For severity grades, a grade number is standardized (“grade 1”), may be reported as MINIMAL scoring, a tissue defined as “ADRENAL GLANDS” is reported as “GLAND, ADRENAL” and will have a modifier of “BILATERAL,” for example, to indicate that both of the pair were observed. Tissues with no abnormalities observed reported as “NORMAL.” These are all examples of SEND Controlled Terminology.

Study Identifier (STUDYID)	Domain Abbreviation (DOMAIN)	Unique Subject Identifier (USUBJID)	Sequence Number (BWSEQ)	Test Short Name (BWTESTCD)	Test Name (BWTEST)	Result or Findings as Collected (BWORRES)	Unit of the Original Result (BWORRESU)
----------------------------	------------------------------	-------------------------------------	-------------------------	----------------------------	--------------------	---	--

TABLE 4.3 Example SEND labels and descriptions.

4.6 SEND STUDY SUBMISSION PACKAGE

Every nonclinical study for which SEND electronic data are required in the FDA submission, a specific collection of files must be included; this full collection of files is commonly called a study SEND Study Submission Package. This package contains the following:

- SEND Datasets using a specified version of controlled terminology
- A define.xml file and associated stylesheet to enable viewing of define.xml with a browser
- A nSDRG.

The SEND datasets must be submitted to the US FDA in version 5 SAS Transport File format. Files in this format have an extension “xpt” and can only be viewed intact by software applications designed to read this format.

A define.xml file, or Data Definition file, must also be provided in a study submission. The define.xml file describes the SEND datasets in machine-readable format. It is considered the most important part of the electronic dataset submission, as it describes the “metadata” of the datasets. It describes what domains are included, with description of each, and it has a description of each variable in each domain, along with a description of entries in those variables. It also has any controlled terminologies and algorithms used, along with any other comments that describe the data.

The nSDRG, or nonclinical Study Data Reviewers Guide, as mentioned earlier in this chapter, is a document that also needs to be included in the submission. It helps the reviewer of the SEND datasets understand the study report and the content of the datasets. Again, this document must be submitted in a PDF format. Some of the information included in the nSDRG for a study is as follows:

- Study design overview or introduction, including a diagram of the study design in the SEND trial design datasets. It also needs to include study identification correspondence to link document with SEND data sets.
- The version of controlled terminology used in the SEND datasets, the rationale for selection of that version, and a list of any nonstandard terms used and definition of each.
- A description of how the SEND datasets were created and verified.
- Reviewer confirmation that SEND data sets accurately represent the study report, or, if needed, a description of any differences between the SEND datasets and individual animal data tables that were in the final study report.

- A list of any FDA rules that the submitted SEND datasets do not comply with, and the rationale for noncompliance,
- Where the SENDIG allows sponsor-defined entries, a definition of those entries.
- Version of define-xml standard used when creating the define.xml file and the rationale for selection of that version.

As mentioned earlier, the data included in a SEND Study Submission Package for each study is included in the submission alongside the Study Report in Module 4 of the eCTD. The location of the SEND Study Submission Package within the eCTD structure is described in the FDA Study Data Technical Conformance Guide, and it is also discussed above.

4.7 DETERMINATION OF STUDIES THAT NEED DATA TO BE SUBMITTED AS SEND FILES

Based on the regulations and guidances, there are four aspects of a nonclinical study that determine whether or not a SEND data set must be included with a submission to the Agency. These would be (i) the FDA center to which the application is submitted, (ii) type of application, (iii) study start date, and (iv) study type.

4.7.1 FDA Center

SEND data standards requirements only apply to certain FDA centers. However, currently, the SEND entry in the FDA Data Standards Catalog shows that out of all the FDA centers (e.g., CBER, CDER, CDRH, CSFAN, CVM, CTP, OC, ORA, and NCTR) SEND file standards are accepted only by the CDER (FDA, CDER Division, 2014).

4.7.2 Type of Application

The following four types of applications require SEND for a submission (IND, NDA, ANDA, BLA); however, that requirement may be predicated on the study start date (see immediately below).

4.7.3 Study Start Date

The FDA has published two “on or after” dates for two categories for inclusion of SEND files: one for studies included in NDAs, ANDAs, and certain BLAs (studies starting on or after December 17, 2016), and one for studies included in INDs (studies starting on or after December 17, 2017). A start date is defined as the date that Study Director signs the study protocol (FDA, 2017).

As with any outsourcing activity, potential SEND partners must be qualified to perform the activities. Unless SEND datasets are used to make study decisions, e.g., if the electronic SEND data are used to perform analyses that contribute to the Study Director's interpretation of the conclusions drawn in the study, then the data sets are not considered to be GLP quality data and are normally not audited by Quality Assurance. Normally, non-GLP activities are not audited; however, if the SEND data files are not correct in any study, the FDA may not accept the submission. If the study or entire submission is rejected due to SEND database issues, what happens next? Any type of recourse should be addressed in the contract with the supplier, as should be pricing, performance requirements, and data security provisions. Therefore, it is wise to properly and thoroughly qualify vendors or CROs who are preparing the SEND data for the submission. The following items may be useful to assist with discussions during qualifications in advance of hiring a company to prepare SEND data files:

- Assess their SEND knowledge and experience creating SEND from their own data sources.
- Pilot conversion study.
- Participation and keeping current with the SEND community.
- Do data packages (datasets and associated define.xml) and the nSDRG go through quality control procedures to ensure correctness and completeness?
- Is the lab using SEND controlled terminology during data collection?
- Has the lab moved all paper-based data collection to an electronic data capture system and ensured collection of additional metadata associated with the study results and observations?
- What are the lab's practices for receipt and management of electronic data from subcontracted test sites?
- Ensure that all CRO test facilities have detailed comprehension of the standards, e.g., SEND, Define-xml, and Controlled Terminology, and also of regulatory expectations for SEND, and to be prepared to address updates early.

4.8 STORAGE OF FILES AT THE FDA

After the validation, storage of the data takes place in FDA data repositories. These data may be accessed by FDA reviewers who may opt to use analytical tools to analyze the data. Using this system is a huge timesaver for FDA reviewers, since in the past, the reviewers typically transcribed data to spreadsheets and created their own charts and tables to analyze the data.

4.9 RECOMMENDED REGULATORY RESOURCES

The FDA website has valuable information on the topics of eCTD and SEND.

SCREENS IN SAFETY AND HAZARD ASSESSMENT

5.1 INTRODUCTION

In biological research, screens are tests designed and performed to identify agents or organisms having a certain set of characteristics that will either exclude them from further consideration or cause them to be selected for closer attention. In pharmaceutical safety assessment, our use of screens is usually negative (i.e., either to detect a problem or save confidence that there is none)—agents or objects possessing certain biochemical activities are considered to present enough of a hazard that they are not studied further or developed as potential therapeutic agents without compelling reasons (in cases of extreme benefit such as life-saving qualities). Such screens are by definition non-good laboratory practice (GLP) studies, typically performed before a molecular entity is selected for full development—or selected out of this choice (Faqi, 2017). Their design and conduct are thus more flexible than that of the studies conducted on “selected” compounds. The test system employed in screens range from computer programs and bacteria to pigs and dogs (though nonrodents are rarely used.) *in vitro* toxicogenomic assays (addressed separately in Chapter 12) also are becoming increasingly useful. This is an extension of high-throughput screening (HTS). HTS is a valuable tool for screening biological activities, but not the pharmaceutical characteristics (Zhu and Xia, 2019).

In the broadest terms, what is done in preclinical (and, indeed, in phase I clinical) studies can be considered a form of screening (Zbinden et al., 1984). Starting with selection of candidates (Gad, 2005) and the development of formulations (Boersen et al., 2013), screens are employed throughout the evaluation and development process. What varies is the degree of effectiveness of (or our confidence in) each of the tests used. As a general rule, though we think of the expensive and

labor-intensive “pivotal” studies required to support regulatory requirements (4-week to 1-year toxicity studies, carcinogenicity, and segment I–III studies, etc.) as definitive, in fact, they are highly effective (or so, at least, we generally believe) but not necessarily efficient screens. An initial screen, now frequently required by Food and Drug Administration (FDA), is a binding of candidate therapeutic molecules to receptors in a defined panel (such as presented in Table 5.1), as is discussed in Bowes et al., 2012. The purpose is to determine the specificity of the candidate for its target, and the potential risk arising from off-target hits.

Though toxicologists in the pharmaceutical industry are familiar with the broad concepts of screening, they generally do not recognize the applicability of screens. The principles underlying screening are also not generally well recognized or understood. The objective behind the entire safety assessment process in the pharmaceutical industry is to identify those compounds for which the risk of harming humans does not exceed the potential benefit to them. In most cases, this means that if a test or a screen identifies a level of risk that we have confidence in (our “activity criterion”), then the compound that was tested is no longer considered a viable candidate for development. In this approach, what may change from test to test is the activity criterion (i.e., our basis for and degree of confidence in the outcome). We are interested in minimizing the number of false negatives in safety assessment. Anderson and Hauck (1983) should be consulted for statistical methods to minimize false-negative results.

As Figure 5.1 illustrates how currently decisions are more likely to be made on a multidimensional basis, which creates a need for balance between (i) degree of benefit; (ii) confidence that there *is* a benefit (efficacy is being evaluated in “models” or screens at the same time safety is); (iii) type of risk (with, e.g., muscle irritation, mutagenicity, acute lethality,

and carcinogenicity having various degrees of concern attached to them); and (iv) confidence in, and degree of, risk. This necessity for balance is commonly missed by many who voice opposition to screens because “they may cause us to throw out a promising compound based on a finding in which we have only (for example) 80% confidence.” Screens, partic-

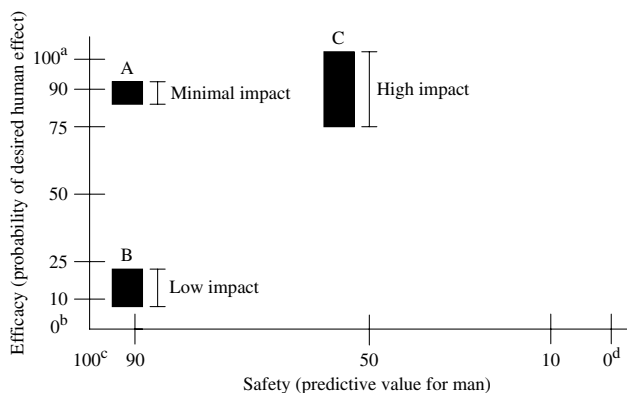

FIGURE 5.1 Decision-making for pharmaceutical candidates based on outcome of screening tests: (a) A 100% probability of efficacy means that every compound that has the observed performance in the model(s) used has the desired activity in man. (b) A 0% probability of efficacy means that every compound that has the observed performance in the model(s) used does not have the desired activity in man. (c) A 100% probability of a safety finding means that such a compound would cause this toxicity in man. (d) A 0% probability means this will never cause such a problem in man. Note: These four cases (a–d) are almost never found.

ularly those performed early in the research and development process should be viewed as the biological equivalent of exploratory data analysis (EDA). They should be very sensitive, which means that they will have a lot of “noise” associated with them. Screens generally do not establish that an agent is (or is not) a “bad actor” for a certain end point. Rather, they confirm that if interest in a compound is sufficient, a more definitive test (a confirmatory test) is required, which frequently will provide a basis for selecting between multiple candidate compounds.

5.2 CHARACTERISTICS OF SCREENS

The terminology involved in screen design and evaluation and the characteristics of a screen should be clearly stated and understood. The characteristics of screen performance are defined as follows:

- *Sensitivity*: the ratio of true positives to total actives.
- *Specificity*: the ratio of true negatives to total inactives.
- *Positive accuracy*: the ratio of true to observed positives.
- *Negative accuracy*: the ratio of true to observed negatives.
- *Capacity*: the number of compounds that can be evaluated.
- *Reproducibility*: the probability that a screen will produce the same results at another time (and, perhaps, in some other lab).

These characteristics may be optimized for a particular use, if we also consider the mathematics underlying them and “errors.”

A brief review of the basic relationships between error types and power starts with considering each of five interacting factors (Gad, 1982a, 1999) that serve to determine power and define competing error rates:

- α , the probability of our committing a type I error (a false positive).
- β , the probability of our committing a type II error (a false negative).
- Δ , the desired sensitivity in a screen (such as being able to detect an increase of 10% in mutations in a population).
- σ , the variability of the biological system and the effects of chance errors.
- n , the necessary sample size needed to achieve the desired levels of each of these factors. We can, by our actions, generally change only this portion of the equation, since n is proportional to

$$\frac{\sigma}{\alpha, \beta, \text{ and } \Delta}$$

The implications of this are, therefore, that (i) the greater σ is, the larger n must be to achieve the desired levels of α , β , and/or Δ ; and (ii) the smaller the desired levels of α , β , and/or Δ , if n is constant, the larger σ must be.

What are the background response level and the variability in our technique? As any good toxicologist will acknowledge, matched concurrent control (or standardization) groups are essential to minimize within group variability as an “error” contributor. Unfortunately, in *in vivo* toxicology test systems, large sample sizes are not readily attainable, and there are other complications to this problem that we shall consider later.

In an early screen, a relatively large number of compounds will be tested. It is unlikely that one will stand out so much as to have greater statistical significance than all the other compounds (Bergman and Gittins, 1985). A continuous range of activities will be found instead. Compounds showing the highest (beneficial) or lowest (adverse) activity will proceed to the next assay or tier of tests in the series and may be used as lead compounds in a new cycle of testing and evaluation.

The height of the “impact” column refers to the relative importance (“human risk”) of a safety finding. Compound A has a high probability of efficacy but also a high probability of having some adverse effect in man. But if that adverse effect is of low impact—say, transitory muscle irritation for a life-saving antibiotic—A should go forward. Likewise, B, which has a low probability of efficacy and a high probability of having an adverse effect with moderate impact, should not be

pursued. Compound C is at a place where the high end of the impact scale should be considered. Though there is only a 5% probability of this finding (say, neurotoxicity or carcinogenicity) being predictive in man, the adverse effect is not an acceptable one. Here a more definitive test is called for or the compound should be dropped.

The balance between how well a screen discovers activities of interest versus other effects (specificity) is thus critical. Table 5.2 presents a graphic illustration of the dynamic relationship between discovery and discrimination.

Both discovery and discrimination in screens hinge on the decision criterion that is used to determine if activity has or has not been detected. How sharply such a criterion is defined and how well it reflects the working of a screening system are two of the critical factors driving screen design.

An advantage of testing many compounds is that it gives the opportunity to average activity evidence over structural classes or to study quantitative structure–activity relationships (QSARs). QSARs can be used to predict the activity of new compounds and thus reduce the chance of *in vivo* testing on negative compounds. The use of QSARs can increase the proportion of truly active compounds passing through the system.

It should be remembered that maximization of the performance of a series of screening assays required close collaboration among the toxicologist, chemist, and statistician. Screening, however, forms only part of a much larger research and development context. Screens thus may be considered the biological equivalent of EDA. EDA methods, in fact, provide several useful possibilities for less rigid and yet utilitarian approaches to the statistical analysis of the data from screens and are one of the alternative approaches presented and evaluated here (Hoaglin et al., 1983, 1985; Redman, 1981; Tukey, 1977). Over the years, the author has published and consulted on many screening studies and projects. These have usually been directed at detecting or identifying potential behavioral toxicants or neurotoxicants, but some have been directed at pharmacological, immunotoxic, and genotoxic agents (Gad, 1988, 1989a).

Table 5.2 Discovery and Discrimination of Toxicants

Screen Outcome	Actual Activity of Agent Tested	
	Positive	Negative
Positive	<i>a</i>	<i>b</i>
Negative	<i>c</i>	<i>d</i>

Discovery (sensitivity) = $a/(a + c)$, where a = all toxicants found positive and $a + c$ = all toxicants tested.

Discrimination (specificity) = $d/(b + d)$, where d = all nontoxicants found negative and $b + d$ = all nontoxicants tested.

The general principles or considerations for screening in safety assessments are as follows:

1. Screens almost always focus on detecting a single point of effect (such as mutagenicity, lethality, neurotoxicity, or developmental toxicity) and have a particular set of operating characteristics in common.
2. A large number of compounds are evaluated so ease and speed of performance (which may also be considered efficiency) are very desirable characteristics.
3. The screen must be very sensitive in its detection of potential effective agents. An absolute minimum of active agents should escape detection; that is, there should be very few false negatives (in other words, the type II error rate or beta level should be low). Stated yet another way, the signal gain should be way up.
4. It is desirable that the number of false positives be small (i.e., there should be a low type I error rate or alpha level).
5. Items 2–4, which are all to some degree contradictory, require the involved researchers to agree on a set of compromises, starting with the acceptance of a relatively high-alpha level (0.10 or more), that is, a higher noise level.
6. In an effort to better serve Item 1, safety assessment screens frequently are performed in batteries so that multiple end points are measured in the same operation. Additionally, such measurements may be repeated over a period of time in each model as a means of supporting Item 2.
7. The screen should use small amounts of compound to make Item 1 possible and should allow evaluation of materials that have limited availability (such as novel compounds) early on in development.
8. Any screening system should be validated initially using a set of blind (positive and negative) controls. These blind controls should also be evaluated in the screening system on a regular basis to ensure continuing proper operation of the screen. As such, the analysis techniques used here can then be used to ensure the quality or modify performance of a screening system.
9. The more that is known about the activity of interest, the more specific the form of screen that can be employed. As specificity increases, so should sensitivity. However, generally the size of what constitutes a meaningful change (that is, the Δ) must be estimated and is rarely truly known.
10. Sample (group) sizes are generally small.
11. The data tend to be imprecisely gathered (often because researchers are unsure what they are looking for), and

therefore, possess extreme within-group variability or modify test performance.

12. Proper dose selection is essential for effective and efficient screen design and conduct. If insufficient data are available, a suitably broad range of doses must be evaluated (however, this technique is undesirable on multiple grounds, as has already been pointed out).

Much of the mathematics involved in calculating screen characteristics came from World War II military-based operations analysis and research, where it was important for design of radar, antiair, and antisubmarine warfare systems and operations (Garrett and London, 1970).

5.3 USES OF SCREENS

The use of screens that first occurs to most pharmaceutical scientists is in pharmacology (Martin et al., 1988). Early experiences with the biological effects of a new molecule are almost always in some form of efficacy or pharmacology screen. The earliest of these tend to be with narrowly focused models, not infrequently performed *in vitro*. The later pharmacology screens, performed *in vivo* to increase confidence in the therapeutic potential of a new agent or to characterize its other activities (cardiovascular, central nervous system [CNS], etc.), can frequently provide some information of use in safety assessment also (even if only to narrow the limits of doses to be evaluated), and the results of these screens should be considered in early planning. In the new millennium, requirements for specific safety pharmacology screens have been promulgated. Additionally, since the late 1990s two new areas of screening have become very important in pharmaceutical safety assessment. The first is the use of screens for detecting compounds with the potential to cause fatal cardiac arrhythmias. These are almost always preceded by the early induction of a prolongation of the $Q-T$ interval. While this should be detected in the electrocardiograms (EKGs) performed in repeat dose canine studies, several early screens (such as the HERG) are more rapid and efficient (though not conclusive) for selecting candidate compounds for further development.

The other area is the use of microassays in toxicogenomic screening—early detection of the potential for compounds to alter gene expressions with adverse consequences (Nuwaysir et al., 1999; Pennie, 2000).

Safety assessment screens are performed in three major settings—discovery support, development (what is generally considered the “real job” of safety assessment), and occupational health/environmental assessment testing. Discovery support is the most natural area of employment of screens and is the place where effective and efficient screen design and conduct can pay the greatest long-range benefits. If

compounds with unacceptable safety profiles can be identified before substantial resources are invested in them—and structures modified to maintain efficacy while avoiding early safety concerns—then long-term success of the entire research and development effort is enhanced. In the discovery support phase, one has the greatest flexibility in the design and use of screens. Here screens truly are used to select from among a number of compounds.

Examples of the use of screens in the development stage are presented in some detail in Section 5.4.

The use of screens in environmental assessment and occupational health is straightforward. On the occupational side, concerns (as addressed in Chapter 25 of this volume) address the potential hazards to those involved in making the bulk drug. The need to address potential environmental concerns covers both true environmental items (aquatic toxicity, etc.) and potential health concerns for environmental exposures of individuals. The resulting work tends to be either regulatory defined tests (for aquatic toxicity) or defined end points such as dermal irritation and sensitization, which have been (in a sense) screened for already in other nonspecific tests.

The most readily recognized examples of screens in toxicology are those that focus on a single end point. The traditional members of this group include genotoxicity tests, lethality tests (particularly recognizable as a screen when in the form of limit tests), and tests for corrosion, irritation (both eye and skin), and skin sensitization. Others that fit this same pattern, as will be shown, include the carcinogenicity bioassay (especially the transgenic mouse models) and developmental toxicity studies.

The “chronic” rodent carcinogenicity bioassay is thought of as the “gold standard” or definitive study for carcinogenicity, but, in fact, it was originally designed as (and functions as) a screen for strong carcinogens (Page, 1977). It uses high doses to increase its sensitivity in detecting an effect in a small sample of animals. The model system (be it rats or mice) has significant background problems of interpretation. As with most screens, the design has been optimized (by using inbred animals, high doses, etc.) to detect one type of toxicant—strong carcinogens. Indeed, a negative finding does not mean that a material is not a carcinogen, but rather that it is unlikely to be a potent one.

Many of the studies done in safety assessment are multiple end point screens. Such study types as a 90-day toxicity study or immunotox/neurotox screens are designed to measure multiple end points with the desire of increasing both sensitivity and reliability (by correspondence/correlation checks between multiple data sets).

5.4 TYPES OF SCREENS

There are three major types of screen designs: the single stage, sequential, and tiered. Both the sequential and tiered are multistage approaches, and each of these types also var-

ies in terms of how many parameters are measured. But these three major types can be considered as having the following characteristics.

5.4.1 Single Stage

A single test will be used to determine acceptance or rejection of a test material. Once an activity criterion (such as X score in a righting reflex test) is established, compounds are evaluated based on being less than X (i.e., negative) or equal to or greater than X (i.e., positive). As more data are accumulated, the criterion should be reassessed.

5.4.2 Sequential

Two or more repetitions of the same test are performed, one after the other, with the severity of the criterion for activity being increased in each sequential stage. This procedure permits classification of compounds into a set of various ranges of potencies. As a general rule, it appears that a two-stage procedure, by optimizing decision rules and rescreening compounds before declaring compounds “interesting,” increases both sensitivity and positive accuracy; however, efficiency is decreased (or is throughput rate).

5.4.3 Tier (or Multistage)

In this procedure, materials found active in a screen are reevaluated in one or more additional screens or tests that have greater discrimination. Each subsequent screen or test is both more definitive and more expensive.

For purposes of our discussion here, we will primarily focus on the single-stage system, which is the simplest. The approaches presented here are appropriate for use in any of these screening systems, although establishment of activity criteria becomes more complicated in successive screens. Clearly, the use of multistage screens presents an opportunity to obtain increased benefits from the use of earlier (lower-order) screening data to modify subsequent screen performance and the activity criterion.

5.5 CRITERION: DEVELOPMENT AND USE

In any early screen, a relatively large number of compounds will be evaluated with the expectation that a minority will be active. It is unlikely that anyone will stand out so much as to have greater statistical significance than all the other compounds based on a formal statistical test. A continuous range of activities will be found. Compounds displaying a certain degree of activity will be identified as “active” and handled as such. For safety screens, those which are “inactive” go on to the next test in a series and may be used as lead compounds in a new cycle of testing and evaluation. The single

most critical part of the use of screens is how to make the decision that activity has been found.

Each test or assay has an associated activity criterion. If the result for a particular test compound meets this criterion, the compound is “active” and handled accordingly. Such a criterion could have a statistical basis (e.g., all compounds with observed activities significantly greater than the control at the 5% level could be tagged). However, for early screens, a statistical criterion may be too strict, given the power of the assay, resulting in a few compounds being identified as “active.” In fact, a criterion should be established (and perhaps modified over time) to provide a desired degree of confidence in the predictive value of the screen.

A useful indicator of the efficiency of an assay series is the frequency of discovery of truly active compounds. This is related to the probability of discovery and to the degree of risk (hazard to health) associated with an active compound passing a screen undetected. These two factors, in turn, depend on the distribution of activities in the series of compounds being tested, and the chances of rejecting and accepting compounds with given activities at each stage.

Statistical modeling of the assay system may lead to the improvement of the design of the system by reducing the interval between discoveries of active compounds. The objectives behind a screen and considerations of (i) costs for producing compounds and testing and (ii) the degree of uncertainty about test performance will determine desired performance characteristics of specific cases. In the most common case of early toxicity screens performed to remove possible problem compounds, preliminary results suggest that it may be beneficial to increase the number of compounds tested, decrease the numbers of animals (or other test models) per assay, and increase the range and number of doses. The result will be less information on more structures, but there will be an overall increase in the frequency of discovery of active compounds (assuming that truly active compounds are entering the system at a random and steady rate).

The methods described here are well suited to analyzing screening data when the interest is truly in detecting the absence of an effect with little chance of false negatives. There are many forms of graphical analysis methods available, including some newer forms that are particularly well suited to multivariate data (the types that are common in more complicated screening test designs). It is intended that these aspects of analysis will be focused on in a later publication.

The design of each assay and the choice of the activity criterion should, therefore, be adjusted, bearing in mind the relative costs of retaining false positives and rejecting false negative (Bickis, 1990). Decreasing the group sizes in the early assays reduced the chance of obtaining significance at any level (such as 5%), so that the activity criterion must be relaxed, in a statistical sense, to allow more compounds through. At some stage, however, it becomes too expensive to

continue screening many false positives, and the criteria must be tightened accordingly. Where the criteria are set depends on what acceptable noise levels are in a screening system.

Criteria can be simple (lethality) or as complex (several clinical chemical and hematologic parameters) as required. The first step in establishing them should be an evaluation of the performance of test systems that have not been treated (i.e., negative controls). There will be some innate variability in the population, and understanding this variability is essential to setting some “threshold” for “activity” that has an acceptably low level of occurrence in a control population. Figure 5.2 illustrates this approach.

What end points are measured as inputs to an activity criterion are intrinsic in the screen system, but may be either direct (i.e., having some established mechanistic relationship to the end point that is being predicted in man, such as gene mutations as predictive of carcinogenicity in man) or correlative. Correlated variables (such as many of those measured in *in vitro* systems) are “black box” predictors—compounds causing certain changes in these variables have a high probability of having a certain effect in man, though the mechanisms (or commonality of mechanism) are not established. There is also, it should be noted, a group of effects seen in animals the relevance of which in man is not known. This illustrates an important point to consider in the design of a screen—one should have an understanding (in advance) of the actions to be taken given each of the possible outcomes of a screen.

5.6 ANALYSIS OF SCREENING DATA

Screening data presents a special case that, due to its inherent characteristics, is not well served by traditional approaches (Gad, 1982b, 1988, 1989a, 1989b, 1989c).

FIGURE 5.2 Setting thresholds using historical control data.

The figure shows a Gaussian (“normal”) distribution of screen parameters; 99.7% of the observations in the population are within three standard deviations (SD) of the historic mean. Here the threshold (i.e., the point at which a datum is outside of normal) was set at $X_c = \text{mean} + 3 \text{ SD}$. Note that such a screen is one-sided.

Why? First consider which factors influence the power of a statistical test. Gad (1988) established the basic factors that influence the statistical performance of any bioassay in terms of its sensitivity and error rates. Recently, Healy (1987) presented a review of the factors that influence the power of a study (the ability to detect a dose-related effect when it exists). In brief, the power of a study depends on seven aspects of study design:

- Sample size
 - Background variability (error variance)
 - Size of true effect to be detected (i.e., objective of the study)
 - Type of significance test
 - Significance level
 - Decision rule (the number of false positives one will accept)
- There are several ways to increase power—each with a consequence.

Action	Consequence
Increase the sample size	Greater resources required
Design test to detect larger differences	Less useful conclusions
Use a more powerful significance test	Stronger assumptions required
Increase the significance level	Higher statistical false positive rate
Use one-tailed decision rule	Blind to effects in the opposite direction

Timely and constant incorporation of knowledge of test system characteristics and performance will reduce background variability and allow sharper focus on the actual variable of interest. There are, however, a variety of nontraditional approaches to the analysis of screening data.

5.7 UNIVARIATE DATA

5.7.1 Control Charts

The control chart approach (Montgomery, 1985), commonly used in manufacturing quality control in another form of screening (for defective product units), offers some desirable characteristics.

By keeping records of cumulative results during the development of screen methodology, an initial estimate of the variability (such as standard deviation [SD]) of each assay will be available when full-scale use of the screen starts. The initial estimates can then be revised as more data are generated (i.e., as we become more familiar with the screen).

The following example shows the usefulness of control charts for control measurements in a screening procedure. Our

example test for screening potential muscle strength suppressive agents measures reduction of grip strength by test compounds compared with a control treatment. A control chart was established to monitor the performance of the control agent (i) to establish the mean and variability of the control, and (ii) to ensure that the results of the control for a given experiment are within reasonable limits (a validation of the assay procedure).

As in control charts for quality control, the mean and average range of the assay were determined from previous experiments. In this example, the screen had been run 20 times previous to collecting the data shown. These initial data showed a mean grip strength \bar{X} of 400 g and a mean range R of 90 g. These values were used for the control chart (Figure 5.3). The subgroups are of size 5. The action limits for the mean and range charts were calculated as follows:

$$X \pm 0.58R = 400 \pm 0.58 \times 90 = 348 - 452 \text{ (from the } X \text{ chart)}$$

Then, using the upper limit (du) for an n of 5,

$$2.11R = 2.11 \times 90 = 190 \text{ (the upper limit for the range)}$$

Note that the range limit, which established a limit for the variability of our data, is, in fact, a “detector” for the presence of outliers (extreme values).

Such charts may also be constructed and used for proportion or count types of data. By constructing such charts for the

FIGURE 5.3 Example of a control chart used to “prescreen” data (actually, explore and identify influential variables) from a portion of a functional observational battery.

range of control data, we may then use them as rapid and efficient tools for detecting effects in groups being assessed for that same activity end point.

5.7.2 Central Tendency Plots

The objective behind our analysis of screen data is to have a means of efficiently, rapidly, and objectively identifying those agents that have a reasonable probability of being active. Any materials that we so identify may be further investigated in a more rigorous manner, which will generate data that can be analyzed by traditional means. In other words, we want a method that makes out-of-the-ordinary results stand out. To do this, we must first set the limits on “ordinary” (summarize the control case data) and then overlay a scheme that causes those things that are not ordinary to become readily detected (“exposed,” in EDA terms (Tufté, 1983; Velleman and Hoaglin, 1981). One can then perform “confirmatory” tests and statistical analysis (using traditional hypothesis testing techniques), if so desired.

If we collect a set of control data on a variable (say scores on our observations of the righting reflex) from some number of “ordinary” animals, we can plot it as a set of two histograms (one for individual animals and the second for the highest total score in each randomly assigned group of five animals), such as those shown in Figure 5.4 (the data for which came from 200 actual control animals).

Such a plot identifies the nature of our data, visually classifying them into those that will not influence our analysis (in the set shown, clearly scores of 0 fit into this category) and those that will critically influence the outcome of an analysis. In so doing, the position of control (“normal”) observations is readily revealed as a “central tendency” in the data (hence, the name for this technique).

We can (and should) develop such plots for each of our variables. Simple inspection makes clear that answers having no discriminatory power (0 values in Figure 5.4) do not interest us or influence our identifying of an outlier in a group and should simply be put aside or ignored before continuing on with analysis. This first stage, summarizing the control data, thus gives us a device for identifying data with discriminatory power (extreme values), thus allowing us to set aside the data without discriminatory power.

Focusing our efforts on the remainder, it becomes clear that although the incidence of a single, low, nonzero observation in a group means nothing, total group scores of 2 or more occurred only 5% of the time by chance. So we can simply perform an extreme value screen on our “collapsed” data sets, looking for total group values or individual values that are beyond our acceptance criteria.

The next step in this method is to develop a histogram for each ranked or quantal variable, by both individual and group.

“Useless” data (those that will not influence the outcome of the analysis) are then identified and dropped from analysis.

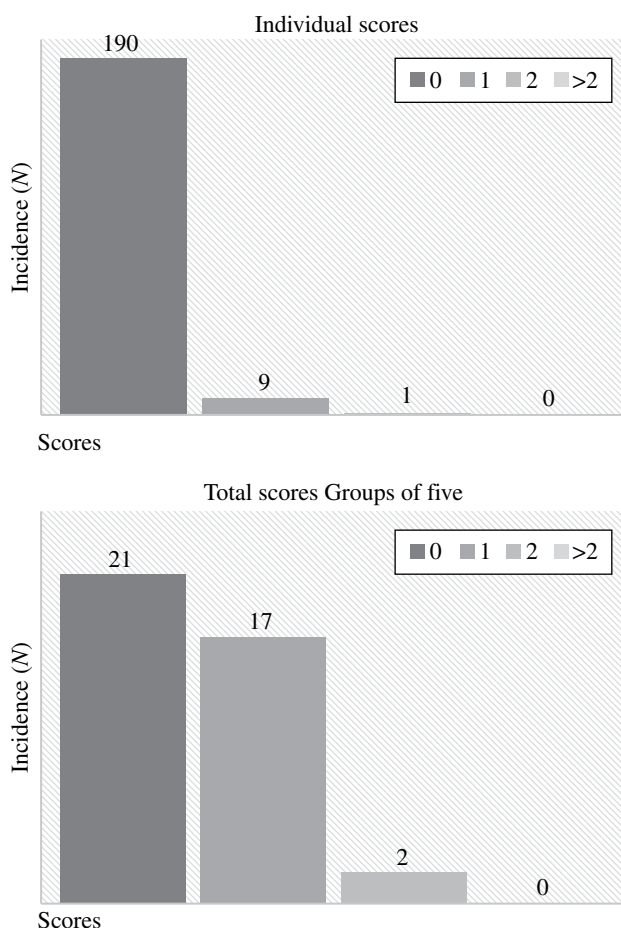

FIGURE 5.4 Plotting central tendency. Possible individual scores for righting reflexes may range from 0 to 8. *Source:* Adapted from (Gad, 1982a). Group total scores would thus range from 0 to 40. (Shown are the number of groups that contain individual scores in the individual categories.)

Group scores may then be simply evaluated against the baseline histograms to identify those groups with scores divergent enough from control to be either true positives or acceptably low-incidence false positives. Additional control data can continue to be incorporated in such a system over time, both increasing the power of the analysis and providing a check on screen performance.

5.7.3 Multivariate Data

The traditional acute, subchronic, and chronic toxicity studies performed in rodents and other species also can be considered to constitute multiple end point screens. Although the numerically measured continuous variables (body weight, food consumption, and hematology values) generally can be statistically evaluated individually by traditional means, the same concerns of loss of information present in

groups $\times 53$ times $\times 50$ animals. Means alone constituted some 1600 four-digit numbers.

Body weight gains from the period immediately preceding each consumption measurement were used, since these were less correlated. For each variable and at each time, the sums of squares for group differences were divided into four meaningful contrasts:

Control A versus control B

Control A + B versus low

Control A + B + low versus medium

Control A + B + low + medium versus high

To make the variables comparable, the sums of squares were standardized by the within-group standard deviations. Contrast involving doses can be compared with the contrast for the difference between the controls, which should be random. The clearest feature is the high-dose effect for food consumption. However, this seems not to be closely correlated with changes in body weight gains. Certain changes can be seen at the later measurement times, probably because of dying animals.

There are numerous approaches to the problem of capturing all the information in a set of multi-end point data. When the data are continuous in nature, approaches such as the analog plot can be used (Chambers et al., 1983; Chernoff, 1973). A form of control chart also can be derived for such uses when detecting effect rather than exploring relationships between variables is the goal. When the data are discontinuous, other forms of analysis must be used. Just as the control chart can be adapted to analyzing attribute data, an analog plot can be adapted. Other methods are also available.

FORMULATIONS, ROUTES, AND DOSAGE REGIMENS

6.1 INTRODUCTION

The perfect drug would be along the lines of Paul Ehrlich's "magic bullet, a drug molecule is readily administered, completely absorbed, moves to the desired therapeutic target site (receptor), does what is supposed to, and is completely eliminated." The most pressing (and rewarding, if successful) area for drug development currently is optimizing the drug a therapeutic target delivery part of this process. One of the key steps in the nonclinical and clinical formulation of the drug is the selection of vehicles and of the inactive ingredients (excipients). Excipients are essential components of drug products (DP) in the United States, and one must adequately address the safety of the proposed exposure to the excipients in those products. The specific safety data that may be needed will vary depending upon the clinical situation, including such factors as the duration, level, and route of exposure (i.e., actual means of clinical drug administration).

Many guidances exist to aid in the development of pharmaceutical drugs, but very few guidances (and no regulations) exist to aid in the formulation of drugs for nonclinical safety evaluation or for the assessment of pharmaceutical excipient safety. The Food and Drug Administration (FDA)/Center for Drug Evaluation and Research (CDER) adopted, in 2005, the guidance for industry "Nonclinical Studies for Development of Pharmaceutical Excipients" which focuses on the development of safety profiles to support use of new excipients as components of drug or biological products for humans.

A similar guidance was published by International Pharmaceutical Excipients Council (IPEC) "Excipient Safety Evaluation Guidance" in 1995 (updated in IPEC (2012)). These guidelines are presented in a tiered approach of recommended data that should be available on an excipient to pro-

vide a pharmaceutical formulator with a rational basis for including a new excipient in a drug formulation.

Regulatory requirements and expectations for delivery of sufficient (exaggerated) doses to satisfy reviewers while also minimizing vehicle volumes and occurrence of confounding or masking effects have historically occurred with nonclinical drug delivery. Contract testing labs used to have a small internal preclinical formulation procedure/process, but that is no longer the case. An overwhelming focus is on oral route, followed by intravenous, then topical (dermal) are the next most common (Gad et al., 2016; Gad and Spainhour, 2018). Formulation and delivery methodologies are most needed for these routes.

Regulatory requirements are that administered doses must be evaluated at levels much higher than will be used in clinical studies (or will occur occupationally/environmentally). Toxicologists evaluate the upper end of the dose–response curve to be able to detect potentially weak signals in small sample sizes. In a sense, every test animal "stands in place" of thousands of volunteer patients. Exposure most commonly is evaluated as measured systemic (usually plasma) levels—most commonly AUCs. Routes and regimens employed should be those for which there is intended clinical exposure. Formulations, routes, and regimens of administration should cause minimal or at least (marginal and reversible) predictable effects to not "mask" or confound understanding causality of drug/agent effects. You are not limited to approved clinical formulation components (FDA IND excipients or vehicles) except in the case of topical or inhalation drugs where non-clinical studies must be conducted using intended clinical formulation.

The objective of the proposed approach in this chapter is to codify existing excipients and provide a logical and rational approach to qualifying new excipients. The final aim of these

safety evaluation guidelines for excipients is to provide an important element in the acceptability of a new excipient by regulators independent of the approval of a specific drug formulation.

The three essential requirements of active pharmaceutical ingredient (API) principles are compared with those of excipients. Fundamental to both are quality and safety. The requirement of therapeutic efficacy for drugs is replaced by that of functionality for the excipient, defined as “the physical, physicochemical and biopharmaceutical properties” of the same.

Throughout the development process for pharmaceuticals, formulation development proceeds with several objectives in mind. The importance of each of these factors changes over time (Monkhouse and Rhodes, 1998) and as illustrated in Figure 6.1. First is optimizing the bioavailability of the therapeutic agent at the target organ site by the intended

clinical route. Clinical route(s) is selected on a number of grounds (nature of the drug, patient acceptance, issues of safety, marketability, competition). Second is minimizing any safety concerns. This means not just the systemic toxicity but also local tissue tolerance at the site of application. Third is optimizing the stability of the drug active ingredient. Its activity and integrity must be maintained for a period of sufficient duration to be made effectively available to patients. Early on in preclinical development, simplicity and maximized bioavailability are essential. Early single-dose studies in animals are the starting place and usually bear no relationship to what is used later.

Formulations used to administer potential drugs undergoing development occupy an unusual place in pharmaceutical safety assessment compared to the rest of industrial toxicology. Eventually, a separate function in the pharmaceutical

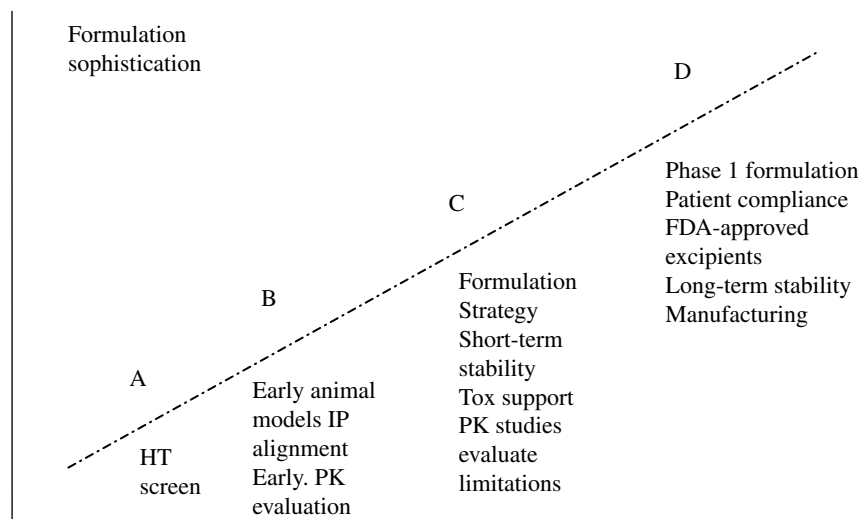

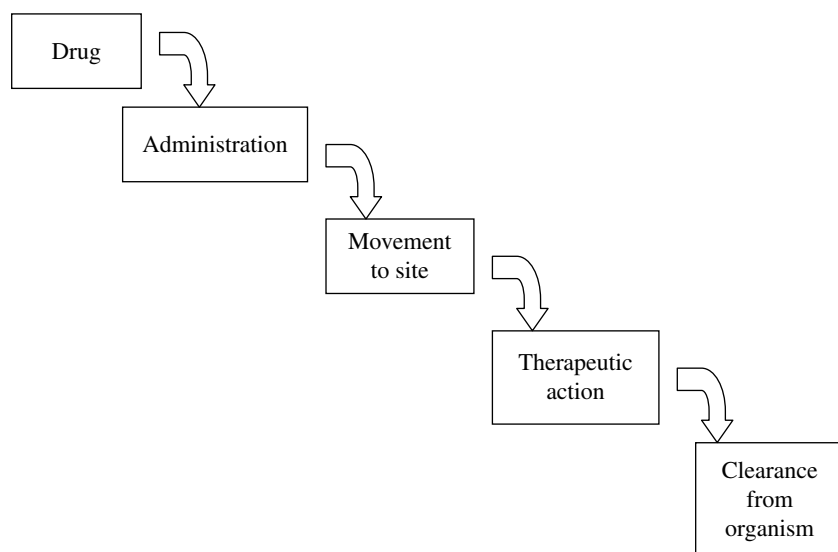

FIGURE 6.1 Evolution of formulations through phase I.

company developing a drug will develop a specific formulation that is to be administered to people—a formulation that optimizes the conditions of absorption and stability for the drug entity (Racy, 1989). The final formulation will need to be assessed to see if it presents any unique, local, or short-term hazards, but as long as its nonactive constituents are drawn from the approved formulary lists, no significant separate evaluation of their safety is required preclinically. They can, of course, alter the toxicity of the drug under study.

Simultaneous with this development of an optimized clinical formulation, nevertheless, preclinical evaluations of the safety of the drug moiety must be performed. Separate preclinical formulations (which generally are less complex than the clinical ones) are developed, sometimes by a formulation group and other times, by a toxicology group itself. These preclinical formulations will frequently include much higher concentrations of the drug moiety being tested than do any clinical formulations. The preclinical formulations are developed and evaluated with the aim of reproducibly delivering the drug (if at all possible by the route intended in man), maintaining drug stability through an optimum period of time, and occluding the observed effects of the drug with vehicle effects to the minimum extent possible, and these preclinical formulations are not restricted to materials that will or could be used in final clinical formulations (Gad, 2008; Boersen et al., 2014).

In pivotal studies, the actual blood levels of an active moiety that is achieved will be determined so that correlations to later clinical studies can be made.

The formulations that are developed and used for preclinical studies are sometimes specific for the test species to be employed, but their development always starts with consideration of the route of exposure that is to be used clinically and, if possible, in accordance with a specified regimen of treatment (mirroring the intended clinical protocol as much as possible). One aspect of both nonclinical and clinical formulation and testing which prevents an important but often overlooked aspect of pharmaceutical safety assessment is the special field of excipients. These will be considered at the end of this chapter.

Among the cardinal principles of both toxicology and pharmacology are that the means by which an agent comes in contact with or enters the body (i.e., the route of exposure or administration) does much to determine the nature and magnitude of an effect. However, a rigorous understanding of the formulations, the routes, and their implications to the design and analysis of safety studies is not widespread, and in the day-to-day operations of performing studies in animals, such an understanding of routes, their manipulation, means, and pitfalls of achieving them, and the art and science of vehicles and formulations are essential to the sound and efficient conduct of a study.

As presented in Table 6.1, there are at least 26 potential routes of administration, of which 10 are commonly used in safety assessment and, therefore, are specifically addressed here.

TABLE 6.1 Potential Routes of Administration

A. Oral routes	
1.	Oral (PO) ^a
2.	Inhalation ^a
3.	Sublingual
4.	Buccal
B. Placed into a natural orifice in the body other than the mouth	
1.	Intranasal
2.	Intraauricular
3.	Rectal
4.	Intravaginal
5.	Intrauterine
6.	Intraurethral
C. Parenteral (injected into the body or placed under the skin)	
1.	Intravenous (IV) ^a
2.	Subcutaneous (SC) ^a
3.	Intramuscular (IM) ^a
4.	Intra-arterial
5.	Intradermal (ID) ^a
6.	Intralesional
7.	Epidural
8.	Intrathecal
9.	Intracisternal
10.	Intracardial
11.	Intraventricular
12.	Intraocular
13.	Intraperitoneal (IP) ^a
D. Topical routes	
1.	Cutaneous
2.	Transdermal (also called percutaneous) ^a
3.	Ophthalmica

^a Commonly used in safety assessment.

6.2 MECHANISMS

There are three primary sets of reasons why differences in formulations and the route of administration are critical in determining the effect of an agent of the biological system. These are (i) local effects, (ii) absorption and distribution, and (iii) metabolism.

6.2.1 Local Effects

Local effects are those that are peculiar to the first area or region of the body to which a test material gains entry or that it contacts. For the dermal route, these include irritation, corrosion, and sensitization. For the parenteral routes, these include irritation, pyrogenicity, sterility, and blood compatibility. In general, these same categories of possible adverse

effects (irritation, immediate immune response, local tissue/cellular compatibility, and physicochemical interactions) are the mechanisms of, or basis for, concern.

In general, no matter what the route, certain characteristics will predispose a material to have local effects (and, by definition, if present, tend to limit the possibility of local effects). These factors include pH, redox potential, high molar concentration, and the low level of flexibility (malleability) and sharp edges of certain solids. These characteristics will increase the potential for irritation by any route and, subsequent to the initial irritation, other appropriate regional adaptive responses (for orally administered materials, e.g., emesis and diarrhea).

6.2.2 Absorption and Distribution

For a material to be toxic, it must be absorbed into the organism (local effects are largely not true toxicities by this definition).

There are characteristics that influence absorption by the different routes, and these need to be understood by any person trying to evaluate and/or predict the toxicities of different moieties. Some key characteristics and considerations are summarized in the following by route.

Table 6.2 presents the normal pH ranges for human physiologies fluids. These need to be considered in terms of the impact on solubility and stability of a formulation and active drug:

A. Oral and rectal routes (gastrointestinal (GI) tract)

1. Lipid-soluble compounds (nonionized) are more readily absorbed than water-soluble compounds (ionized).
 - a. Weak organic bases are in the nonionized, lipid-soluble form in the intestine and tend to be absorbed there.
 - b. Weak organic acids are in the nonionized, lipid-soluble form in the stomach, and one would suspect that they would be absorbed there, but absorption in the intestine is greater because of time and area of exposure.

TABLE 6.2 Normal pH Range for Human Physiologic Fluids

Medium	Normal pH Range
Tears	7.35–7.45
Saliva	6.0–8.0
Gastric juice	1.5–6.5
Intestinal juice	6.5–7.6
Blood	7.35–7.45
Skin (sweat)	4.0–6.8

2. Specialized transport systems exist for some moieties: sugars, amino acids, pyrimidines, calcium, and sodium.
 3. Almost everything is absorbed—at least to a small extent (if it has a molecular weight below 10 000).
 4. Digestive fluids may modify the structure of a chemical.
 5. Dilution increases toxicity because of more rapid absorption from the intestine, unless stomach contents bind or degrade the moiety.
 6. Physical properties are important; for example, dissolution of metallic mercury is essential to allow its absorption.
 7. Age is important; for example, neonates have a poor intestinal barrier.
 8. Effect of fasting on absorption depends on the properties of the chemical of interest.
- B. Inhalation (lungs)
1. Aerosol deposition
 - a. Nasopharyngeal—5 μm or larger in man, less in common laboratory animals
 - b. Tracheobronchial—1 to 5 μm
 - c. Alveolar—1 μm
 2. If an inhalant is a solid, mucociliary transport from lungs to GI tract may clear it out of the pulmonary system.
 3. Lungs are anatomically good for absorption.
 - a. Large surface area (50–100 m²)
 - b. Blood flow being high
 - c. Accessibility to blood (10 μm between gas media and blood)
 4. Absorption of gases is dependent on solubility of the gas in blood.
 - a. Chloroform, for example, has high solubility and is all absorbed, though respiration is limited.
 - b. Ethylene has low solubility and only a small percentage is absorbed—blood flow limits absorption.
- C. Parenteral routes
1. Irritation at the site of injection is influenced by solubility, toxicity, temperature, osmolality, and pH of injected solution.
 2. Pyrogenicity and blood compatibility are major concerns for intravenously administered materials.
 3. Solubility of test material in an aqueous or modified aqueous solution is the chief limitation on how much material may be given intravenously (Stiegeland and Noseworthy, 1963).

D. Dermal routes

1. In general, any factor that increases the absorption through the stratum corneum will also increase the severity of an intrinsic response. Unless this factor mirrors potential exposure conditions, it may, in turn, adversely affect the relevance of test results.
2. The physical nature of solids must be carefully considered both before testing and in interpreting results. Shape (sharp edges), size (small particles may abrade the skin due to being rubbed back and forth under the occlusive wrap), and rigidity (stiff fibers or very hard particles will be physically irritating) of solids may all enhance an irritation response and alter absorption.
3. The degree of occlusion (in fact, the tightness of the wrap over the test site) also alters percutaneous absorption and therefore irritation. One important quality control issue in the laboratory is achieving a reproducible degree of occlusion in dermal wrappings.
4. Both the age of the test animal and the application site (saddle of the back vs. flank) can markedly alter test outcomes. Both of these factors are also operative in humans, of course, but in dermal irritation tests, the objective is to remove all such sources of variability. In general, as an animal ages, the sensitivity to irritation decreases, and the skin on the middle of the back (other than directly over the spine) tends to be thicker (and therefore less sensitive to irritations) than that on the flanks.
5. The sex of the test animals can also alter study results because both regional skin thickness and surface blood flow vary between males and females.

As a generalization, there is a pattern of relative absorption rates that characterizes the different routes that are commonly employed. This order of absorption (by rate from fastest to slowest and, in a less rigorous manner, by degree of absorption from most to least) is IV > inhalation > IM > IP > SC > oral > ID > other.

6.2.3 Metabolism

Metabolism is directly influenced both by the region of the body onto which or into which a material is initially absorbed and by the resultant distribution (both the rate and the pattern). Rate determines whether the primary enzyme systems will handle the entire xenobiotic dose or if these are excessively saturated and overwhelmed. The pattern determines which routes of metabolism are operative.

Absorption (total amount and rate, distribution, metabolism, and species similarity in response) is the reason for

selecting particular routes in toxicology in general. In the safety assessment of pharmaceuticals, however, the route is usually dictated by the intended clinical route and dosing regimen. If this intended route of human exposure is uncertain or if there is the potential for a number of other routes, where the human absorption rate and pattern are greater, then the most common route or the route with the greater degree of human absorption rate and more desirable pattern, the most common plan forward becomes that of the most conservative approach. This approach stresses maximizing potential absorption in the animal species (within the limits of practicality) and selecting from among those routes commonly used in the laboratory that get the most material into the animal's system as quickly and completely as possible to evaluate the potential toxicity. Under this approach, many compounds are administered intraperitoneally in acute testing, though there is little or no real potential for human exposure by this route.

Assuming that a material is absorbed, distribution of a compound in early preclinical studies is usually of limited interest. In so-called "heavy acute studies" (Gad et al., 1984) where acute systemic toxicity is intensive and evaluated to the point of identifying target organs, or in range-finder-type study results, for refining the design of longer-term studies, distribution would be of interest. Some factors that alter distribution are listed in Table 6.3.

The first special case is the parenteral route, where the systemic circulation presents a peak level of the moiety of interest to the body at one time, tempered only by the results of a first pass through the liver.

The second special case arises in cases of inhalation exposures. Because of the arrangement of the circulatory system, inhaled compounds (and those administered via the buccal route) enter the full range of systemic circulation without any "first-pass" metabolism by the liver. Kerberle (1971) and O'Reilly (1972) have previously published reviews of absorption, distribution, and metabolism that are relevant to acute testing.

6.3 COMMON ROUTES

Each of the 10 routes most commonly used in safety assessment studies has its own peculiarities, and for each, there are practical considerations and techniques ("tricks") that should either be known or readily available to the practicing toxicologist.

6.3.1 Dermal Route

For all agents of concern in occupational toxicology (except therapeutic agents), the major route by which the general population is most frequently exposed is via the percutaneous

TABLE 6.3 Selected Factors That May Affect Chemical Distribution to Various Tissues

-
- A. Factors relating to the chemical and its administration
1. Degree of binding of chemical to plasma proteins (i.e., agent affinity for proteins) and tissues
 2. Chelation to calcium, which is deposited in growing bones and teeth (e.g., tetracyclines in young children)
 3. Whether the chemical distributes evenly throughout the body (one-compartment model) or differentially between different compartments (models of two or more compartments)
 4. Ability of chemical to cross the blood–brain barrier
 5. Diffusion of chemical into the tissues or organs and degree of binding to receptors that are and are not responsible for the drug’s beneficial effects
 6. Quantity of chemical given
 7. Route of administration or exposure
 8. Partition coefficients (nonpolar chemicals are distributed more readily to fat tissues than are polar chemicals)
 9. Interactions with other chemicals that may occupy receptors and prevent the drug from attaching to the receptor, inhibit active transport, or otherwise interfere with a drug’s activity
 10. Molecular weight of the chemical
- B. Factors relating to the test subject
1. Body size
 2. Fat content (e.g., obesity affects the distribution of drugs that are highly soluble in fats)
 3. Permeability of membranes
 4. Active transport for chemicals carried across cell membranes by active processes
 5. Amount of proteins in blood, especially albumin
 6. Pathology or altered homeostasis that affects any of the other factors (e.g., cardiac failure, renal failure)
 7. Presence of competitive binding substances (e.g., specific receptor sites in tissues bind drugs)
 8. pH of blood and body tissues
 9. pH of urine
 10. Blood flow to various tissues or organs (e.g., well-perfused organs usually tend to accumulate more chemical than less well-perfused organs)
-

^a The pH of urine is usually more important than the pH of blood.

(dermal) route. Brown (1980) has previously reviewed background incidence data on pesticides that shows such a route of exposure to be common. Dermal (or topical) drugs, although not as common, are certainly numerous in occurrence.

Percutaneous entry into the body is really by separate means (Marzulli, 1962; Blank and Scheuplein, 1964; Scheuplein, 1965, 1967):

- Between the cells of the stratum corneum
- Through the cells of the stratum corneum
- Via the hair follicles
- Via the sweat glands
- Via the sebaceous glands

Certain important aspects of the material of interest, as well as those of the test animals, involving application and absorption (Blank and Scheuplein, 1964) are the following:

1. Small molecules penetrate skin better than large molecules.
2. Undissociated molecules penetrate skin better than do ions.
3. Preferential solubility of the toxicant in organic solvents indicates better penetration characteristics than preferential solubility in water.
4. The less viscous or more volatile the toxicant, the greater its penetrability.
5. The nature of the vehicle and the concentration of the toxicant in the vehicle both affect absorption (vehicles are discussed later in this chapter).
6. Hydration (water content) of the stratum corneum affects penetrability.
7. Ambient temperature can influence the uptake of toxicant through the skin. The warmer it is, the greater the blood flow through the skin and, therefore, the greater the degree of percutaneous absorption.
8. Molecular shape (particularly symmetry) influences absorption (Medved and Kundiev, 1964).

There are at least two excellent texts on the subject of percutaneous absorption (Brandau and Lippold, 1982; Bronaugh and Maibach, 1985) that go into great detail.

6.3.2 Parenteral Routes

The parenteral routes include three major ones—intravenous (IV), intramuscular (IM), and subcutaneous (SC)—and a number of minor routes (such as intra-arterial) that are not considered here. Administration by the parenteral routes raises a number of special safety concerns in addition to the usual systemic safety questions. These include irritation

(vascular, muscular, or SC), pyrogenicity, blood compatibility, and sterility (Avis, 1985). The background of each of these, along with the underlying mechanisms and factors that influence the level of occurrence of such an effect, is discussed in Chapter 13.

The need for a rapid onset of action (and/or clearance) usually requires that an IV route be used, although at a certain stage of cardiopulmonary resuscitation, for example, the need for an even more rapid effect may require the use of an intracardiac injection. The required site of action may influence the choice of route of administration (e.g., certain radiopaque dyes are given intra-arterially near the site being evaluated; streptokinase is sometimes injected experimentally into the coronary arteries close to coronary vessel occlusion during a myocardial infarction to cause lysis of the thrombus and therefore reestablish coronary blood flow).

The characteristics of the fluid to be injected will also influence the choice of parenteral routes. The drug must be compatible with other fluids (e.g., saline, dextrose, and Ringer's lactate) with which it may be combined for administration to the patient, as well as with the components of the blood itself.

There are certain clinical situations in which a parenteral route of administration is preferred to other possible routes. These include the following:

1. When the amount of drug given to a subject must be precisely controlled (e.g., in many pharmacokinetic studies), it is preferable to use a parenteral (usually IV) route of administration.
2. When the "first-pass effect" of a drug going through the liver must be avoided, a parenteral route of administration is usually chosen, although a sublingual route or dermal patch will also avoid the first-pass effect.
3. When one requires complete assurance that an uncooperative subject has actually received the drug and has not rejected it (e.g., via forced emesis).
4. When subjects are in a stupor, coma, or otherwise unable to take a drug orally.
5. When large volumes (i.e., more than a liter) of fluid are injected (such as in peritoneal dialysis, hyperalimentation, fluid replacement, and other conditions). Special consideration of fluid balance must be given to patients receiving large volumes, as well as careful consideration of the systemic effects of injection fluid components (e.g., amino acids and their nephrotoxicity).

Each of the three significant parenteral routes we are concerned with here has a specific set of either advantages and

disadvantages or specific considerations that must be kept in mind.

6.3.2.1 Intravenous Route The IV route is the most common method of introducing a drug directly into the systemic circulation. It has the following advantages:

1. Rapid onset of effect
2. Usefulness in situations of poor GI absorption
3. Avoidance of tissue irritation that may be present in IM or other routes (e.g., nitrogen mustard)
4. More precise control of levels of drug than with other routes, especially of toxic drugs, where the levels must be kept within narrow limits
5. Ability to administer large volumes over time by a slow infusion
6. Ability to administer drugs at a constant rate over a long period of time

It also suffers from the following disadvantages:

1. Higher incidence of anaphylactic reactions than with many other routes
2. Possibility of infection or phlebitis at site of injection
3. Greater pain to patients than with many other routes
4. Possibility that embolic phenomena may occur—either air embolism or vascular clot—as a result of damage to the vascular wall
5. Impossibility of removing or lavaging a drug after it is given, except by dialysis
6. Inconvenience in many situations
7. Possibility that rapid injection rates may cause severe adverse reactions
8. Patient dislike of, and psychological discomfort with, the injection procedure

For IV fluids, it must be determined how the dose will be given (i.e., by bolus or slow injection, intermittent or constant infusion, or constant drip) and whether special equipment will be used to control and monitor the flow. Drugs with short half-lives are usually given by a constant drip or infusion technique. All IV fluids given immediately subsequent to an IV drug must be evaluated for their compatibility with the study drug. Suspensions are generally not given intravenously because of the possibility of blocking the capillaries.

In the IV route, anaphylactic reactions (caused by administration of an agent to an animal previously sensitized to it or to a particularly sensitive species such as a guinea pig) may be especially severe—probably because of sudden massive antigen–antibody reactions. When the drug is given by

other routes, its access to antibody molecules is necessarily slower; moreover, its further absorption can be retarded or prevented at the first sign of a serious allergic reaction.

Embolism is another possible complication of the IV route. Particulate matter may be introduced if a drug intended for IV use precipitates for some reason or if a particular suspension intended for IM or SC use is inadvertently given into a vein. Hemolysis or agglutination of erythrocytes may be caused by injection of hypotonic hypertonic solutions or by more specific mechanisms (Gray, 1978).

6.3.3 Bolus versus Infusion

Technically, for all the parenteral routes (but in practice only for the IV route), there are two options for injecting a material into the body. The bolus and infusion methods are differentiated on the single basis of rate of injection, but they differ on a wide range of characteristics.

The most commonly exercised option is the bolus, “push,” injection, in which the injection device (syringe or catheter) is appropriately entered into the vein and a defined volume of material is introduced through the device. The device is then removed. In this operation, it is relatively easy to restrain an experimental animal, and the stress on the animal is limited. Though the person doing the injection must be skilled, it takes only a short amount of time to become so, and the one variable to be controlled in determining dosage is the total volume of material injected (assuming dosing solutions have been properly prepared). See Chapter 10 for a more complete discussion.

For infusion, a port (particularly over a period of weeks or more) (Garramone, 1986) is typically installed to minimize cumulative injection site trauma.

6.3.3.1 Subcutaneous Route Drugs given by the SC route are forced into spaces between connective tissues, as with IM injections. Vasoconstrictors and drugs that cause local irritation should not be given subcutaneously under usual circumstances, since inflammation, abscess formation, or even tissue necrosis may result. When daily or even more frequent SC injections are made, the site of injection should be continually changed to prevent local complications. Fluids given subcutaneously must have an appropriate tonicity/osmolality to prevent pain. Care must be taken to prevent injection of the drug directly into veins.

The absorption of drugs from an SC route is influenced by blood flow to the area, as with IM injections. The rate of absorption may be retarded by cooling the local area to cause vasoconstriction, adding epinephrine to the solution for the same purpose (e.g., with local anesthetics), decreasing blood flow with a tourniquet, or immobilizing the area. The opposite effect may be achieved by warming the injection region or by using the enzyme hyaluronidase, which breaks down mucopolysaccharides of the connective tissue matrix to allow the

injected solution to spread over a larger area and thus increase its rate of absorption (Ballard, 1968).

Absorption from SC injection sites is affected by the same factors that determine the rate of absorption from IM sites (Schou, 1971). Blood flow through these regions is generally poorer than in muscles, so the absorption rate is generally slower.

The rate of absorption from an SC injection site may be retarded by immobilization of the limb, local cooling to cause vasoconstriction, or application of a tourniquet proximal to the injection site to block the superficial venous drainage and lymphatic flow. In small amounts, adrenergic stimulants, such as epinephrine, will constrict the local blood vessels and, therefore, slow systemic absorption. Conversely, cholinergic stimulants (such as methacholine) will induce very rapid systemic absorption subcutaneously. Other agents may also alter their own rate of absorption by affecting local blood supply or capillary permeability.

A prime determinant of the absorption rate from an SC injection is the total surface area over which the absorption can occur. Although the SC tissues are somewhat loose and moderate amounts of fluid can be administered, the normal connective tissue matrix prevents indefinite lateral spread of the injected solution. These barriers may be overcome by agents that break down mucopolysaccharides of the connective tissue matrix; the resulting spread of injected solution leads to a much faster absorption rate.

In addition to fluids, solid forms of drugs may be given by SC injection. This has been done with compressed pellets of testosterone placed under the skin, which are absorbed at a relatively constant rate over a long period.

6.3.3.2 Intramuscular Route The IM route is frequently used for drugs dissolved in oily vehicles or for those in a microcrystalline formulation that are poorly soluble in water (e.g., procaine or penicillin G). Advantages include rapid absorption (often in under 30 min), the opportunity to inject a relatively large amount of solution, and a reduction in pain and local irritation compared with SC injections. Potential complications include infections and nerve damage. The latter usually results from the choice of an incorrect site for injection.

Although the time to peak drug concentration is often in the order of 1–2 h, depot preparations given by IM injection are absorbed extremely slowly. Numerous physiochemical properties of a material given intramuscularly will affect the rate of absorption from the site within the muscle (e.g., ionization of the drug, lipid solubility, osmolality of the solution, and volume given). The primary sites used for IM injections in people are the gluteal (buttock), deltoid (upper arm), and epaxial and lateral vastus (lateral thigh) muscles, with the corresponding sites in test animals being species-specific. The rate of drug absorption and the peak drug levels obtained will often differ between sites used for IM injections because of

differences in blood flow between muscle groups. The site chosen for an IM injection in humans and some animals may be a critical factor in whether or not the drug exhibits an effect (Schwartz et al., 1974). Agents injected into the larger muscle masses are generally absorbed rapidly.

Blood flow through muscles in a resting animal is about $0.02\text{--}0.07\text{ mL min}^{-1}\text{ g}^{-1}$ of tissue, and this flow rate may increase many times during exercise, when additional vascular channels open. Large amounts of solution can be introduced intramuscularly, and there are usually less pain and local irritation than is encountered by the SC route. Ordinary aqueous solutions of chemicals are usually absorbed from an IM site within 10–30 min, but faster or slower absorption is possible, depending on the vascularity of the site, the ionization and lipid solubility of the drug, the volume of the injection, the osmolality of the solution, animal temperature, and other variables. Small molecules are absorbed directly into the capillaries from an IM site, whereas large molecules (e.g., proteins) gain access to the circulation by way of the lymphatic channels. Radiolabeled compounds of widely differing molecular weights (maximum 585) and physical properties have been shown to be absorbed from rat muscle at virtually the same rate, about 16% per minute (i.e., the absorption process is limited by the rate of blood flow.).

Drugs that are insoluble at tissue pH, or that are in an oily vehicle, form a depot in the muscle tissue, from which absorption proceeds very slowly.

6.3.3.3 Intraperitoneal Route Kruger et al. (1962) demonstrated the efficiency of absorption of some chemicals injected IP, while Lukas et al. (1971) showed that compounds administered IP are absorbed primarily through the portal circulation.

A prime practical consideration in the use of the IP route for acute testing should be the utilization of aseptic techniques to preclude bacterial or viral contamination. If these are not exercised, the resulting infected and compromised animals cannot be expected to produce either valid or reproducible indications or actual chemical toxicity.

Compounds that are very lipophilic will be quickly absorbed systemically by the IP route, but not by the IM or SC route.

6.3.4 Oral Route

The versions of the oral route, the most commonly used routes for the administration of drugs, both because of ease of administration and because they are the most readily accepted route of administration. Although the dermal route may be as common for occupational exposure, it is much easier to accurately measure and administer doses by the oral route.

Enteral routes technically include any that will put a material directly into the GI tract, but the use of enteral routes

other than oral (such as rectal) is rare in toxicology. Though there are a number of variations of technique and peculiarities of animal response that are specific to different animal species, there is also a great deal of commonality across species in methods, considerations, and mechanisms.

6.3.4.1 Mechanisms of Absorption Ingestion is generally referred to as oral or peroral (PO) exposure and includes direct intragastric exposure in experimental toxicology. The regions for possible agent action and absorption from PO absorption should receive separate consideration.

Because of the rich blood supply to the mucous membranes of the mouth (buccal cavity), many compounds can be absorbed through them. Absorption from the buccal cavity is limited to nonionized, lipid-soluble compounds. Buccal absorption of a wide range of aromatic and aliphatic acids and basic drugs in human subjects has been found to be parabolically dependent on $\log P$, where P is the octanol–water partition coefficient. The ideal lipophilic character ($\log P_0$) for maximum buccal absorption has also been shown to be in the range 4.2–5.5 (Lien et al., 1971). Compounds with high molecular weights are poorly absorbed in the buccal cavity, and, since absorption increases linearly with concentration and there is generally no difference between optical enantiomorphs of several compounds known to be absorbed from the mouth, it is believed that uptake is by passive diffusion rather than by active transport chemical moieties.

A knowledge of the buccal absorption characteristics of a chemical can be important in a case of accidental poisoning. Although an agent taken into the mouth will be voided immediately on being found objectionable, it is possible that significant absorption can occur before any material is swallowed.

Unless voided, most materials in the buccal cavity are ultimately swallowed. No significant absorption occurs in the esophagus, and the agent passes on to enter the stomach. It is a common practice in safety assessment studies to avoid the possibility of buccal absorption by intubation (gavage) or by the administration of the agent in gelatin capsules designed to disintegrate in the gastric fluid.

Absorption of chemicals with widely differing characteristics can occur at different levels in the GI tract (Hogben et al., 1959; Schranker, 1960; Bates and Gibaldi, 1970; Gad, 2007). The two factors primarily influencing this regional absorption are (i) the lipid–water partition characteristics of the undissociated toxicant and (ii) the dissociation constant (pK_a) that determines the amount of toxicant in the dissociated form. There are also species differences (Schranker et al., 1957).

Therefore, weak organic acids and bases are readily absorbed as uncharged lipid-soluble molecules, whereas ionized compounds are absorbed only with difficulty and nonionized toxicants with poor lipid-solubility characteristics are

absorbed slowly. Lipid-soluble acid molecules can be absorbed efficiently through the gastric mucosa, but bases are not absorbed in the stomach.

In the intestines, the nonionized form of the drug is preferentially absorbed, and the rate of absorption is related to the lipid-water partition coefficient of the toxicant. The highest pK_a value for a base compatible with efficient gastric absorption is about 7.8, and the lowest pK_a for an acid is about 3.0, although a limited amount of absorption can occur outside these ranges. The gastric absorption and the intestinal absorption of a series of compounds with different carbon chain lengths follow two different patterns. Absorption from the stomach increases as the chain lengthens from methyl to *n*-hexyl, whereas intestinal absorption increases over the range methyl to *n*-butyl and then diminishes as the chain length further increases. Share et al. (1971) and Houston et al. (1974) concluded that to explain the logic of optimal partition coefficients for intestinal absorption, it was necessary to postulate a two-compartment model with a hydrophilic barrier and a lipoidal membrane and that if there is an acceptable optimal partition coefficient for gastric absorption, it must be at least 10 times greater than the corresponding intestinal value.

Because they are crucial to the course of an organism's response, the rate and extent of absorption of biologically active agents from the GI tract also have major implications for the formulation of test material dosages and for how production (commercial) materials may be formulated to minimize potential accidental intoxications while maximizing the therapeutic profile.

There are a number of separate mechanisms involved in absorption from the GI tract.

Passive Absorption The membrane lining of the tract has a passive role in absorption. As toxicant molecules move from the bulk water phase of the intestinal contents into the epithelial cells, they must pass through two membranes in series, one layer of water and the other the lipid membrane of the microvillar surface (Wilson and Dietschy, 1974). The water layer may be the rate-limiting factor for passive absorption into the intestinal mucosa, but it is not rate limiting for active absorption. The concentration gradient in addition to the physicochemical properties of the drug along with the lining membrane is the major controlling factor. Chemicals that are highly lipid soluble are capable of passive diffusion, and they pass readily from the aqueous fluids of the gut lumen through the lipid barrier of the intestinal wall and into the bloodstream. The interference in the absorption process by the water layer increases with increasing absorbability of the substances in the intestine (Winne, 1978).

Aliphatic carbamates are rapidly absorbed from the colon by passive uptake (Wood et al., 1978), and it is found that there is a linear relationship between $\log k_a$ and $\log P$ for absorption of these carbamates in the colon and the stomach, whereas there is a parabolic relationship between these two

values for absorption in the small intestine. The factors to be considered are the following:

P = octanol-buffer partition coefficient

k_a = absorption rate constant

t = time

$$t^{1/2} = \text{half-life} = \frac{\ln 2}{k_a}$$

Organic acids that are extensively ionized at intestinal pHs are absorbed primarily by simple diffusion.

Facilitated Diffusion A temporary combination of the chemical with some form of "carrier" occurs in the gut wall, facilitating the transfer of the toxicant across the membranes. This process is also dependent on the concentration gradient across the membrane, and there is no energy utilization in making the translocation. In some intoxications, the carrier may become saturated, making this the rate-limiting step in the absorption process.

Active Transport As mentioned, the process depends on a carrier but differs in that the carrier provides energy for translocation from regions of lower concentration to regions of higher concentration.

Pinocytosis This process by which particles are absorbed can be an important factor in the ingestion of particulate formulations of chemicals (e.g., dust formulations, suspensions of wettable powders); however, it must not be confused with absorption by one of the aforementioned processes, where the agent has been released from particles.

Absorption via Lymphatic Channels Some lipophilic chemicals dissolved in lipids may be absorbed through the lymphatics.

Convective Absorption Compounds with molecular radii of less than 4 nm can pass through pores in the gut membrane. The membrane exhibits a molecular sieving effect.

Characteristically, within certain concentration limits, if a chemical is absorbed by passive diffusion, then the concentration of toxicant in the gut and the rate of absorption are linearly related. However, if absorption is mediated by active transport, the relationship between concentration and rate of absorption conforms to Michaelis-Menten kinetics and a Lineweaver-Burk plot (i.e., reciprocal of rate of absorption plotted against reciprocal of concentration), which graphs as a straight line.

Differences in the physiological chemistry of GI fluids can have a significant effect on toxicity. Both physical and chemical differences in the GI tract can lead to species differences in susceptibility to acute intoxication. The anthelmintic pyrinium chloride has an identical LD_{50} value when administered intraperitoneally to rats and mice ($\sim 4 \text{ mg kg}^{-1}$); when administered orally, however, the LD_{50} value in mice was found to be 15 mg kg^{-1} , while for the rat, the LD_{50} values were 430 mg kg^{-1} for females and 1550 mg kg^{-1} for males. It is

thought that this is an absorption difference rather than a metabolic difference (Ritschel et al., 1974).

Most of any exogenous chemical absorbed from the GI tract must pass through the liver via the hepatic portal system (leading to the so-called “first-pass effect”), and, as mixing of the venous blood with arterial blood from the liver occurs, consideration and caution are called for in estimating the amounts of chemical in both the systemic circulation and the liver itself.

Despite the GI absorption characteristics discussed earlier, it is common for absorption from the alimentary tract to be facilitated by dilution of the toxicant. Borowitz et al. (1971) have suggested that the concentration effects they observed in atropine sulfate, aminopyrine, sodium salicylate, and sodium pentobarbital were due to a combination of rapid stomach emptying and the large surface area for absorption of the drugs.

Major structural or physiological differences in the alimentary tract (e.g., species differences or surgical effects) can give rise to modifications of toxicity. For example, ruminant animals may metabolize toxicants in the GI tract in a way that is unlikely to occur in nonruminants.

The presence of bile salts in the alimentary tract can affect absorption of potential toxicants in a variety of ways, depending on their solubility characteristics.

6.3.4.2 Factors Affecting Absorption Test chemicals are given most commonly by mouth. This is certainly the most convenient route, and it is the only one of practical importance for self-administration. Absorption, in general, takes place along the whole length of the GI tract, but the chemical properties of each molecule determine whether it will be absorbed in the strongly acidic stomach or in the nearly neutral intestine. Gastric absorption is favored by an empty stomach, in which the chemical, in undiluted gastric juice, will have good access to the mucosal wall. Only when a chemical would be irritating to the gastric mucosa it is rational to administer it with or after a meal. However, the antibiotic Griseofulvin is an example of a substance with poor water solubility, the absorption of which is aided by a fatty meal. The large surface area of the intestinal villi, the presence of bile, and the rich blood supply all favor intestinal absorption of griseofulvin and physiochemically similar compounds.

The presence of food can impair the absorption of chemicals given by mouth. Suggested mechanisms include reduced mixing, complexing with substances in the food, and retarded gastric emptying. In experiments with rats, prolonged fasting has been shown to diminish the absorption of several chemicals, possibly by deleterious effects upon the epithelium of intestinal villi.

Chemicals that are metabolized rapidly by the liver cannot be given for systemic effect by the enteral route because the

portal circulation carries them directly to the liver. For example, lidocaine, a drug of value in controlling cardiac arrhythmias, is absorbed well from the gut, but is completely inactivated in a single passage through the liver.

The principles governing the absorption of drugs from the GI lumen are the same as for the passage of drugs across biological membranes elsewhere. A lower degree of ionization, high lipid–water partition coefficient of the nonionized form, and a small atomic or molecular radius of water-soluble substances all favor rapid absorption. Water passes readily in both directions across the wall of the GI lumen. Sodium ion is probably transported actively from the lumen into the blood. Magnesium ion is very poorly absorbed and therefore acts as a cathartic, retaining an osmotic equivalent of water as it passes down the intestinal tract. Ionic iron is absorbed as an amino acid complex, at a rate usually determined by the body’s need for it. Glucose and amino acids are transported across the intestinal wall by specific carrier systems. Some compounds of high molecular weight (polysaccharides and large proteins) cannot be absorbed until they are degraded enzymatically. Other substances cannot be absorbed because they are destroyed by GI enzymes—insulin, epinephrine, and histamine are examples. Substances that form insoluble precipitates in the GI lumen or that are insoluble either in water or in lipid clearly cannot be absorbed.

Absorption of Weak Acids and Bases Human gastric juice is very acidic (about pH 1), whereas the intestinal contents are nearly neutral (actually very slightly acidic). The pH difference between plasma (pH 7.4) and the lumen of the GI tract plays a major role in determining whether a drug that is a weak electrolyte will be absorbed into plasma or excreted from plasma into the stomach or intestine. For practical purposes, the mucosal lining of the GI tract is impermeable to the ionized form of a weak acid or base, but the nonionized form equilibrates freely. The rate of equilibration of the nonionized molecule is directly related to its lipid solubility. If there is a pH difference across the membrane, then the fraction ionized may be considerably greater on one side than on the other. At equilibrium, the concentration of the nonionized moiety will be the same on both sides, but there will be more total drug on the side where the degree of ionization is greater. This mechanism is known as *ion trapping*. The energy for sustaining the unequal chemical potential of the acid or base in question is derived from whatever mechanism maintains the pH difference. In the stomach, this mechanism is the energy-dependent secretion of hydrogen ions.

Consider how a weak electrolyte is distributed across the gastric mucosa between plasma (pH 7.4) and gastric fluid (pH 1.0). In each compartment, the Henderson–Hasselbalch equation gives the ratio of acid–base concentrations. The negative logarithm of the acid dissociation constant is designated

here by the symbol pK_a , rather than the more precisely correct pK^1 :

$$\begin{aligned} \text{pH} &= pK_a + \log \frac{[\text{base}]}{[\text{acid}]} \\ \log \frac{[\text{base}]}{[\text{acid}]} &= \text{pH} - pK_a \\ \frac{[\text{base}]}{[\text{acid}]} &= \text{antilog}(\text{pH} - pK_a) \end{aligned}$$

The implications of the preceding equations are clear. Weak acids are readily absorbed from the stomach. Weak bases are not absorbed well; indeed, they would tend to accumulate within the stomach at the expense of agent in the bloodstream. Naturally, in the more alkaline intestine, bases would be absorbed better, acids more poorly.

It should be realized that although the principles outlined here are correct, the system is dynamic, not static. Molecules that are absorbed across the gastric or intestinal mucosa are removed constantly by blood flow; thus, simple reversible equilibrium across the membrane does not occur until the agent is distributed throughout the body.

Absorption from the stomach, as determined by direct measurements, conforms, in general, to the principles outlined earlier. Organic acids are absorbed well since they are all almost completely nonionized at the gastric pH; indeed, many of these substances are absorbed well since they are all almost completely nonionized at the gastric pH; indeed, many of these substances are absorbed faster than ethyl alcohol, which had long been considered one of the few compounds that were absorbed well from the stomach. Strong acids whose pK_a values lie below 1, which are ionized even in the acid contents of the stomach, are not absorbed well. Weak bases are absorbed only negligibly, but their absorption can be increased by raising the pH of the gastric fluid.

As for bases, only the weakest are absorbed to any appreciable extent at normal gastric pH, but their absorption can be increased substantially by neutralizing the stomach contents. The quaternary cations, however, which are charged at all pH values, are not absorbed at either pH.

The accumulation of weak bases in the stomach by ion trapping mimics a secretory process; if the drug is administered systemically, it accumulates in the stomach. Dogs given various drugs intravenously by continuous infusion to maintain a constant drug level in the plasma had the gastric contents sampled by means of an indwelling catheter. The results showed that stronger bases ($pK_a > 5$) accumulated in stomach contents to many times their plasma concentrations; the weak bases appeared in about equal concentrations in gastric juice and in plasma. Among the acids, only the weakest appeared in detectable amounts in the stomach. One might wonder why the strong bases, which are completely

ionized in gastric juice, whose theoretical concentration ratios (gastric juice/plasma) are very large should nevertheless attain only about a 40-fold excess over plasma. Direct measurements of arterial and venous blood show that essentially all the blood flowing through the gastric mucosa is cleared of these agents; obviously, no more chemical can enter the gastric juice in a given time period than is brought there by circulation. Another limitation comes into play when the base pK_a exceeds 7.4; now a major fraction of the circulating base is cationic, and a decreasing fraction is nonionized, so the effective concentration gradient for diffusion across the stomach wall is reduced.

The ion-trapping mechanism provides a method of some forensic value for detecting the presence of alkaloids (e.g., narcotics, cocaine, amphetamines) in cases of death suspected to be due to overdosage of self-administered drugs. Drug concentrations in gastric contents may be very high even after parenteral injection.

Absorption from the intestine has been studied by perfusing drug solutions slowly through rat intestine *in situ* and by varying the pH as desired. The relationships that emerge from such studies are the same as those for the stomach, the difference being that the intestinal pH is normally very near neutrality. As the pH is increased, the bases are absorbed better, the acids more poorly. Detailed studies with a great many drugs in unbuffered solutions revealed that in the normal intestine, acids with $pK_a > 3.0$ and bases with $pK_a < 7.8$ are very well absorbed; outside these limits, the absorption of acids and bases falls off rapidly. This behavior leads to the conclusion that the "virtual pH" in the microenvironment of the absorbing surface in the gut is about 5.3; this is somewhat more acidic than the pH in the intestinal lumen is usually considered to be.

Absorption from the buccal cavity has been shown to follow the same principles as those described for absorption from the stomach and intestine. The pH of human and canine saliva is usually about 6. Bases in people are absorbed only on the alkaline side of their pK_a , that is, only in the nonionized form. At normal saliva pH, only weak bases are absorbed to a significant extent.

6.3.4.3 Bioavailability and Thresholds The difference between the extent of availability (often designated solely as bioavailability) and the rate of availability is illustrated in Figure 6.2, which depicts the concentration–time curve for a hypothetical agent formulated into three different dosage forms. Dosage forms A and B are designed so that the agent is put into the blood circulation at the same rate, but twice as fast as for dosage form C. The times at which agent concentrations reach a peak are identical for dosage forms A and B and occur earlier than the peak time for dosage form C. In general, the relative order of peak times following the administration of different dosage forms of the drug corresponds to the rates of availability of the

FIGURE 6.2 Three different systemic absorption curves.

chemical moiety from the various dosage forms. The extent of availability can be measured by using either chemical concentrations in the plasma or blood or amounts of unchanged chemical in the urine. The area under the blood concentration–time curve for an agent can serve as a measure of the extent of its availability. In Figure 6.2, the areas under curves A and C are identical and twice as great as the area under curve B. In most cases, where clearance is constant, the relative areas under the curves or the amount of unchanged chemical excreted in the urine will quantitatively describe the relative availability of the agent from the different dosage forms. However, even in nonlinear cases, where clearance is dose-dependent, the relative areas under the curves will yield a measurement of the rank order of availability from different dosage forms or from different routes of administration.

Because there is usually a critical concentration of a chemical in the blood that is necessary to elicit either a pharmacological or toxic effects, both the rate and extent of input or availability can alter the toxicity of a compound. In the majority of cases, the duration of effects will be a function of the length of time the blood–concentration curve is above the threshold concentration; the intensity of the effect for many agents will be a function of the elevation of the blood–concentration curve above the threshold concentration.

Thus, the three different dosage forms depicted in Figure 6.2 will exhibit significant differences in their levels of “toxicity.” Dosage form B requires that twice the dose be administered to attain blood levels equivalent to those for dosage form A. Differences in the rate of availability are particularly important for agents given acutely. The dosage for A reaches the target concentration earlier than chemical from dosage form C; concentrations from A reach a higher level and remain above the minimum effect concentration for a longer period of time. In a multiple dosing regimen, dosage forms A and C will yield the same average blood concentrations, although dosage form A will show some-what greater maximum and lower minimum concentrations.

For most chemicals, the rate of disposition or loss from the biological system is independent of rate of input, once the agent is absorbed. Disposition is defined as what happens to the active molecule after it reaches a site in the blood circulation where concentration measurements can be made (the systemic circulations, generally). Although disposition processes may be independent of input, the inverse is not necessarily true, because disposition can markedly affect the extent of availability. Agents absorbed from the stomach and the intestine must first pass through the liver before reaching the general circulation (Figure 6.3). Thus, if a compound is

FIGURE 6.3 Path of drugs through the body after absorption by one of three routes of administration.

metabolized in the liver or excreted in bile, some of the active molecules absorbed from the GI tract will be inactivated by hepatic processes before they can reach the systemic circulation and be distributed to their sites of action. If the metabolizing or biliary excreting capacity of the liver is great, the effect on the extent of availability will be substantial. Thus, if the hepatic blood clearance for the chemical is large, relative to hepatic blood flow, the extent of availability for this chemical will be low when it is given by a route that yields first-pass metabolic effects. This decrease in availability is a function of the physiological site from which absorption takes place, and no amount of modification to dosage form can improve the availability under linear conditions. Of course, toxic blood levels can be reached by this route of administration if larger doses are given.

It is important to realize that chemicals with high extraction ratios (i.e., greater extents of removal by the liver during first-pass metabolism) will exhibit marked intersubject variability in bioavailability because of variations in hepatic function or blood flow or both. For the chemical with an extraction ratio of 0.90 that increases to 0.95, the bioavailability of the agent will be halved, from 0.10 to 0.05. These relationships can explain the marked variability in plasma or blood drug concentrations that occurs among individual animals given similar doses of a chemical that is markedly extracted. Small variations in hepatic extraction between individual animals will result in large differences in availability and plasma drug concentrations.

The first-pass effect can be avoided, to a great extent, by use of the sublingual route and by topical preparations (e.g., nitroglycerine ointment), and it can be partially avoided by using rectal suppositories. The capillaries in the lower and middle sections of the rectum drain into the interior and middle hemorrhoidal veins, which, in turn, drain into the inferior vena cava, thus bypassing the liver. However, suppositories tend to move upward in the rectum into a region where veins that lead to the liver predominate, such as the superior hemorrhoidal vein. In addition, there are extensive connections between the superior and middle hemorrhoidal veins, and thus probably only about 50% of a rectal dose can be assumed to bypass the liver. The lungs represent a good temporary clearing site for a number of chemicals (especially basic compounds) by partition into lipid tissues, as well as serve a filtering function for particulate matter that may be given by IV injection. In essence, the lung may cause first-pass loss by excretion and possible metabolism for chemicals input into the body by the non-GI routes of administration.

Biological (test subject) factors that can influence absorption of a chemical from the GI tract are summarized in Table 6.4.

There are also a number of chemical factors that may influence absorption from the GI tract. These are summarized in Table 6.5.

6.3.4.4 Techniques of Oral Administration There are three major techniques for oral delivery of drugs to test animals. The most common way is by gavage, which requires that the material be in a solution or suspension for delivery by tube to the stomach. Less common materials may be given as capsules (particularly to dogs) or in diet (for longer-term studies). Rarely, oral studies may also be done by inclusion of materials in drinking water.

Test materials may be administered as solutions or suspensions as long as they are homogeneous and delivery is accurate. For traditional oral administration (gavage), the solution or suspension can be administered with a suitable stomach tube or feeding needle ("Popper" tube) attached to a syringe. If the dose is too large to be administered at one time, it can be divided into equal subparts with 2–4 h between each administration; however, this subdivided dosing approach should generally be avoided.

Test chemicals placed into any natural orifice exert local effects and, in many instances, systemic effects as well. The possibility of systemic effects occurring when local effects are to be evaluated should be considered.

For routes of administration in which the chemical is given orally or placed into an orifice other than the mouth, clear instructions about the correct administration of the chemical must be provided. Many cases are known of oral pediatric drops for ear infections being placed into the ear, and vice versa (eardrops being swallowed) in humans. Errors in test-article administration are especially prevalent when a chemical form is being used in a nontraditional manner (e.g., suppositories that are given by the buccal route).

Administration of drug in a capsule is a common means of dosing larger test animals (particularly dogs). It is labor-intensive (each capsule must be individually prepared, though robotic systems are now available for this), but capsules offer the advantages that neat drug may be used (no special formulation need be prepared, and the questions of formulation or solution stability are avoided), the dogs are less likely to vomit, and the actual act of dosing requires less labor than using a gavage tube. Capsules may also be used with primates, though they are not administered as easily.

Incorporation of a drug in the diet is commonly used for longer-term studies (particularly carcinogenicity studies, though the method is not limited to these). Dosing by diet is much less-labor intensive than any other oral dosing methodology, which is particularly attractive over the course of a long (13-week, 1-year, 18-month, or 2-year) study.

The most critical factor to dietary studies is the proper preparation of the test chemical–diet admixtures. The range of physical and chemical characteristics of test materials requires that appropriate mixing techniques be determined on an individual basis. Standard practices generally dictate the preparation of a premix to which is added appropriate amounts of feed to achieve the proper concentrations.

TABLE 6.4 Test Subject Characteristics That Can Influence GI Tract Absorption^a**A. General and inherent characteristics**

1. General condition of the subject (e.g., starved vs. well fed, ambulatory vs. supine)
2. Presence of concurrent diseases (i.e., diseases may either speed or slow gastric emptying)
3. Age
4. Weight and degree of obesity

B. Physiological function

1. Status of the subject's renal function
2. Status of the subject's hepatic function
3. Status of the subject's cardiovascular system
4. Status of the subject's gastrointestinal motility and function (e.g., ability to swallow)
5. pH of the gastric fluid (e.g., affected by fasting, disease, food intake, and drugs)
6. Gastrointestinal blood flow to the area of absorption
7. Blood flow to areas of absorption for dose forms other than those absorbed through gastrointestinal routes

C. Acquired characteristics

1. Status of the subject's anatomy (e.g., previous surgery)
2. Status of the subject's gastrointestinal flora
3. Timing of drug administration relative to meals (i.e., presence of food in the gastrointestinal tract)
4. Body position of subject (e.g., lying on the side slows gastric emptying)
5. Psychological state of subject (e.g., stress increases gastric emptying rate, and depression decreases rate)
6. Physical exercise of subject may reduce gastric emptying rate

D. Physiological principles

1. Food enhances gastric blood flow, which should theoretically increase the rate of absorption
2. Food slows the rate of gastric emptying, which should theoretically slow the rate of passage to the intestines where the largest amounts of most agents are absorbed. This should decrease the rate of absorption for most agents. Agents absorbed to a larger extent in the stomach will have increased time for absorption in the presence of food and should be absorbed more completely than in fasted patients
3. Bile flow and secretion are stimulated by fats and certain other foods. Bile salts may enhance or delay absorption depending on whether they form insoluble complexes with drugs or enhance the solubility of agents
4. Changes in splanchnic blood flow as a result of food depend on direction and magnitude of the type of food ingested
5. Presence of active (saturable) transport mechanisms places a limit on the amount of a chemical that may be absorbed

^a The minimization of variability due to these factors rests on the selection of an appropriate animal model, careful selection of healthy animals, and use of proper techniques.

Dietary preparation involving liquid materials frequently results in either wet feed in which the test article does not disperse or formation of “gumballs”—feed and test material that form discernible lumps and chemical “hot spots.” Drying and grinding of the premix to a free-flowing form prior to mixing the final diets may be required; however, these actions can affect the chemical nature of the test article.

Solid materials require special techniques prior to or during addition to diets. Materials that are soluble in water may be dissolved and added as described previously for liquids. Nonwater-soluble materials may require several preparatory steps. The test chemical may be dissolved in corn oil, acetone, or other appropriate vehicle prior to addition to the weighed diet. When an organic solvent such as acetone is used, the mixing time for the premix should be sufficient for the solvent

to evaporate. Some solids may require grinding in a mortar and pestle with feed added during the grinding process.

Prior to study initiation, stability of the test chemical in the diet must be determined over a test period at least equivalent to the time period during which animals are to be exposed to a specific diet mix. Stability of test samples under the conditions of the proposed study is preferable. Labor and expense can be saved when long-term stability data permit mixing of several weeks (or a month) of test diet in a single mixing interval.

Homogeneity and concentration analysis of the test-article–diet admixture are performed by sampling at three or four regions within the freshly mixed diet (e.g., samples from the top, middle, and bottom of the mixing bowl or blender).

A variety of feeders are commercially available for rats and mice. These include various-sized glass jars and stainless steel

TABLE 6.5 Chemical Characteristics of a Drug That May Influence Absorption

-
- A. Administration of chemical and its passage through the body
1. Dissolution characteristics of solid dosage forms, which depend on formulation in addition to the properties of the chemical itself (e.g., vehicle may decrease permeability of suspension or capsule to water and retard dissolution and diffusion)
 2. Rate of dissolution in gastrointestinal fluids. Chemicals that are inadequately dissolved in gastric contents may be inadequately absorbed
 3. Chemicals that are absorbed into food may have a delayed absorption
 4. Carrier-transported chemicals are more likely to be absorbed in the small intestine
 5. Route of administration
 6. Chemicals undergo metabolism in the gastrointestinal tract
- B. Physiochemical properties of chemicals
1. Chemicals that chelate metal ions in food may form insoluble complexes and will not be adequately absorbed
 2. pH of dosing solutions—weakly basic solutions are absorbed to a greater degree in the small intestine
 3. Salts used
 4. Hydrates or solvates
 5. Crystal form of chemical (e.g., insulin)
 6. “Pharmaceutical” form (e.g., fluid, solid, suspension)
 7. Enteric coating
 8. Absorption of quaternary compounds (e.g., hexamethonium, amiloride) is decreased by food.
 9. Molecular weight of chemical (e.g., when the molecular weight of a drug is above about 1000, absorption is markedly decreased)
 10. pK_a (dissociation constant)
 11. Lipid solubility (i.e., a hydrophobic property relating to penetration through membranes)
 12. Particle size of chemical in solid dosage form—smaller particle sizes will increase the rate and/or degree of absorption if dissolution of the chemical is the rate-limiting factor in absorption. Chemicals that have a low dissolution rate may be made in a micronized form to increase their rate of dissolution
 13. Particle size of the dispersed phase in an emulsion
 14. Type of disintegrating agent in the formulation
 15. Hardness of a solid (granule, pellet, or tablet) (i.e., related to amount of compression used to make tablet) or capsule if they do not disintegrate appropriately
-

or galvanized feed cups, which can be equipped with restraining lids and food followers to preclude significant losses of feed due to animals digging in the feeders. Slotted metal feeders are designed so that animals cannot climb into the feed, and they also contain mesh food followers to prevent digging.

Another problem sometimes encountered is palatability—the material may taste so strongly that animals will not eat it. As a result, palatability, stability in diet, and homogeneity of mix must all be ensured prior to the initiation of an actual study.

Inclusion in drinking water is rarely used for oral administration of human drugs to test animals, though it sees more frequent use for the study of environmental agents.

Physiochemical properties of the test material should be a major consideration in selecting drinking water as a dosing matrix. Unlike diet preparation or preparation of gavage

dose solutions and suspensions where a variety of solvents and physical processes can be utilized to prepare a dosable form, preparations of drinking water solutions are less flexible. Water solubility of the test chemical is the major governing factor and is dependent on factors such as pH, dissolved salts, and temperature. The animal model itself sets limitations for these factors (acceptability and suitability of pH and salt-adjusted water by the animals as well as animal environmental specifications such as room temperature).

Stability of the test chemical in drinking water under study conditions should be determined prior to study initiation. Consideration should be given to conducting stability tests on test chemical–drinking water admixtures presented to some test animals. Besides the difficulties of inherent stability, changes in chemical concentrations may result from other influences. Chemicals with low-vapor pressure can volatilize

from the water into the air space located above the water of an inverted water bottle; thus, a majority of the chemical may be found in the “dead space,” not in the water.

Certain test chemicals may be degraded by contamination with microorganisms. A primary source of these microorganisms is the oral cavity of rodents. Although rats and mice are not as notorious as the guinea pig in spitting back into water bottles, significant bacteria can pass via the sipper tubes and water flow restraints into the water bottles. Sanitation and sterilization procedures for water bottles and sipper tubes must be carefully attended to.

Many technicians may not be familiar with terms such as sublingual (under the tongue), buccal (between the cheek and gingiva), otic, and so on. A clear description of each of these nontraditional routes (i.e., other than gavage routes) should be discussed with technicians, and instructions may also be written down and given to them. Demonstrations are often useful to illustrate selected techniques of administration (e.g., to use an inhaler or nebulizer). Some chemicals must be placed by technicians into body orifices (e.g., medicated intrauterine devices such as Progestasert).

6.3.5 Minor Routes

The minor routes do see some use in safety assessment and at least three should be briefly presented here.

6.3.5.1 Periocular Route The administration of drugs or accidental exposure of chemicals to the eyes is not commonly a concern in systemic toxicity due to the small surface area exposed and the efficiency of the protective mechanisms (i.e., blink reflex and tears). As long as the epithelium of the eyes remains intact, it is impermeable to many molecules, but, if the toxicant has a suitable polar–nonpolar balance, penetration may occur (Kondrizer et al., 1959; Swan and White, 1942).

Holmstedt (1959) and Brown and Muir (1971) have reviewed periocular absorption of pesticides. More recently, Sinow and Wei (1973) have shown that the quaternary herbicide paraquat can be lethal to rabbits if applied directly to the surface of the eyes. Parathion, in particular, is exceedingly toxic when administered via the eye—a concern that must be kept in mind for the protection of pesticide applicators.

6.3.5.2 Rectal Administration Since a number of therapeutic compounds are given in the form of suppositories, an indication of the toxicity after rectal administration is sometimes required. Toxicity studies and initial drug formulations of such compounds are usually performed by the oral route, and the rectal formulation comes late in development and marketing. In view of the difference between laboratory animals and man in the anatomy and microflora of the colon and rectum, animal toxicity studies

late in drug development are of limited value. However, in a case where there is an indication of potential rectal hazard or bioavailability, the compound may be introduced into the rectum of the rat using an oral dosing needle to prevent tissue damage. To avoid the rapid excretion of the unabsorbed dose, anesthetized animals should be used, and the dose retained with an inert plug or bung (such as a cork).

Drugs (and, therefore, test chemicals) are occasionally administered by rectum, but most are not as well absorbed here as they are from the upper intestine. Aminophylline, used in suppository form for the management of asthma, is one of the few drugs routinely given in this way. Inert vehicles employed for suppository preparations include cocoa butter, glycerinated vehicles, gelatin, and polyethylene glycol. Because the rectal mucosae are irritated by nonisotonic solutions, fluids administered by this route should always be isotonic with plasma (e.g., 0.9% NaCl).

6.3.5.3 Vaginal Administration Though not a common one, some materials do have routine exposure by this route (e.g., spermicides, tampons, douches, and antibiotics) and, therefore, must be evaluated for irritation and toxicity by this route. The older preferred models used rabbits and monkeys (Eckstein et al., 1969), but, more recently, a model that uses rats has been developed (Staab et al., 1987). McConnell (1974) clearly described the limitations, particularly of volume of test material, involved in such tests.

6.3.5.4 Nasal Administration A route that has gained increasing popularity of late for pharmaceutical administration in man is the intranasal route. The reasons for this popularity are the ease of use (and, therefore, ready patient acceptance and high compliance rate), the high degree and rate of absorption of many substances (reportedly for most substances up to 1000 molecular weight; McMartin et al., 1987), and the avoidance of the highly acid environment in the stomach and first-pass metabolism in the liver (particularly important for some of the newer peptide moieties) (Attman and Dittmer, 1971). The only special safety concerns are the potential for irritation of the mucous membrane and the rapid distribution of administered materials to the CNS.

A number of means may be used to administer materials nasally—nebulizers and aerosol pumps being the most attractive first choices. Accurate dose administration requires careful planning, evaluation of the administration device, and attention to technique.

6.3.5.5 Volume Limitations by Route In the strictest sense, absolute limitations on how much of a dosage form may be administered by any particular route are determined by specific aspects of the test species or dosage form. But there are some general guidelines (determined by issues of humane treatment of animals, accurate deliver of dose, and such others) that can be put forth. These are summarized in Table 6.6. Appendix E

TABLE 6.6 Volume Guidelines for Administration of Compounds by Route of Administration to Laboratory Animals

*Single dose per day except where noted, otherwise.

** Solution properties such as tonicity, pH, etc., need to be taken into account when approaching the volume limits or determining the volume to be infused IV. The recommended working range for pH is 4.5–8.0. The order of degree of tolerance of pH for different dosing routes is oral > intravenous > intramuscular > subcutaneous > intraperitoneal. Animal health must also be taken into consideration, such as kidney function and cardiovascular function. These systems must be normal to handle increased fluid volumes.

*** When administering a solution IP, the viscosity, concentration, tonicity, and pH of the solution need to be taken into account.

**** When administering a solution SC, the concentration, tonicity, and pH of the solution must be taken into account.

***** NIA—no information currently available.

^a To accommodate a larger volume, the dose may be divided over time (e.g., 20 mL kg⁻¹ administered four times per day to reach a total of 80 mL kg⁻¹ in a 24 h period).

^b To accommodate a larger volume, the dose may be divided over time (e.g., 10 mL kg⁻¹ administered four times per day to reach a total of 40 mL kg⁻¹ in a 24 h period).

^c Rabbits should not be fed prior to administration. Rabbits should be fed after the completion of dose administration.

^d These volumes may also be used for intra-arterial injection.

^e Not often used.

^f If volumes greater than those cited earlier are used, the volume must be divided over multiple sites.

^g May be used if divided over multiple sites and alternating legs, maximum of five sites per leg. Final volume not to exceed 0.10 mL.

^h 0.05 mL total volume limit per site.

ⁱ 3 mL total volume limit per site.

^j 5 mL total volume limit per site.

^k Up to 20 mL kg⁻¹ if divided over multiple sites.

^l 3 mL total volume limit.

^m Repeat dose 67 µL in the rabbit.

* Solution properties such as tonicity, pH, etc., need to be taken into account when determining the volume that may be infused IV. Animal health must also be taken into consideration, such as kidney function and cardiovascular function. These systems need to be normal to handle increased fluid volumes.

and Section 5.3 should, of course, be checked to see if there is specific guidance due to the characteristics of a particular vehicle. The one **required** regulatory exception to these limits is in the acute systemic toxicity test for extracts derived from medical devices (ISO-10993-11, 2017), where dosing volumes of 50 mL kg⁻¹ are required.

6.3.6 Route Comparisons and Contrasts

The first part of this chapter described, compared, and contrasted the various routes used in toxicology and presented guidelines for their use. There are, however, some exceptions to the general rules that the practicing toxicologist should keep in mind.

The relative ranking of efficacy of routes that was presented earlier in the chapter is not absolute; there can be striking exceptions. For example, though materials are usually much quicker acting and more potent when given by the oral route than by the dermal, this is not always the case. In the literature, Shaffer and West (1960) reported that tetram as an aqueous solution was more toxic when applied dermally than when given orally to rats. LD₅₀s reported were as follows (LD₅₀ (mg kg⁻¹) of tetram; 95% confidence limits):

Rat	Oral (mg kg ⁻¹)	Percutaneous (mg kg ⁻¹)
Male	9 (7–13)	2 (1–3)
Female	8 (6–11)	2 (1–3)

The author has in the past experienced this same phenomenon. Several materials that were found to be relatively nontoxic orally were extremely potent by the dermal route (differences in potency of more than an order of magnitude have been seen at least twice).

A general rule applicable to routes and vehicles should be presented here.

6.3.6.1 Vehicles that Can Mask the Effects of Active Ingredients Particularly for clinical signs, attention should be paid to the fact that a number of vehicles (e.g., propylene glycol) cause transient neurobehavioral effects that may mask similar short-lived (though not necessarily equally transient and reversible) effects of test materials.

6.4 FORMULATION OF TEST MATERIALS

One of the areas that is overlooked by virtually everyone in toxicology testing and research, yet is of crucial importance, is the need for formulation of candidate drugs and the use of vehicles and excipients in the formulation of test chemicals for administration to test animals (Strickley, 2008). For a number of reasons, a drug of interest is rarely administered or applied as is (“neat”). Rather, it must be put in a form that can be accurately given to animals in such a way that it will

be absorbed and not be too irritating. Most laboratory toxicologists come to understand vehicles and formulation, but to the knowledge of the author, guidance on the subject is limited to a short chapter on formulations by Fitzgerald et al. (1983). There is also a very helpful text on veterinary dosage forms by Hardee and Baggot (1998).

Table 6.7 presents an overview of typical forms of excipients for oral dosage forms. The entire process of drug development—even during the preclinical and nonclinical phase—includes a continuous development (with increased sophistication) of formulation. The use of nanoparticles (actually, developed as seeking even finer *micronized* particles in dosing formulations; it has been around for decades) is the latest approach.

Regulatory toxicology in the United States can be said to have arisen, due to the problem of vehicles and formulation, in the late 1930s, when attempts were made to formulate the new drug sulfanilamide. This drug is not very soluble in water, and a US firm called Massengill produced a clear, syrupy elixir formulation that was easy to take orally. The figures illustrate how easy it is to be misled. The drug sulfanilamide is not very soluble in glycerol, which has an LD₅₀ in mice of 31.5 g kg⁻¹, but there are other glycols that have the characteristic sweet taste and a much higher solvent capacity. Ethylene glycol has an LD₅₀ of 13.7 g kg⁻¹ in mice and 8.5 g kg⁻¹ in rats, making it slightly more toxic than diethylene glycol, which has an LD₅₀ in rats of 20.8 g kg⁻¹, similar to that for glycerol. The drug itself, which is inherently toxic, was marketed in a 75% aqueous diethylene glycol-flavored elixir. Then early in 1937 appeared the first reports of deaths, but the situation remained obscure for about 6 months until it became clear that the toxic ingredient in the elixir was the diethylene glycol. Even as late as March 1937, Haag and Ambrose were reporting that the glycol was excreted substantially unchanged in dogs, suggesting that it was likely to be safe (Hagenbusch, 1937). Within a few weeks, Holick (1937) confirmed that a low concentration of diethylene in drinking water was fatal to a number of species. Hagenbusch (1937) found that the results of necropsies performed on patients who had been taking 60–70 mL of the solvent per day were similar to those of rats, rabbits, and dogs taking the same dose of solvent with or without the drug. This clearly implicated the solvent, although some authors considered that the solvent was simply potentiating the toxicity of the drug. Some idea of the magnitude of this disaster may be found in the paper of Calvary and Klump (1939), who reviewed 105 deaths and a further 2560 survivors who were affected to varying degrees, usually with progressive failure of the renal system. It is easy to be wise after the event, but the formulator fell into a classic trap, in that the difference between acute and chronic toxicity had not been adequately considered. In passing, the widespread use of ethylene glycol itself as an antifreeze has led to a number of accidental deaths, which suggests that the lethal dose in man is around 1.4 mL kg⁻¹, or a volume of about 100 mL. In the preface to the first US Pharmacopeia (USP), published in 1820, there is a

TABLE 6.7 Examples of Excipients in Drug Formulation (Other than Vehicles)

statement that “It is the object of the Pharmacopoeia to select from among substances which possess medical power, those, the utility of which is most fully established and best understood; and to form from them preparations and compositions, in which their powers may be exerted to the greatest advantage.” This statement suggests that the influence that formulation and preparation may have on the biological activity of a drug (and on nonpharmaceutical chemicals) has been appreciated for a considerable time.

Available and commonly used vehicles and formulating agents are reviewed, along with basic information on their characteristics and usages, in Appendix E at the end of this book. There is a general presumption that those excipients and formulating agents listed in the Pharmacopoeia or in the *Inactive Ingredient Guide* prepared by the FDA are safe to use and without biological effect. This may not always be the case in either experimental or humans (see Weiner and Bernstein, 1989), either directly or in how they alter absorption of and response to the active ingredient.

There are some basic principles to be observed in developing and preparing test material formulations. These are presented in Table 6.8. A start to all of this should be preformulation–characterization of the chemical, physical, and physical chemistry aspects of the drug molecule

(Neervannan, 2006). Parts of this are identifying the optimal phase of the drug for formulation (Palucki et al., 2010) and useful salts (Stahl and Wermuth, 2011).

6.4.1 Preformulation

While advances in molecular biology and genomics have produced a flood of molecules with vastly improved target receptor specificity, these molecules have frequently turned out to be very difficult to get absorbed and to the desired target tissue site.

Lipinski’s rule of five (RO5) (Lipinski et al., 2001; Lipinski, 2004) predates these recent target advances in specificity, but not the problems. In its original form, the RO5 proposed four guiding principles:

1. No more than five hydrogen bond donors (the total number of nitrogen–hydrogen and oxygen–hydrogen bonds)
2. Not more than 10 hydrogen bond acceptors (all nitrogen or oxygen atoms)
3. A molecular mass less than 500 Da
4. An octanol–water partition coefficient (log *P*) not greater than 5

TABLE 6.8 Basic Principles to Be Observed in Developing and Preparing Test Material Formulations

-
- A. Preparation of the formulation should not involve heating of the test material anywhere near to the point where its chemical or physical characteristics are altered.
- B. If the material is a solid, and it is to be assessed for dermal effects, its shape and particle size should be preserved. If intended for use in man, topical studies should be conducted with the closest possible formulation to that to be used on humans.
- C. Multicomponent test materials (mixtures) should be formulated so that the administered form accurately represents the original mixture (i.e., components should not be selectively suspended or taken into solution).
- D. Formulation should preserve the chemical stability and identity of the test material.
- E. The formulation should be such as to minimize total test volumes. Use just enough solvent or vehicle.
- F. The formulation should be easy to administer accurately.
- G. pH of dosing formulations should be between 5 and 9, if possible.
- H. Acids or bases should not be used to divide the test material (for both humane reasons and to avoid pH partitioning in either the gut or the renal tubule).
- I. If a parental route is to be employed, final solutions should be as nearly isotonic as possible. Do not assume a solution will remain such upon injection into the bloodstream. It is usually a good idea to verify that the drug stays in solution upon injection by placing some drops into plasma.
- J. Particularly if use is to be more than a single injection, steps (such as filtration) should be taken to ensure suitable sterility.
-

While Lipinski *prima facie* applies to oral route drugs, it also is useful for other routes.

For clinically useful drugs (and therefore for drugs proceeding through preclinical and nonclinical evaluation and development), there are a number of desirable attributes:

- A simple structure
- Simple and efficient synthesis
- Nonhygroscopic
- Avoidance of chiral centers
- Lack of mutagenicity
- Crystalline with solid-state stability
- No strong odors, colors, or (of oral) tastes
- Compatible with standard excipient
- Stable at ambient temperatures and at physiologic pH's (Niazi, 2007; Adeyeye and Brittain, 2008; Gibson, 2009)

Bioavailability is defined as the fraction of the dose reaching either the therapeutic target organ or tissue or the systemic circulation as unchanged compound following administration by any route. For an agent administered orally, bioavailability may be less than unity, for several reasons. The molecule may be incompletely absorbed. It may be metabolized in the gut, the gut wall, the portal blood, or the liver prior to entry into the systemic circulation (see Figure 6.3). It may undergo enterohepatic cycling with incomplete reabsorption following elimination into the bile. Biotransformation of some chemicals in the liver following oral administration is an important factor in the pharmacokinetic profile, as will be discussed further. Bioavailability measures following oral administration are generally given as the percentage of the dose available to the systemic circulation.

As the components of a mixture may have various physicochemical characteristics (solubility, vapor pressure, density,

etc.), great care must be taken in preparing and administering any mixture so that what is actually tested is the mixture of interest.

Examples of such procedures are making dilutions (not all components of the mixture may be equally soluble or miscible with the vehicle) and generating either vapors or respirable aerosols (not all the components may have equivalent volatility or surface tension, leading to a test atmosphere that contains only a portion of the components of the mixture).

By increasing or decreasing the viscosity of a formulation, the absorption of a toxicant can be altered (Ritschel et al., 1974). Conversely, the use of absorbents to diminish absorption has been used as an antidote therapy for some forms of intoxication. Using the knowledge that rats cannot vomit, there have been serious attempts at making rodenticides safer to nontarget animals by incorporating emetics into the formulations, but this has had only a limited degree of success. Gaines used *in vivo* liver perfusion techniques to investigate the apparent anomaly that the carbamate Isolan was more toxic when administered to rats percutaneously than when administered orally (Gaines, 1960). It has been shown that these results, a manifestation of different formulations, have been used for the two routes of exposure (oral and percutaneous) in estimating the LD₅₀ values using a common solvent, *n*-octanol. It was found that Isolan was significantly more toxic by the oral route than by the percutaneous route; by regression analysis, it was found that at no level of lethal dose values was the reverse correct.

Although the oral route is the most convenient for most therapeutic uses, there are numerous factors that make it unpredictable, particularly for drug molecules that have very limited water solubility (Liu, 2008). Absorption by this route is subject to significant variation from animal to animal and even in the same individual animal at different times. Considerable effort has been spent by the pharmaceutical

industry to develop drug formulations with absorption characteristics that are both effective and dependable. Protective enteric coatings for pharmaceuticals were introduced long ago to retard the action of gastric fluids and then disintegrate and dissolve after passage of a tablet into the human intestine. The purposes of these coatings for drugs are to protect the active ingredient, which would be degraded in the stomach, to prevent nausea and vomiting caused by local gastric irritation (also a big problem in rodent studies, where over a long time period gastric irritation frequently leads to forestomach hyperplasia), to obtain higher local concentrations of the active ingredient intended to act locally in the intestinal tract, to produce a delayed biological effect, or to deliver the active ingredient to the intestinal tract for optimal absorption there. Such coatings are generally fats, fatty acids, waxes, or other such agents, and all of these intended purposes for drug delivery can readily be made to apply for some toxicity studies. Their major drawback, however, is the marked variability in time for a substance to be passed through the stomach. In humans, this gastric emptying time can range from minutes to as long as 12 h. One would expect the same for animals, as the limited available data suggest is the case. Similar coating systems, including microencapsulation (see Melnick et al., 1987), are available for, and currently used in, animal toxicity studies.

The test chemical is unlikely to be absorbed or excreted unless it is first released from its formulation. It is this stage of the process that is the first and most critical step for the activity of many chemicals. If the formulation does not release the chemical, the rest of the process becomes somewhat pointless.

It might be argued that the simplest way around the formulation problem is to administer any test as a solution in water, thereby avoiding the difficulties altogether. However, since multiple, small, accurately measured doses of a chemical are required repeatedly, reproducible dilutions must be used. Also, the water itself is to be regarded as the formulation vehicle, and the test substance must be water soluble and stable in solution and many are not. If one takes into account this need for accuracy, stability, and optimum performance *in vivo*, the whole problem becomes very complex.

It is uncommon for direct connections between observed toxicity and formulation components to be made. Indeed, it is usually assumed that vehicles and other nontest chemical components are innocuous or have only transitory pharmacological effects. Historically, however, this has certainly not been the case. Even lactose may have marked toxicity in individual test animals (or humans) who are genetically incapable of tolerating it.

The initial stage of drug release from the formulation, both in terms of the amount and the rate of release, may exercise considerable influence at the clinical response level. A close consideration of the formulation parameters of any chemical is therefore essential during the development of any new drug, and, indeed, there are examples where formulations of

established drugs also appear to require additional investigation.

The effects of formulation additives on chemical bioavailability from oral solutions and suspensions have been previously reviewed by Swarbrick (2006). He pointed out how the presence of sugars in a formulation may increase the viscosity of the vehicle. However, sugar solutions alone may delay stomach-emptying time considerably when compared to solutions of the same viscosity prepared with celluloses, which may be due to sugar's effect on osmotic pressure. Sugars of different types may also have an effect on fluid uptake by tissues, and this, in turn, correlates with the effect of sugars such as glucose and mannitol on drug transport.

Surfactants have been explored widely for their effects on drug absorption, in particular using experimental animals (Gibaldi and Feldman, 1970; Gibaldi, 1976). Surfactants alter dissolution rates (of lipid materials), surface areas of particles and droplets, and membrane characteristics, all of which affect absorption.

Surfactants may increase the solubility of the drug via micelle formation, but the amounts of material required to increase solubility significantly are such that at least orally the laxative effects are likely to be unacceptable. The competition between the surfactant micelles and the absorption sites is also likely to reduce any useful effect and make any prediction of net overall effect difficult. However, if a surfactant has any effect at all, it is likely to be in the realm of agents that help disperse suspensions of insoluble materials and make them available for solution. Natural surfactants, in particular bile salts, may enhance absorption of poorly soluble materials.

The effective surface area of an ingested chemical is usually much smaller than the specific surface area that is an idealized *in vitro* measurement. Many drugs whose dissolution characteristics could be improved by particle-size reduction are extremely hydrophobic and may resist wetting by GI fluids. Therefore, the GI fluids may come in intimate contact with only a fraction of the potentially available surface area. The effective surface area of hydrophobic particle can often be increased by the addition of a surfaceactive agent to the formulation, which reduces the contact angle between the solid and the GI fluids, thereby increasing effective surface area and dissolution rate.

Formulations for administering dermally applied toxicants present different considerations and problems. The extent of penetration and speed with which a biologically active substance penetrates the skin or other biological membrane depend on the effect that the three factors—vehicle, membrane, and chemical—exert on the diffusion process. It is now accepted that they together represent a functional unit that controls the penetration and location of the externally applied chemicals in the deeper layers of the skin or membrane layer. The importance of the vehicle for the absorption process has been neglected until recently. One of the few requirements demanded of the vehicle has been that it acts as an inert medium that incorporates the test chemical in the most homogeneous

distribution possible. In addition, chemical stability and good cosmetic appearance have been desirable characteristics. Most formulations in toxicology are based on empirical experience.

The chemical incorporated in a vehicle should reach the surface of the skin at a suitable rate and concentration. If the site of action lies in the deeper layers of the epidermis or below, the substance must cross the stratum corneum, if the skin is intact. Both processes, diffusion from the dosage form and diffusion through the skin barriers, are inextricably linked. They should be considered simultaneously and can be influenced by the choice of formulation.

The thesis that all lipid-soluble compounds basically penetrate faster than water-soluble ones cannot be supported in this absolute form. A lipophilic agent can penetrate faster or slower or at the same rate as a hydrophilic agent, depending on the vehicle used.

Disregarding such chemical-specific properties as dissociation constants (in the case of ionic compounds), particle size, and polymorphism, as well as side effects of viscosity, binding to vehicle components, complex formulation, and the like, the following formulation principles arise:

- Optimization of the concentration of chemical capable of diffusion by testing its maximum solubility
- Reduction of the proportion of solvent to a degree that is adequate to keep the test material still in solution
- Use of vehicle components that reduce the permeability barriers

These principles lead to the conclusion that each test substance requires an individual formulation. Sometimes different ingredients will be required for different concentrations to obtain the maximum rate of release. No universal vehicle is available for any route, but a number of primary approaches are. Any dosage preparation lab should be equipped with glassware, a stirring hot plate, a sonicator, a good homogenizer, and a stock of the basic formulating material, as detailed at the end of this chapter.

6.4.2 Dermal Formulations

Preparing formulations for application to the skin has special considerations associated with it, which, in the case of human pharmaceuticals, has even led to a separate book (Barry, 1983).

The physical state of the skin is considerably affected by external factors such as relative humidity, temperature, and air movement at the skin surface. If this contact is broken (e.g., by external applications of ointments or creams), it is reasonable to assume that the new skin will change in some way, sometimes to an extent that creates new conditions of permeability for the test material. This would be the case, for example, if the stratum corneum becomes more hydrated than normal due to the topical delivery form. Temperature might also have an

effect, as is the case when any constituents of the vehicle affect the inner structure of the skin through interactions with endogenous skin substances. Often, several of these processes occur together. Figure 6.4 shows the relationship between water content (%) and relative humidity (%).

Since this is a question of interactions between the vehicle and the skin (and the latter cannot be viewed as an inert medium), the composition of the vehicle itself may be altered (e.g., by incorporation into skin constituents or through loss of volatile components).

The first contact between vehicle and skin occurs on the skin's surface. The first phase of interaction undoubtedly begins with the lipid mantle, in the case of so-called "normal skin." If the skin has been damaged by wounds, the surface can form a moist milieu of serous exudate, resulting in abnormal wetting properties. Normally, it is impregnated with oily sebaceous secretions and horny fat, presenting a hydrophobic surface layer. Water will not spread out as a film but will form droplets, while bases with a high affinity to the skin surface constituents spread spontaneously into a film and can wet. In the case of a base of a low viscosity, the degree of wetting can often be determined by measuring the angle of contact. If the preparation that wets the skin surface is drawn by capillary action from the visible area into the large inner surface of the stratum corneum, and is transported away into the interior, then it is said that the ointment or cream penetrates well. Spreading and wetting are purely surface phenomena, not penetration in the strict sense. If the skin shows a high content of its own lipids, spreading is limited. It is also reduced if the value of the surface tension of the skin (σ_s) decreases compared to the value of the interfacial force between the skin and subject liquid ($\gamma_{s/l}$) and the surface tension of the subject liquid (σ_l), as is the case with aqueous bases. Addition of amphiphilic compounds decreases σ_l and $\gamma_{s/l}$ and thus spreadability increases.

How much the endogenous emulsifying substances of the fatty film, such as cholesterol esters and fatty acid salts, affect

FIGURE 6.4 Course of moisture absorption of skin.

this spreading process is not clear. They can probably promote the emulsification of hydrophobic substances with water. Whether the sebaceous and epidermal lipids alone are sufficient to emulsify water and so form a type of emulsive film remains controversial. However, it is assumed that they, together with appropriate vehicle components, improve the spreading of the applied vehicle and that this effect can be potentiated by mechanical means such as intensive rubbing in. A good spreadability ensures that the active ingredient is distributed over a large area.

High-local concentrations are avoided, and, at the same time, close contact is made between the chemical and the upper layers of the skin.

In grossly simplified terms, hydrogels, suspensions, and water emulsions behave on the skin surface similarly to aqueous solutions. By contrast, pastes and water–oil emulsions act like oil. The ability of an organic solvent to stick or wet depends on its specific properties (e.g., its viscosity and its surface tension).

At present, the information concerning alterations in vehicle composition on the skin surface is sparse. However, two possible extremes are conceivable. On the one hand, if the vehicle has a high-vapor pressure, it often completely evaporates shortly after application. On the other hand, the vehicle may remain on the skin surface in an almost completely unchanged composition, (e.g., highly viscous vaseline or similar thick covering systems). Between these two extremes lie the remaining types of vehicles.

The first situation applies for the short-chain alcohols, acetone, or ether. After their evaporation, the drug remains finely dispersed on or in the skin at 100% concentration.

If individual components evaporate, the structure of the vehicle changes, and, under certain circumstances, also the effective drug concentration. Oil–water emulsions lose water rapidly, giving rise to the well-known cooling effect. If evaporation continues, the dispersed oil phase coalesces and forms a more or less occlusive film on the skin, together with the emulsifier and the drug. Of course, it is possible that a certain hydrophilic proportion of the drug is then present in suspended form or at least can react with charged molecules and is thus removed from the diffusion process at the start; at the same time, it is to be expected that soluble constituents of the skin are incorporated so that a new system can be formed on the surface and the adjoining layers of skin. Comparable transformations probably also occur after application of water–oil emulsions, provided that one realizes that the water evaporates more slowly, the cooling effect is less strong, and, due to the water–oil character of the molecule, the occlusive effect can be more marked because of the affinity of the oily components for the skin.

By contrast, vaseline and similar highly viscous, lipid bases from the outset form an impenetrable layer, virtually unaffected by external factors or effects emanating from the skin itself. Interactions with the skin lipids are only likely at the boundary between ointment and skin.

The evaporation of the water from the skin into the atmosphere is a continuous process. It can be increased or decreased by the use of suitable vehicles. An evaporation increase will always occur if the water vapor from the vehicle is taken away more quickly than water can diffuse from the deeper layers into the stratum corneum. This applies in principle to all hydrophilic bases, particularly for systems with an oil–water character. After loss of most of their own water, hydrophilic bases develop a true draining effect that can lead to the drying out of the underlying tissue. How much the penetration of hydrophilic drugs can be proved with the help of oil–water systems depends on the solution properties of the rest of the components in the skin. Generally, such compounds can only seldom reach deeper layers. It is equally difficult to show an adequate release of water from hydrophilic systems to a dry skin. If any such effects do occur, they are short term and are quickly overtaken by the opposing processes. The same seems to apply to most of the traditional moisturizers such as glycerin and propylene glycol (Powers and Fox, 1957; Rieger and Deems, 1974). They can also cause a large rise in the rate of evaporation, depending on the relative humidity, and thus increase the transepidermal loss of water. It is probably impossible to prevent this drying out without preparations having some occlusive properties.

In contrast, vehicles that are immiscible with water and those with a high proportion of oils have occlusive effects. They reduce both insensible perspiration and the release of sweat. The sweat collects as droplets at the opening of the glands but does not spread as a film between the hydrophobic skin surface and the lipophilic base because the free surface energy of the vehicle–skin interface is smaller than that between water and skin. If a lipophilic layer of vehicle is present, this is not spontaneously replaced by the water–skin layer if sweat is secreted.

The horny layer consists of about 10% extracellular components such as lipids, proteins, and mucopolysaccharides. Around 5% of the protein and lipids form the cell wall. The majority of the remainder is present in the highly organized cell contents, predominantly as keratin fibers, which are generally assigned an α -helical structure. They are embedded in a sulfur-rich amorphous matrix, enclosed by lipids that probably lie perpendicular to the protein axis. Since the stratum corneum is able to take up considerably more water than the amount that corresponds to its volume, it is assumed that this absorbed fluid volume is mainly located in the region of these keratin structures.

Some insight into where on the relative humidity continuum water molecules are absorbed can be gained from equilibrium isotherms (Ziegenmeyer, 1982) (Figure 6.4), which show a characteristic sigmoidal shape. At low-relative humidity, water is first absorbed at specific skin sites, probably in the region of the peptide compounds and the various polar side chains. At higher moisture content, layers of water form on the skin. By using Zimm–Lundberg cluster theory

(Zimm and Lundberg, 1956), additional information can be obtained about the nature of the absorbed water.

Because of thick intertwining protein fibers in the cell and in the area of the cell membrane, cell structure is rigid and remains so but is altered by the osmotic effect of the penetrating water. The uptake of water entails a continual shifting of the cell matrix, which gradually develops elastic opposing forces that increasingly resist further expansion. Eventually, an equilibrium is reached if both forces balance each other. In the case of water, it takes quite a long time to completely hydrate the cell. This process can, however, be shortened if there are components present with a solvent effect diffusing out of a basic vehicle. The duration and degree of swelling depend on the affinity of all the dissolved substances for the tissue and on the size of the maximum possible elastic reaction, which stabilizes cell structure.

6.4.3 Interactions Between Skin, Vehicle, and Test Chemical

The diffusion coefficient of the hydrated stratum corneum is larger than that of dry skin. Therefore, hydration increases the rate of passage of all substances that penetrate the skin. If the hydrated keratin complex is represented by a biphasic system, then it can be considered to exist as a continuous region covered with layers of water and intervening layers of lipids. Nonpolar compounds are predominantly dissolved in the nonpolar lipid matrix and diffuse through it. Polar substances, by contrast, pass through the aqueous layers. The diffusion of water and low molecular weight hydrophilic molecules through these layers of water is more difficult than a corresponding free diffusion in an aqueous solution. This could, under certain circumstances, be due to a higher degree of organization of water in the protein structures (than in plasma or the free state), in the sense that this water is only available as the driving force of the diffusion process to a limited degree.

The degree of hydration can be controlled by the choice of vehicle. Lipophilic paraffin bases are available, but vehicles such as water–oil emulsions are more acceptable since they are less occlusive and offer ease of formulation.

In principle, temperature can also have an effect on penetration, which may be exerted on the basic vehicle if it contains temperature-sensitive components (e.g., nonionic entities or thermotherapeutic agents; Groves, 1966). Room and body temperatures can be enough to change the hydrophilic–lipophilic balance and thus possibly change the entire system. It has long been known that increasing temperature can considerably reduce diffusional resistance and thereby increase the rate of penetration of substances. In practice, however, this effect is of no importance. Of course, skin temperature will be increased a few degrees by occlusion because of the prevention of sweating and restriction of heat radiation. However, compared to the increase in penetration

achieved by the simultaneous hydration process, this effect is insignificant.

Additives aimed at accelerating penetration always attempt to enable diffusion of pharmacologically active compounds into or through the stratum corneum without damaging it and without causing undesirable systemic effects. Although attempts have been made to limit these effects, this goal has not been achieved yet. There are numerous substances that decrease the diffusional resistance of the skin, such as propylene glycol, tensides, parotid substances such as urea, dimethyl sulfoxide (DMSO), dimethylformamide (DMF), and various other organic solvents, mostly of medium chain length. They all improve the penetration of dissolved agents, but only at the cost of the integrity of skin structure, raising the question of the degree of damage and reversibility.

If the substances have passed the stratum corneum, they also generally diffuse into the living part of the epidermis, reach the circulation, and then have systemic effects depending on the amount absorbed. Because these are often constituents of formulations, one generally expects them to have little direct influence on skin penetration. However, their amphiphilic properties allow them to form new systems with the body's constituents and even to change the physical state of water in the skin. By this means, a pathway is cleared for other hydrophilic substances to gain entry into the general circulation.

Most of a permeability enhancer (such as tenside) is bound to the stratum corneum. It is assumed that the underlying mechanism of the process involves interactions with keratin structures. Positively and negatively charged ionic groups of proteins have been suggested as the binding sites for ionic substances. Ion pairs can also form. On the other hand, hydrophobic areas are present that can bind with the uncharged part of the enhancers. The total free binding energy of molecules to keratin is made up of the contributions arising from electrostatic and nonpolar interactions. Nonpolar interactions increase with chain length of the molecule. This would be the reason why predominantly anionic molecules of medium chain length exert stronger effects on the keratin structure than those of shorter chain length (Dominguez et al., 1977).

In order to reach the interior of the tightly enmeshed keratin, the molecule must overcome the elastic energy of the polypeptide matrix. The energy necessary to do this is proportional to the volume of the penetrating molecule. The larger the volume, the more difficult it will be for the molecule to approach the various binding sites of proteins in the interior of the keratin complex. Thus, the size of the penetrating molecule is subject to certain limitations. If more molecules are present than can become bound, it is possible that a few of them will reach the living layers of the epidermis, as has been described for several anionic, mostly medium-chain enhancer molecules such as tensides. It remains unclear whether this is a consequence of pure saturation or if other interactions are

involved (e.g., with structural lipids or hydrophilic materials from the intercellular lipids).

The extent to which the vehicle can affect the entire diffusion process can be shown by an example. In a four-component system of 40% oil, 40% water, and 20% of an emulsifying agent and coemulsifier, alteration of only the proportion of emulsifier to coemulsifier leads to systems of completely different colloidal–chemical structures, which can be labeled as either creams, gels, or microemulsions.

Dermal administration presents fewer logistic difficulties than oral administration. Liquids can be administered as supplied, and powders or solids can be moistened with saline to form a thick paste or slurry or can be applied dry and moistened with saline. Solid materials (sheets or plastic, fabric, etc.) can also be administered dermally. Liquid materials or slurries are applied directly to the skin, taking care to spread the material evenly over the entire area or as much of the area as can reasonably be covered and then covering with a strip of gauze. If a large amount of material is being administered and the abdominal skin will be exposed, it is sometimes necessary to apply material to the gauze and to the skin. Dry materials are weighed out, then placed on the gauze strip, and moistened with physiological saline (generally 15 mL) so that they will adhere to the gauze. The gauze is then wrapped around the animal. This porous gauze dressing is then held in place by an additional wrapping, generally of an impervious material, to create an “occlusive” covering. This occlusion enhances penetration and prevents ingestion or evaporation of the test material.

Another recently developed approach is the use of plastic containment capsules (modified Hilltop Chambers) for administration of well-measured doses in a moisturized microenvironment (Derelanko et al., 1987).

Finally, it should be noted that for some agents (contrary to the general rule), decreasing the concentration of chemical in a vehicle may increase its apparent intrinsic toxicity.

6.4.4 Oral Formulations

The physical form of a material destined for oral administration often presents unique challenges. Liquids can be administered as supplied or diluted with an appropriate vehicle, and powders or particulates can often be dissolved or suspended in an appropriate vehicle. However, selection of an appropriate vehicle is often difficult. Water and oil (such as the vegetable oils) are used most commonly. Materials that are not readily soluble in either water or oil can frequently be suspended in a 1% aqueous mixture of methylcellulose. Occasionally, a more concentrated methylcellulose suspension (up to 5%) may be necessary. Materials for which appropriate solutions or suspensions cannot be prepared using one of these three vehicles often present major difficulties.

Limited solubility or suspendability of a material often dictates preparation of dilute mixtures that may require large volumes to be administered. The total volume of liquid dosing solution or suspension that can be administered to a rodent is limited by the size of its stomach. However, because rats lack a gagging reflex and have no emetic mechanism, any material administered will be retained. Guidelines for maximum amounts to be administered are given in Table 6.6.

Limitations on total volume, therefore, present difficulties for materials that cannot easily be dissolved or suspended. The most dilute solutions that can be administered for a limit-type test (5000 mg kg⁻¹), using the maximum volumes shown in Table 6.6, generally are 1% for aqueous mixtures and 50% for other vehicles.

Although vehicle control animals are not required for commonly used vehicles (e.g., water, oil, methylcellulose), most regulations require that the biological properties of a vehicle be known and/or that historical data be available. Unfortunately, the best solvents are generally toxic and, thus, cannot be used as vehicles. Ethanol and acetone can be tolerated in relatively high doses but produce effects that may complicate interpretation of toxicity associated with the test material alone. It is sometimes possible to dissolve a material in a small amount of one of these vehicles and then dilute the solution in water or in oil.

Gels and resins often present problems because of their viscosity at room temperature. Warming these materials in a water bath to a temperature of up to 50°C will frequently facilitate mixing and dosing. However, it is important to ascertain that no thermal degradation occurs and that administered formulations be at or near body temperature.

Other possibilities for insoluble materials are to mix the desired amount of material with a small amount of the animal's diet or to use capsules. The difficulty with the diet approach is the likelihood that the animal will not consume all the treated diet or that it may selectively not consume chunks of test material. Use of capsules, meanwhile, is labor-intensive. In rare cases, if all of these approaches fail, it may not be possible to test a material by oral administration. In capsules, particle size is generally inversely related to solubility and bioavailability. However, milling of solids may adversely affect their chemical nature and/or pose issues of safety.

If necessary, the test substance should be dissolved or suspended as a suitable vehicle, preferably in water, saline, or an aqueous suspension such as 0.5% methylcellulose in water. If a test substance cannot be dissolved or suspended in an aqueous medium to form a homogeneous dosage preparation, corn oil, or another solvent can be used. The animals in the vehicle control group should receive the same volume of vehicle given to animals in the highest-dose group.

The test substance can be administered to animals at a constant concentration across all dose levels (i.e., varying the dose volume) or at a constant dose volume (i.e., varying the

dose concentration). However, the investigator should be aware that the toxicity observed by administration in a constant concentration may be different from that observed when given in a constant dose volume. For instance, when a large volume of corn oil is given orally, GI motility is increased, causing diarrhea and decreasing the time available for absorption of the test substance in the GI tract. This situation is particularly true when a highly lipid-soluble chemical is tested.

If an organic solvent is used to dissolve the chemical, water should be added to reduce the dehydrating effect of the solvent within the gut lumen. The volume of water or solvent–water mixture used to dissolve the chemical should be kept low, since excess quantities may distend the stomach and cause rapid gastric emptying. In addition, large volumes of water may carry the chemical through membrane pores and increase the rate of absorption. Thus, if dose-dependent absorption is suspected, it is important that the different doses are given in the same volume of solution.

Large volumes than those detailed earlier may be given, although nonlinear kinetics seen under such circumstances may be due to solvent-induced alteration of intestinal function. The use of water-immiscible solvents such as corn oil (which are sometimes used for gavage doses) should be avoided, since it is possible that mobilization from the vehicle may be rate limiting. Magnetic stirring bars or homogenizers can be used in preparing suspensions. Sometimes a small amount of a surfactant such as Tween 80, Span 20, or Span 60 is helpful in obtaining a homogeneous suspension.

A large fraction of such a material may quickly pass through the GI tract and remain unabsorbed. Local irritation by a test substance generally decreases when the material is diluted. If the objective of the study is to establish systemic toxicity, the test substance should be administered in a constant volume to minimize GI irritation that may, in turn, affect its absorption. If, however, the objective is to assess the irritation potential of the test substance, then it should be administered undiluted.

6.4.5 Parenteral Formulations

Parenteral dose forms include aqueous, organic, and oily solutions, emulsions, suspensions, and solid forms for implantation. These parenterals need to be sterile and pyrogen-free. Additionally, they are, if possible, buffered as close to normal physiological pH and preferably are isotonic with the body fluids.

The preparation of parenteral dosage forms of approved and potential drugs for animals is the same as for humans. Turco and King (1974) provide a comprehensive review of the subject, which were written with human therapeutics in mind and contains very little that is not applicable to animals. Sterility, lack of pyrogenicity, blood compatibility, and low to no irritation at the point of injection are biological require-

ments; there are also a corresponding set of physicochemical requirements.

Parenteral products are usually given to humans when an immediate effect is needed, when a patient is unable to accept medication by the oral route, or when the drug will be ineffective by the oral route. These conditions apply to animals used in safety evaluation.

Parenteral products can be easily administered to confined or restrained animals, leaving no doubt that the animal received its medication.

To be acceptable, an SC or IM formulation should cause only a minimum amount of irritation and no permanent damage to the tissues and be systemically distributed and active when administered by this route. The ideal parenteral product is an aqueous solution isotonic with the body fluids with a pH between 7 and 8. When the drug lacks sufficient aqueous solubility, a suspension may be considered; however, in most cases, the bioavailability of the drug may be affected and encapsulation by the body at the site of injection is extremely likely. The solubility of the drug in water may be improved by the addition of cosolvents such as alcohol, propylene glycol, polyethylene glycol, dimethylacetamide, DMSO, or DMF. The resulting solution must have additional tolerance for water so that the drug will not precipitate at the site of injection when the solution is diluted by body fluids. If precipitation occurs at the site of injection, the absorption of the drug may be delayed or even completely inhibited.

Water-miscible solvents alone can be used when the drug is chemically unstable in the presence of any water. The number of solvents available for this purpose is extremely limited. The classic review of this subject was made in 1963 (Stiegeland and Noseworthy, 1963), and some 30 years later, no additional solvents are available. This is unlikely to change in the near future due to the extensive effort necessary to determine the safety of a solvent used as a vehicle. When a nonaqueous vehicle is used, one can invariably expect some degree of pain upon injection, and subsequent tissue destruction is possible. This damage may be due in part at least to the heat of solution as vehicle mixes with body fluids; it may be associated with tissues rejecting the solvent; or it may be an inherent property of the solvent.

Fixed oils of vegetable origin and their esters may be used as parenteral vehicles for some drugs, particularly steroidal hormones. While an oleaginous vehicle may delay or impair absorption of the drug, this characteristic has been used to advantage with some drugs where a small dose is desired over a long period of time. The formulator must know which species will receive the formulation and the type of equipment used in its administration. A product intended for a dog or a primate is usually given to a single animal at a time. Conventional glass or disposable syringes will be used with a 20- or 22-gauge needle, which may impede the flow of the liquid, especially when an oleaginous vehicle is used.

Impedance is usually compensated for by using small animals, since the volume of injection is small and no more than one injection is normally given at one time.

The viscosity of the solution will influence its acceptability when automatic injection equipment is used. If many animals are injected at one time, a viscous solution that requires a great deal of force to eject will rapidly tire the user. When the automatic injector is refilled from a reservoir, a viscous solution will be slow to fill the volumetric chamber. The subjective aspect of measuring the ease of expelling a dose can be eliminated by constructing an apparatus that will measure the pressure needed to expel a dose. An objective means of measuring ease will allow the formulator to vary the composition of the injection and measure any improvement in injectability. For example, the addition of a wetting agent can be investigated, and, if improvement is seen, the level of use can be optimized.

A parenteral product in a multidose vial must contain a preservative to protect the contents of the vial against contamination during repeated withdrawal of dose aliquots.

6.5 DOSING CALCULATIONS

One of the first things a new technician (or graduate student) must learn is how to calculate dose. Generally, administered doses in systemic toxicity studies are based on the body weight of the animal (expressed as either weight or volume—for liquids—of the test substance per kilogram of body weight of the animal), although some would maintain that surface area may be a more appropriate basis on which to gauge individual dose. The weight (or dose) of the test substance is often expressed in milligrams or grams of active ingredient if the test substance is not pure (i.e., if it is not 100% active ingredient).

Ideally, only the 100% pure sample should be tested; however, impurity-free samples are difficult to obtain, and preparation of formulations (as previously discussed) is frequently essential. The toxicity of impurities or formulation components should be examined separately if the investigator feels that they may contribute significantly to the toxicity of the test substance.

If the test substance contains only 75% active ingredient and the investigator chooses a constant dose volume of 10 mL kg⁻¹ bw across all dose levels, it will be more convenient to prepare a stock solution such that when 10 mL kg⁻¹ of this stock solution is given to the animal, the dose will be the desired one (say, 500 mg kg⁻¹ of active ingredient). The concentration of this stock solution would be (500 mg 10 mL⁻¹)/0.75 = 66.7 mg of the test substance per milliliter of diluent.

Aliquots of the test substance for other dose levels can then be prepared by dilution of the stock solution. For example, the solution concentration for a 250 mg kg⁻¹ dose level is

(200 mg 10 mL⁻¹)/0.75 = 26.7 mg of the test substance per milliliter of diluent.

This solution can be prepared by diluting the stock solution 25 times; that is, for each mL of the 26.7 mg mL⁻¹ solution to be prepared:

$$\frac{(26.7 \text{ mg mL}^{-1})}{66.7 \text{ mg mL}^{-1}} = 0.400 \text{ mL of the stock solution}$$

This amount should be diluted to a final volume of 1 mL with the vehicle.

The other way to express a relative dose in animals or humans is to do so in terms of body surface area. There are many reasons for believing that the surface area approach is more accurate for relating doses between species (Schmidt-Nielsen, 1984)—and especially between test animals and humans—but this is still a less common approach in safety assessment, although it is the currently accepted norm in a couple of areas—carcinogenesis and chemotherapy, for example.

6.6 CALCULATING MATERIAL REQUIREMENTS

One of the essential basic skills for the efficient design and conduct of safety assessment studies is to be able to accurately project compound requirements for the conduct of a study. In theory, this simply requires plugging numbers into a formula such as

$$(A \times B \times C \times D) 1.1 = \text{total compound requirement}$$

where

A = number of animals in each study group

B = the sum of doses of the dose groups (such as 0.1 + 0.3 + 1.0 mg kg⁻¹ = 1.4 mg kg⁻¹)

C = the number of doses to be delivered (usually the length of the study in days)

D = the average body weight per animal (assuming dosing is done on a per body weight basis)

1.1 = a safety factor (in effect, 10%) to allow for spillage, wall loss on glassware and containers, and computation errors.

As an example of this approach, consider a study that calls for 10 dogs/sex/group (*A* = 10 × 2 = 20) to receive 0, 10, 50, or 150 mg kg⁻¹ day⁻¹ (*B* = 10 + 50 + 150 = 210 mg kg⁻¹) for 30 days (*C* = 30). On average, the dogs of the age range used weigh 10 kg (*D* = 10 kg). Our compound need is then (20 × 210 mg kg⁻¹ × 30 × 10 kg) 1.1 = 1.386 kg.

The real-life situation is a bit more complicated, since animal weights change over time, diet studies have doses dependent on daily diet consumption, the material may be a salt, but dosage should be calculated on the basis of the parent compound, and not all animals may be carried through the entire study.

TABLE 6.9 Standardized Total Compound Requirements for Rodent Diet Studies^{a,b}

Length of Study (Days)	Total Compound Requirement (g) per Dose (mg kg ⁻¹ day ⁻¹)					
	1	3	10	30	100	300
Rat^c						
2 weeks	0.2	0.4	1.2	4	10.6	32
4 weeks	0.43	0.7	2.5	7.5	25	75
13 weeks	0.8	2.6	8.5	25.5	85	260
52 weeks	7	21	70	210	0.7 ^d	2.1 ^d
2 years	15	45	150	450	1.5 ^d	4.5 ^d
Mouse						
2 weeks	0.03	0.06	0.22	0.65	2.2	6.4
4 weeks	0.08	0.14	0.8	1.4	8	14
13 weeks	0.14	0.42	1.4	4.2	14	42
18 months	0.85	2.5	8.5	25	85	250

^a Based on 10 animals per sex per group for the length of the study that are 6–8 weeks old at study initiation. Animals are weighed to determine body weights.

^b See Katdare and Chaubal (2006).

^c Sprague–Dawley rats (body weights and compound requirements for Fischers would be less).

^d In kilograms.

For rats and mice (where weight change is most dramatic and diet studies most common), Table 6.9 presents some reliable planning values for compound requirements during diet studies.

6.7 EXCIPIENTS

Excipients are usually thought of as being inert substances (such as gum arabic and starch) that form the vehicle or bulk of the dosage form of a drug. They are, of course, both much more complicated than this and not necessarily inert. A better definition would be that of the USP and National Formulary (USP, 2014), which defined excipients as any component, other than the active substances (i.e., drug substances or DS) intentionally added to the formulation of a dosage form. These substances serve a wide variety of purposes: enhancing stability, adding bulking, increasing and/or controlling absorption, providing or masking flavor, coloring, and serving as a lubricant in the manufacturing process. They are, in fact, essential for the production and delivery of marketed DP. As will soon be made clear, they are regulated both directly and as part of the DP. For the pharmaceutical manufacturers, the use of established and accepted excipients (such as can be found

in Smolinske (1992) or APA (1994)—though these lists are not complete) is much preferred. However, both pharmaceutical manufacturers and the companies which supply excipients must from time to time utilize (and therefore develop, evaluate for safety, and get approved) new excipients.

In the last 10 years, the use of nanosuspensions as components of formulations has presented a new set of opportunities—and potential problems (Rabinow, 2004).

While for the purpose of nonclinical formulation, our concerns are generally limited to vehicles, their formulation components can be important. Table 6.7 lists examples of this.

6.7.1 Regulation of Excipients

Table 6.10 lists the relevant sections of CFR 21 which govern excipients. Under Section 201(g)(1) of the Federal Food, Drug, and Cosmetic Act (FD&C Act; 1), the term *drug* is defined as follows:

(A) articles recognized in the official *United States Pharmacopeia*, official *Homeopathic Pharmacopeia of the United States*, or official *National Formulary*, or any supplement to any of them; and (B) Articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals; and (C) Articles (other than food) intended to affect the structure of any function of the body of man or other animals; and (D) Articles intended for use as a component of any articles specified in clause (A), (B), or (C).

An excipient meets the definitions as listed in (A) and (D) above.

In 21 CFR § 210.3(b)(8)(2), an “inactive ingredient means any component other than an active ingredient.” According to the CFR, the term “inactive ingredient” includes materials in addition to excipients. 21 CFR § 201.117 states the following:

Inactive ingredients: A harmless drug that is ordinarily used as an inactive ingredient, such as a coloring, emulsifier, excipient, flavoring, lubricant, preservative, or solvent in the preparation of other drugs shall be exempt from Section 502(f)(1) of the Act. This exemption shall not apply to any substance intended for a use which results in the preparation of a new drug, unless an approved new-drug application provides for such use.

Excipients also meet the definition of component in the Good Manufacturing Practice (GMP) regulations in 21 CFR § 210.3(b)(3): “Component means any ingredient intended for use in the manufacture of a drug product, including those that may not appear in such drug product.”

The *NF Admissions Policy* in the *USP 30/National Formulary 25* defines the word *excipient* (3): “An excipient is any component other than the active substance(s), intentionally

	21 CFR § 201.22	Prescription drugs containing sulfites; required warning statements

added to the formulation of a dosage form. It is not defined as an inert commodity or an inert component of a dosage form.”

Similar to all other drugs, excipients must comply with the adulteration and misbranding provisions of the FD&C Act. Under Section 501(a), an excipient shall be deemed to be adulterated if it consists in whole or in part of any filthy, putrid, or decomposed substance, or if it has been prepared, packed, or held under unsanitary conditions whereby it may have been contaminated with filth, or whereby it may have been rendered injurious to health. An excipient is adulterated if the methods used in or the facilities or controls used for its

manufacture, processing, packing, or holding do not conform to or are not operated or administered in conformity with current GMP to assure that such drug meets the requirements of the act as to safety and has the identity and strength and meets the quality and purity characteristics which it purports or is represented to possess. In addition, under Section 501(b), an excipient shall be deemed to be adulterated if it purports to be or is represented as a drug the name of which is recognized in an official compendium, and its strength differs from, or its quality or purity falls below, the standards set forth in such compendium.

In 2005, the US FDA promulgated new guidance on the selection and use of excipients in nonclinical and clinical studies. US FDA compliance officials require the use of inactive ingredients that meet compendial standards when standards exist and either have previous use in US FDA approved pharmaceuticals or that they be qualified as “novel” excipients (with studies as summarized in Table 6.11) (FDA, 2005). The FDA/CDER maintains an Inactive Ingredient Committee whose charter includes the evaluation of the safety of inactive ingredients on an as-needed basis, preparation of recommendations concerning the types of data needed for excipients to be declared safe for inclusion in a drug product, and other related functions.

From a regulatory standpoint, the FDA’s concern regarding safety involves the toxicity, degradants, and impurities of

excipients, as discussed in other chapters in this book. In addition, other chapters of this book address types of toxicity concerns, toxicity testing strategies, and exposure and risk assessment of excipients.

Excipients must be safe for their intended use. Under 21 CFR § 330.1(e), over the counter (OTC) human drugs that are generally recognized as safe and effective and not misbranded may only contain inactive ingredients if they are suitable and if the amounts administered are safe and do not interfere with the effectiveness of the drug or with required tests or assays. Color additives may be used in accordance with the provisions of the FD&C Act and the regulations of 21 CFR Parts 70–82. The FDA proposed that to make it clear that, to be considered as suitable within the meaning of 21 CFR § 330.1(e), each inactive ingredient in an OTC human drug product should

TABLE 6.11 Summary of Toxicological Studies Recommended for New Pharmaceutical Excipients Based on Route of Exposure

perform a specific function (5). The proposed regulation defined *safe and suitable* to mean that the inactive ingredient meets various conditions as mentioned in the foregoing. OTC drug manufacturers are responsible for assuring that these conditions are met. There is no formal approval mechanism.

In the United States, the safety and suitability of excipients used in new drugs are considered as part of the New Drug Application (NDA) process. There is no separate and independent review and approval system for excipients. There are no specific regulations or guidelines that specify the requirements needed to gain approval of a new drug that contains a new excipient. Generally, pharmaceutical companies choose excipients that previously have been approved for commercial use in other NDAs. The FDA's *Inactive Ingredient Guide* (6), discussed later in this chapter, contains a listing of inactive ingredients present in approved drug products. There is currently no way of gaining a listing for an excipient in the guide independent of the NDA route. The FDA reviews the status of an excipient in food as information to support its use in drug products. Factors relative to the use of an excipient, such as dosing regimen and route of administration, are also reviewed. Advances in excipient technology and drug dosage from technology have created a need for a separate regulatory approval process for new excipients. The *USP* published IPEC's Excipient Safety Evaluation Guidelines as Information Chapter 1074, Excipient Biological Safety Evaluation Guideline.

Information on existing or new excipients can be described and provided to the FDA in an NDA directly. Alternatively, the manufacturers of excipients may prepare and submit type IV Drug Master Files (DMF) to support the use of an excipient in one or more NDAs. The DMFs are discussed in FDA's regulations under 21 CFR § 314.420 and the FDA-issued Guidance for Drug Master Files (8). When authorized by the DMF submitter (i.e., the excipient manufacturer) and cross-referenced by an NDA submitter, the FDA reviews the DMF to make determinations on the safety, manufacture, and quality of the excipient use in the new drug that is the subject of the then pending NDA. The DMF becomes active when reviewed in conjunction with the review and approval of an NDA.

The *USP/NF* provides a listing of excipients by categories in a table according to the function of the excipient in a dosage form, such as tablet binder, disintegrant, and such. An excellent reference for excipient information is the *Handbook of Pharmaceutical Excipients* (Rowe et al., 2012). Additionally, Gad et al. (2016) provide an excellent and extensive database of nonclinical formulation components and either acceptable maximum usage levels by species route and duration of study.

Excipients have historically not been subjected to extensive safety testing because they have been considered a priori to be biologically inactive and therefore nontoxic. Many, if

not most, excipients used are approved food ingredients, the safety of which has been assured by a documented history of safe use or appropriate animal testing. Some of the excipients are generally recognized as safe (GRAS) food ingredients. The excipient is an integral component of the finished drug preparation and, in most countries, is evaluated as part of this preparation. There has been no apparent need to develop specific guidelines for the safety evaluation of excipients, and most developed countries do not have specific guidelines. However, as drug development has become more complex and/or new dosage forms have developed, improved drug bioavailability has become more important. It was noted that the available excipients were often inadequate, new pharmaceutical excipients specifically designed to meet the challenges of delivering new drugs were needed, and these are being developed. The proper safety evaluation of new excipients has now become an integral part of drug safety evaluation.

In the absence of official regulatory guidelines, the Safety Committees of the IPEC in the United States, Europe, and Japan developed guidelines for the proper safety evaluation of new pharmaceutical excipients (IPEC, 2012). The committees critically evaluated guidelines for the safety evaluation of food ingredients, cosmetics, and other products, as well as textbooks and other appropriate materials. Before initiating a safety evaluation program for a new pharmaceutical excipient, it is advisable to address the following:

1. Chemical and physical properties and functional characterization of the test material (Hawley, 1971)
2. Analytical methods that are sensitive and specific for the test material and that can be used to analyze for the test material in animal food used in the feeding studies or in the vehicle used for other studies
3. Available biological, toxicological, and pharmacological information on the test material and related materials (which involves a thorough search of the scientific literature)
4. Intended conditions of use, including reasonable estimates of exposure
5. Potentially sensitive segments of the population

As discussed in Chapters 1 and 3, a comprehensive and critical search of the scientific literature on the test material and related materials is essential before the start of any testing program.

As pharmaceutical excipients are assumed to be biologically nonreactive, dose–response relations cannot always be established. An acceptable alternative is to use a maximum attainable or maximum feasible dose. This is the highest dose possible that will not compromise the nutritional or health status of the animal. Table 6.12 summarizes the maximum or

TABLE 6.12 Limit Doses for Toxicological Studies

Nature of Test	Species	Limit Dose ^a
Acute oral	Rodent	2000 mg kg ⁻¹ bw
Acute dermal	Rabbit	2000 mg kg ⁻¹ bw
	Rat	
Acute inhalation ^b	Rat	5 mg L ⁻¹ air for 4 h or maximum attainable level under conditions of study
Dermal irritation	Rabbit	0.5 mL liquid
		0.5 g solid
Eye irritation	Rabbit	0.1 mL liquid
		100 mg solid
14-day/28-day oral repeated dosing; 90-day subchronic	Rodent, nonrodent	1000 mg kg ⁻¹ bw day ⁻¹
14-day/28-day oral repeated dosing; 90-day subchronic	Rat, rabbit	1000 mg kg ⁻¹ bw day ⁻¹
Chronic toxicity, carcinogenicity	Rats, mice	5% maximum dietary concentration for nonnutrients
Reproduction	Rats	1000 mg kg ⁻¹ bw day ⁻¹
Developmental toxicity (teratology)	Mice, rats, rabbits	1000 mg kg ⁻¹ bw day ⁻¹

^a mg kg⁻¹ bw, milligrams of test material dosed per kilogram of body weight to the test species.

^b Acute inhalation guidelines that indicate this limit dose are US Environmental Protection Agency Toxic Substance Health Effect Test Guidelines, Oct., 1984; (PB82-232984) Acute Inhalation Toxicity Study; the OECD Guidelines of the Testing of Chemicals, Vol. 2, Section 4; Health Effects, 403, Acute Inhalation Toxicity Study, May 12, 1982; and the *Official Journal of the European Communities*, L383A, Vol. 35, Dec. 29, 1992, Part B.2 (adapted from Weiner and Katkoskie (1999)).

limit doses for various types of studies by different routes of exposure. For example, 2000 mg kg⁻¹ bw of an orally administered test material is the maximum dose recommended for a testing strategy that has been developed for new pharmaceutical excipients that takes into consideration the physicochemical nature of the product and the potential route(s) and duration of exposures, both through its intended use as part of a drug product and through workplace exposure during manufacturing. The number and types of studies recommended in this tiered approach are based on the duration and routes of potential human exposure. Thus, the longer the exposure to the new pharmaceutical excipient, the more studies are necessary to assure safety. Table 6.11 summarizes the entire set of toxicological studies recommended for new pharmaceutical excipients (Weiner and Katkoskie, 1999; IPEC, 2012).

Tests have been outlined for each exposure category to assure safe use of the time period designated. The tests for each exposure category assure the safe use of the new pharmaceutical excipient of the time frame specified for the specific exposure category. Additional tests are required for longer exposure times.

The base set required for all excipients is detailed in Table 6.13. These are sufficient; however, only for those excipients intended for use for up to 2 weeks in man.

If exposure to the new pharmaceutical excipient is expected to occur for longer than 2 but no more than 6 weeks, additional toxicological studies are required, as shown in Table 6.14. The longer the expected human exposure, the more extensive will be the toxicological studies to assure safety. A tiered approach assures that those tests necessary to ensure safety for the expected duration of human exposure are conducted. Thus, to assure safe use for greater than 2 weeks, but no more than 6 weeks in humans, subchronic toxicity and developmental toxicity studies are required. To assure safe use for greater than six continuous weeks, chronic or oncogenicity studies are conditionally required, as per Table 6.14. This means long-term studies should be considered for prolonged human exposures but may not be absolutely required. A thorough scientific review of the data generated in the base set and Appendix 2 studies should be undertaken. From a critical evaluation by a competent toxicologist, the results of the physicochemical properties of the test material, the 28-day and 90-day tests, the ADME–PK acute and repeated-dose tests, and the developmental toxicity test(s), a final determination can be made on the value of chronic toxicity or oncogenicity studies.

For example, if no toxicity is observed at a limit dose of 1000 mg kg⁻¹ bw per day following the 90-day toxicity

TABLE 6.13 Base Set Studies for a Single Dose up to 2-Week Exposure in Humans

Test	Purpose
Acute oral toxicity	To determine the potential acute toxicity/ lethality following a single oral dose
Acute dermal toxicity	To determine the potential acute toxicity/ lethality following a single dermal dose
Acute inhalation toxicity	To determine the potential acute toxicity/ lethality following a single 4 h inhalation exposure to a test atmosphere containing the new pharmaceutical excipient (aerosol, vapor, or particles)
Eye irritation	To determine the potential to produce acute irritation or damage to the eye
Skin irritation	To determine the potential to produce acute irritation or damage to the skin
Skin sensitization	To determine the potential to induce skin sensitization reactions
Ames test	To evaluate potential mutagenic activity in a bacterial reverse mutation system with and without metabolic activation
Micronucleus test	To evaluate the clastogenic activity in mice using polychromatic erythrocytes
ADME-intended route	To determine the extent of absorption, distribution, metabolism, and excretion by the intended route of exposure following a single dose and repeated doses
28-day toxicity-intended route	To assess the repeated-dose toxicity in male and female animals of two species following dosing for 28 days by the intended route of exposure

study, no genotoxicity was found, and the ADME–PK profile indicates that the material is not absorbed and is completely excreted unchanged in the feces, then it is likely that a chronic study is not necessary. The decision to conduct chronic studies should be determined on a

TABLE 6.14 Appendix 3 Studies for Repeated Chronic Exposure in Humans

Test	Purpose
Chronic toxicity	To assess the toxicity following chronic (lifetime) exposure by the route of intended exposure
Oncogenicity	To assess the potential to induce tumors by the intended route of exposure
One-generation reproduction	To assess the potential reproductive and developmental toxicity in males and females by the intended route of exposure

case-by-case basis using scientific judgment. It will be interesting to observe how this scheme may change in light of ICH.

MECHANISMS AND END POINTS OF DRUG TOXICITY

A fundamental precept in toxicology (and in clinical medicine) is that the place to start an evaluation of adverse effects or disease must be a knowledge and understanding of what is normal (the normative or healthy state). We use concurrent controls in nonclinical toxicology studies to provide assurance that the specific experimental units (for the purposes of this chapter, experimental animals from the same source and selected as a random sample from a single lot) treated are evaluated in reference to members of the same population. But what represents a change from normal depends on a learned background knowledge from observation and practice and from databases of laboratory and other measurements taken over time from the pool of a relevant population animals of interest, and what is normal in specific ways between members of a species.

In both toxicology and clinical medicine, adversity is nonrandom (significant) changes in one (or sometimes one of two possible) direction which threatens the health (“normality”) of the exposed organism. Detecting these changes and understanding the significance of (and potential for causality of) the effect are the domain of descriptive toxicology and the heart of regulatory toxicology. These changes we measure are the manifestations of toxicology (Table 7.1). What causes toxicity—the underlying mechanisms generalized in Table 7.2—are the realm of investigative and mechanistic toxicology.

Our traditional systemic (“general”) toxicology studies have their genesis in the 1930s, when the practice of clinical medicine added a host of objective tools for the diagnosis and monitoring of health. All these tools were updated for use in animal studies; we came to look for everything that might help find and understand adverse effects—the shotgun approach. We still use this approach, adding more tools as they become available.

7.1 MANIFESTATIONS

There is a vast and expanding literature on manifestations of toxicity—the product of vast (and continuing) efforts in descriptive toxicology, and much of it is done to meet regulatory needs. Recommended texts which present these in broad categories would include Ballantyne et al. (2009), Hayes (2014), Klaassen (2013), Smart and Hodgson (2009), Gad (2016), and Faqi (2017). Chapter 3 expands on the available sources of such information.

But, at its core, the list of categories of such manifestations (Table 7.1) is rather limited.

In the recent years, six more manifestations more specifically or commonly associated with the effects of drugs have come to be added to this list:

- (i) *Mitochondrial dysfunction*: Increased uptake of calcium (because of ATP depletion) by mitochondria activates phospholipases, resulting in accumulation of free fatty acids. These cause changes in the permeability of mitochondrial membranes, such as the *mitochondrial permeability transition*.
- (ii) *Progressive loss of phospholipids*: Increased degradation by endogenous phospholipases and inability of the cell to keep up with the synthesis of new phospholipids (reacylation, an ATP-dependent process).
- (iii) *Cytoskeletal abnormalities*: Activated proteases lyse cytoskeletal elements and cell swelling cause detachment of cell membrane from the cytoskeleton and stretching of the cell membrane results in increased membrane damage.
- (iv) *Reactive oxygen species*: Produced within the cell and by infiltrating neutrophils and macrophages,

Cellular organelle effects
Biochemical/metabolic effects
Genomic effects

especially after restoration of blood flow to an area (reperfusion injury). Cell injury triggers release of a number of inflammatory cytokines and chemokines which amplify the host immune response and attract neutrophils to the site.

- (v) *Lipid breakdown products*: Unesterified free fatty acids, acylcarnitine, and lysophospholipids. These have a detergent effect on membranes and may exchange with membrane phospholipids, causing permeability changes.
- (vi) *Inflammation*: Across organ systems and chronic diseases (including cancer, autoimmune, and neurodegenerative diseases), it has become clear that chronic tissue inflammation is a broad underlying causality. Such an inflammation may have a large range of underlying causes including foreign body responses and viral infections.

7.2 MECHANISMS OF TOXICITY

Just as manifestations of toxicology are assessed in regulatory safety assessment, studies can be considered as belonging to a limited number of categories, so the mechanisms that cause/underlie these measurable and observable effects can be considered as belonging to a limited number of mechanistic causes (summarized in Table 7.2). These now have become more critical in understanding drug toxicity.

The presentation of the concepts of manifestation and mechanisms of toxicity (not the subject of this volume) allows us to consider the actual components measured and evaluated in our “shotgun” regulatory general toxicity studies.

7.3 END POINTS MEASURED IN GENERAL TOXICITY STUDIES

All general toxicology studies capture some or all of a series of common sets of measurements intended to capture as much information as possible without compromising the health or functionality of the main study test animals. Table 7.3 summarizes these categories for both “pilot” (non-GLP, used to properly set dose levels for the longer GLP IND-enabling studies) and for all the follow-on (regulatory required) GLP general toxicology studies. It should be pointed out that new technologies become available (imaging in smaller animals and use of telemetry, for example—both the subject of later chapters in this book).

7.3.1 Clinical Observations

The value of clinical observations in general toxicology studies depends heavily on both the training (and experience) of the observers/scorers and of the rigor instilled by the data collection method. Appendix A presents a widely accepted (and used) lexicon of clinical observation terms. How these observations correlate with specific target organs—and what other potentially correlating measures may be—is presented in Table 7.4.

While mortality (on study of deaths) and morbidity (on study of occurrences of severe clinical signs) are obviously critical parameters in good toxicology studies, they are generally collected and integrated with other clinical observations.

7.3.2 Body Weights

Change in body weight (and the associated calculated parameter of body weight gain) is a nonspecific, broad screen for adverse systemic toxicity. Animals are initially assigned to groups based on a randomization schemes that have each group vary insignificantly from one another in terms of body weight. In most cases (always in rodent studies), the animals are young at start of the study (really juveniles) and in a predictable near-log growth phase. Weights are measured prior to the initial dose, then typically 1, 3, 5, 7, 11, and 14 days thereafter, then weekly or biweekly after this in longer studies. The frequency of measurement of weights goes down as the study proceeds—after 2 weeks, weighing is typically weekly through 6 weeks, then every other week through 3 months, and monthly thereafter. Because the animals used in these studies are young adults in the early log phase of their growth, decreases in the rate of

TABLE 7.3 Common Evaluation Parameters for Toxicity Studies

Parameter	Time Points Evaluated	Pilot Studies	GLP Repeat-Dose Studies (IND Enabling) ^a	Comments
Mortality/morbidity	1–2× daily	✓	✓	
Clinical observations	Daily	✓	✓	
FOB	After first and last dose		✓	
Body weights	1–2×/week	✓	✓	In 90 days and longer studies, after the first 30 days, measured monthly
Food and water consumption	1–2×/week		✓	Typically calculated as a per cage average for rodents
Clinical chemistry and hematology	At necropsy	✓	✓	Prestudy and interim samples are also often collected for large animals
Urinalysis	1–2 days before necropsy		✓	
Plasma drug levels	Day 1 and last day of dosing in DRF	✓	✓	Still commonly requires satellite groups for rodents because of the limited blood volume available for sampling
Ophthalmology	Prestudy and before each necropsy		✓	
Electrocardiography	Prestudy and before each necropsy		✓	Typically conducted only for nonrodents (dogs, minipigs, and primates)
Gross necropsy	At necropsy	✓	✓	
Organ weights	At necropsy		✓	
Histopathology	Postnecropsy		✓	

^a 14 and 28 days studies; longer-term studies may add additional interim time points.

gain relative to control animals are a very sensitive (albeit nonspecific) indicator of systemic toxicity.

7.3.3 Food and Water Consumption

Food consumption is typically measured with one or two uses in mind. First, it may be explanatory in the interpretation of reductions (either absolute or relative) in body weight. In cases where administration of the test compound is via diet, it is essential to be able to adjust dietary content so as to accurately maintain dose levels. Additionally, the actual parameter itself is a broad and nonspecific indicator of systemic toxicity. Food consumption is usually measured over a period of several days, first weekly and then on a once-a-month basis. Water consumption, which is also sometimes measured, is similar in interpretation and use. Additionally, particularly in nonrodents, loss of appetite is an early indicator of adverse effects in animals.

7.3.4 Clinical Signs

Clinical signs are generally vastly underrated in value, probably because insufficient attention is paid to care in their col-

lection. Two separate levels of data collection are actually involved here. The first is the morbidity and mortality observation, which is made twice a day. This generally consists of a simple cage-side visual assessment of each animal to determine if it is still alive and, if so, whether it appears in good (or at least stable) health. Historically, this regulatory required observation was intended to ensure that tissues from intoxicated animals were not lost for meaningful histopathological evaluation due to autolysis (Arnold et al., 1990).

The second level of clinical observation is the detailed hands-on examination analogous to the human physical examination. It is usually performed against a checklist (see Gad (2016) for an example), and evaluation is of the incidence of observations of a particular type in a group of treated animals compared to controls. Observations range from being indicative of nonspecific systemic toxicity to fairly specific indicators of target organ toxicity. These more detailed observations are typically taken after the first week of a study and on a monthly basis thereafter.

Ophthalmologic examinations are typically made immediately prior to initiation of a study (and thus serve to screen out animals with preexisting conditions) and toward the end of a study.

TABLE 7.4 Correlation of Clinical Signs and Target Organs

Clinical Signs	Potential Target of Toxicity	Potential Correlating Data			
Piloerection	Nonspecific	Physical examination	Behavioral change		
Hypoactivity		Body weight gain measurements	Bleeding from any orifice		
Ruffled fur coat		Food consumption values	Dehydration		
Pustulation		FOB evaluation	Malaise		
Comedone formation		Results of physical examination	Excessive salivation (sialorrhea)		
Abnormal gait		Gross necropsy evaluation	Inability to masticate	Oropharyngeal	Physical examination
Abnormal posture		Clinical chemistry data	Inability to swallow food		Body weight gain measurements
Hunched posture		Hematology data	Foamy froth about mouth + lips + nose		Food consumption values
Self-mutilation		Radiographic data	Excessive salivation (sialorrhea)		FOB observations
Chromodacryorrhea		Ultrasonographic data			Results of physical examination
Bulging eye or eyes		Imaging data			Radiographic data
Restlessness					Ultrasound data
Excessive licking			Straub tail	Central nervous system	Physical examination
Excessive scratching					
Excessive grooming			Tremors		FOB evaluation
Foamy froth about mouth + lips + nose			Convulsions		Gross necropsy
Stiff body movement			Seizures		Clinical chemistry data
Shivering			Stereotypy		Hematology data
Reluctance to move			Aggression		Radiographic data
Lack of interest in surroundings			Loss of motor function		Ultrasound data
Excessive rigidity of tail			Abnormal gait		Imaging data
Hiding			Head tilt		
Avoidance of like kind			Circling		
Withdrawn			Quivering		
Dullness or depression			Trembling		
Squealing or crying			Ataxia		
Facial contortions			Heightened sensitivity to noise		
“Glassy” look to eyes			Lacrimation	Autonomic nervous system	Physical examination
General appearance of dejection			Salivation	or nervous system/nonspecific	FOB observations
Elevated body temperature			Rhinorrhea		Gross necropsy data
Lowered body temperature			Aggression		Radiographic data
Anorexia			Passivity		Ultrasonographic data
Cachexia			Resistance to handling		Imaging data
Emaciation			Vocalization		
Refusal to eat			Hyperactivity		
Refusal to drink			Dry eye		
Rapid weight loss			Abnormal response to light stimuli	Ophthalmic or visual nervous system	Physical examination
Skin sores			Ptosis		Complete ophthalmic exam
Body masses			Blinking		Gross necropsy observation
Decreased body temperature

TABLE 7.4 (Continued)

Clinical Signs	Potential Target of Toxicity	Potential Correlating Data
Obstructive pattern Inspiration difficulty Expiration difficulty Foamy froth about mouth + lips + nose	Endocrine	Physical examination Gross necropsy Clinical chemistry data
Broken bones Generalized malaise Generalized weakness Ataxia		
Excessive drinking Excessive urination Abnormal circadian rhythm Reproductive dysfunction Immune dysfunction	Immune system	Targeted clinical chemistry or <i>in vitro</i> testing to evaluate specific gland dysfunction
Infection(s) Skin infection(s)		

Appendix B and Gad and Chengelis (1999) should be consulted for a lexicon of clinical signs.

Particularly when the agent under investigation either targets or acts via a mechanism likely to have a primary effect on a certain organ for which functional measures are available, an extra set of measurements of functional performance should be considered. The organs or organ systems that are usually of particular concern are the kidneys, liver, cardiovascular, nervous, and immune. Special measures (such as creatinine clearance as a measure of renal function) are combined with other data already collected (organ weights, histopathology, clinical pathology, etc.) to provide a focused “special” investigation or evaluation of adverse effects on the target organ system of concern. In larger animals (dogs and primates), some of these measures (such as ECGs) are made as a matter of course in all studies.

7.3.5 Clinical Chemistry and Pathology

Clinical pathology covers a number of biochemical and morphological evaluations based on invasive and noninvasive sampling of fluids from animals that are made periodically during the course of a subchronic study. These evaluations

are sometimes labeled as clinical (as opposed to anatomical) pathology determinations and are now commonly the result of evaluations by automated analysis (Thomas, 1979). Table 7.5 presents a summary of the parameters measured under the headings of clinical chemistry, hematology, and urinalysis using samples of blood and urine collected at pre-determined intervals during the study. Conventionally, these intervals are typically at three points evenly spaced (chronologically) over the course of the study, with the first being 1 month after study initiation and the last being immediately prior to termination of the test animals. For a 3-month study, this means that samples of blood and urine would be collected at 1, 2, and 3 months after study initiation (i.e., after the first day of dosing of the animals). There are some implications of

TABLE 7.5 Clinical Pathology Measures

Clinical Chemistry	Hematology	Urinalysis
Albumin	Erythrocyte count (RBC)	Chloride
Alkaline phosphatase (ALP)	Hemoglobin (HGB)	Bilirubin
Blood urea nitrogen (BUN)	Hematocrit (HCT)	Glucose
Calcium	Mean corpuscular hemoglobin (MCH)	Occult blood
Chloride	Mean corpuscular volume (MCV)	pH
Creatine	Platelet count	Phosphorus
Creatine phosphokinase (CPK)	Prothrombin time	Potassium

these sampling plans that should be considered when the data are being interpreted. Many of the clinical chemistry (and some of the hematologic) markers are really the result of organ system damage that may be transient in nature (see Table 7.6 for a summary of interpretations of clinical chemistry findings and Table 7.7 for a similar summary for hematologic findings). The samples on which analysis is performed are from fixed points in time, which may miss transient changes (typically, increases) in some enzyme levels. Thrall et al. (2012) provides excellent detailed coverage of veterinary hematology and clinical chemistry.

There is now a concerted effort to improve the predictive value of nonclinical safety assessment studies for major classes of issues that are “discovered” in clinical trials and marketed use of new drugs. There are efforts to identify biomarkers which can be measured in animal studies and have relevance and more similarity for clinical findings (Gupta, 2014).

Focus has been on biomarkers for the heart (see Braunwald, 2008), kidney, and liver. The kidney guidance is quite recent with European Medicines Agency (EMA) and FDA announcing in late May 2008 that they have accepted seven biomarkers (Kim-1, albumin, total protein, cystatin C, β 2-microglobulin, urinary clusterin, and urinary trefoil factor 3) for use in preclinical studies. The liver guidance is also recent (EMA, 2008), though this reflects an ongoing effort (see Kaplowitz, 2005) to try and reduce the occurrence of “idiosyncratic” liver toxicity occurrences in the clinic. Table 7.8 presents a list of available clinical chemistry measures that are considered preclinical alerts for the three major categories of hepatic toxicity.

It would seem likely that rather than these being adapted out of whole cloth into the standard design of repeat-dose studies, they are likely to be used in a more considered measure when there is cause for specific concern. Most CROs (as of this writing) have not added these to their standard designs or, indeed, offered them as validated, waiting for client demand for same.

A difficulty with detecting potential hepatic toxicities in humans (DLTs—delayed liver toxicities) (Kumar et al., 2015) is that their appearance in limited parts of a patient population is typically after some months of use—the results of first an (innate) immunity inflammatory response followed by a longer-term adaptive immune response. According to the FDA, drug-induced DLTs are the leading cause of acute liver failure (ALF). Nonclinical studies, particularly the 30-day studies that enable INDs and FIM studies, are just not long enough.

7.3.6 Hematology

In general toxicity studies, we primarily measure the formed blood elements (red and white cells, including their subsets, and platelets), hemoglobin levels in red cells, and the functionality of coagulation. Collectively, these serve to transport oxygen to the tissues of the body, as essential components of

the immune system, and to respond to hemorrhagic events. The actual target organ for formed blood element toxicity is the stem cells located in specific tissues of the body (Weiss and Wardrop, 2010; Kaushansky et al., 2011).

7.3.7 Gross Necropsy and Organ Weights

The end of the “in-life” phase of general toxicity studies is the euthanasia of the animals (usually immediately preceded or accompanied by the collection of urine and blood samples) followed by visual examination and preservation of tissues (see list in Table 7.9), with weighing of the selected organs (as denoted in Table 7.9). Observed abnormalities seen on visual examination are investigated in the histopathological examination of the preserved tissues, with attempts to correlate the two results. Organ weights are usually statistically evaluated as ratios using total body weight as their weights change as body weights change (the exception being the brain).

These changes in relative body weights are sensitive indicators of effects on the specific organs of the body and indicators of target organ toxicity.

7.3.8 Histopathology

Histopathology is generally considered the single most significant portion of data to come out of a repeat-dose toxicity study. It consists of three related sets of data (gross pathology observations, organ weights, and microscopic pathology) that are collected during the termination of the study animals. At the end of the study, several tissues are collected immediately after termination from all animals that survived until the end of the study (test and control). Organ weights and terminal body weights are recorded at study termination so that absolute and relative (to body weight) values can be statistically evaluated.

These tissues, along with the organs for which weights are determined, are listed in Table 7.9. All tissues collected are typically processed for microscopic observation, but only those from the high-dose and control groups are necessarily minimally evaluated microscopically. If a target organ is discovered in the high-dose group, then successively lower-dose groups are examined until a “clean” (devoid of effect) level is discovered (Haschek et al., 2013). A fundamental understanding of what is normal in tissue structure for a specific organ from a specific mammalian species is essential in such evaluations and is the result of years of study and experience (Minckler, 1971).

In theory, all microscopic evaluations should be performed blind (without the pathologist knowing from which dose group a particular animal came), but this is difficult to do in practice and such an approach frequently degrades the quality of the evaluation. Like all the other portions of data in the study, proper evaluation benefits from having access to all

TABLE 7.6 Association of Changes in Biochemical Parameters with Actions at Particular Target Organs

Parameter	Blood	Heart	Lung	Kidney	Liver	Bone	Intestine	Pancreas	Notes
Albumin				↓	↓				Produced by the liver. Very significant reductions indicate extensive liver damage
ALP					↑	↑	↑		Elevations usually associated with cholestasis. Bone alkaline phosphatase tends to be higher in young animals
Bilirubin (total)	↑				↑				Usually elevated due to cholestasis, either due to obstruction or hepatopathy
BUN				↑	↓				Estimates blood-filtering capacity of the kidneys. Doesn't become significantly elevated until the kidney function is reduced to 60–75%
Calcium				↑					Can be life-threatening and result in acute death
Cholinesterase				↑	↓				Found in plasma, brain, and RBC
CPK		↑							Most often elevated due to skeletal muscle damage but can also be produced by cardiac muscle damage. Can be more sensitive than histopathology
Creatinine				↑					Also estimates blood-filtering capacity of kidney as BUN does
Glucose								↑	Alterations other than those associated with stress are uncommon and reflect an effect on the pancreatic islets or anorexia
GGT					↑				Elevated in cholestasis. This is a microsomal enzyme and levels often increase in response to microsomal enzyme induction
HBDH		↑			↑				
KIM-1				↑					A renal transmembrane molecule released when the kidney is damaged
LDH		↑	↑	↑	↑				Increase usually due to skeletal muscle, cardiac muscle, or liver damage. Not very specific
Protein (total)				↓	↓				Absolute alterations are usually associated with decreased production (liver) or increased loss (kidney). Can see increase in case of muscle “wasting” (catabolism)
SGOT		↑		↑	↑			↑	Present in skeletal muscle and heart and most commonly associated with damage to these
SGPT					↑				Elevations usually associated with hepatic damage or disease
SDH					↑↓				Liver enzyme which can be quite sensitive but is fairly unstable. Samples should be processed as soon as possible
Trophonil		↑							Marker for muscle fiber damage. Cardiac specific form is short lived in plasma after damage to cells, but a sensitive and specific marker.

↑, increase in chemistry values; ↓, decrease in chemistry values. ALP, alkaline phosphatase; BUN, blood urea nitrogen; CPK, creatinine phosphokinase; GGT, gamma glutamyl transferase; HBDH, hydroxybutyric dehydrogenase; LDH, lactic dehydrogenase; RBC, red blood cells; SDH, sorbitol dehydrogenase; SGOT, serum glutamic oxaloacetic transaminase (also called aspartate aminotransferase [AST]); SGPT, serum glutamic pyruvic transaminase (also called alanine aminotransferase [ALT]).

TABLE 7.7 Some Probable Conditions Affecting Hematological Changes

Parameter	Elevation	Depression	Parameter	Elevation	Depression
Red blood cells	1. Vascular shock 2. Excessive diuresis 3. Chronic hypoxia 4. Hyperadrenocorticism	5. Anemias a. Blood loss b. Hemolysis c. Low RBC production	Platelets		1. Bone marrow depression 2. Immune disorder
Hematocrit	1. Increased RBC 2. Stress 3. Shock a. Trauma b. Surgery 3. Polycythemia	1. Anemias 2. Pregnancy 3. Excessive hydration	Neutrophils	1. Acute bacterial infections 2. Tissue necrosis 3. Strenuous exercise 4. Convulsions 5. Tachycardia 6. Acute hemorrhage	
Hemoglobin	1. Polycythemia (increase in production of RBC)	1. Anemias 2. Lead poisonings	Lymphocytes	1. Leukemia 2. Malnutrition 3. Viral infections	
Mean cell volume	1. Anemias 2. B12 deficiency	1. Iron deficiency	Monocytes	1. 1. Protozoal infections	
Mean corpuscular hemoglobin	1. Reticulocytosis	1. Iron deficiency	Eosinophils	1. Allergy 2. Irradiation 3. Pernicious anemia 4. Parasitism	
White blood cells	1. Bacterial infections 2. Bone marrow stimulation	1. Bone marrow depression 2. Cancer chemotherapy 3. Chemical intoxication 4. Splenic disorders	Basophils	1. Lead poisoning	

RBC, red blood cell.

data that addresses the relevance, severity, timing, and potential mechanisms of a specific toxicity. Blind examination is best applied in peer review or consultations on specific findings.

In addition to the “standard” set of tissues specified in Table 7.9, observations during the study or in other previous studies may dictate that additional tissues be collected or special examinations (e.g., special stains, polarized light or electron microscopy, immunocytochemistry, or quantitative morphometry) be undertaken to evaluate the relevance of, or understand the mechanisms underlying, certain observations.

Histopathology testing is a terminal procedure, and, therefore, sampling of any single animal is a one-time event (except in the case of a tissue collected by biopsy). As it is a regulatory requirement that the tissues from a basic number of animals be examined at the stated end of the study, an assessment of effects at any other time course (most commonly, to investigate recovery from an effect found at study termination) requires that satellite groups of animals be incorporated into the study at start-up. Such animals are randomly assigned at the beginning of the study and otherwise treated the same as the equivalent treatment (or control animals).

7.3.9 Ophthalmology

Ophthalmological examination of all animals in a study (particularly nonrodents) should be performed both before study initiation and at the completion of the period at which the drug is administered. This should be performed by an experienced veterinary ophthalmologist.

TABLE 7.9 Tissues for Histopathology

Adrenals ^a	Mainstream Bronchi
Body and cervix	Major salivary gland
Brain, all three levels ^a	Mesenteric lymph nodes
Cervical lymph nodes	Ovaries and tubes

Larynx with thyroid and parathyroid	Trachea
Liver ^a	Urinary bladder
Lungs ^a	Uterus including horns

^aOrgans to be weighed.

7.3.10 Cardiovascular Function

Particularly considering recent concerns with drug-induced arrhythmias, careful consideration must be given to incorporate adequate evaluation of drug-induced alterations on cardiovascular function. This is usually achieved by measuring blood pressure, heart rate, and an ECG prestudy and periodically during the course of the study (usually at least one intermediate period and at the end of the study) in the nonrodent species being employed.

7.3.11 Neurotoxicology

Table 7.10 presents the FDA’s current draft criteria (FDA, 1993, 2007) for end points to be incorporated in studies as a screen for neurotoxicity. In practice, a functional observation battery is employed at several end points (usually 1 and 3 months into the study) to fill these requirements.

7.3.12 Immunotoxicology

In response to concerns about potential effects of drugs on the immune system, ICH and FDA (2006) have promulgated a guidance calling for a basic set of potential indicators of immunotoxicity (Table 7.11) be evaluated and considered in standard repeat-dose studies. Most of these end points are, it should be noted, already collected in traditional subchronic designs (Nikita 2014).

TABLE 7.10 FDA Criteria for a Neurotoxicity Screen as a Component of Acute, Pilot, and Subchronic Studies

Histopathological examination of tissues representative of the nervous system, including the brain, spinal cord, and peripheral nervous system
Quantitative observations and manipulative test to detect neurological, behavioral, and physiological dysfunctions. These may include the following:
General appearance
Body posture
Incidence and severity of seizure
Incidence and severity of tremor, paralysis, and other dysfunction
Level of motor activity and arousal
Level of reactivity to stimuli
Motor coordination
Strength
Gait
Sensorimotor response to primary sensory stimuli
Excessive lacrimation or salivation
Piloerection
Sampling and staining of brain tissues
Diarrhea
Ptosis
Other signs of neurotoxicity deemed appropriate

TABLE 7.11 FDA Draft Recommendation for Type I Immunotoxicity Test That Can Be Included in Repeated-Dose Toxicity Studies

Type I Test	
Hematology	Clinical chemistry
White blood cell counts	Total serum production
Differential white blood cell counts	Albumin
Lymphocytosis	Albumin-to-globulin ratio
Lymphopenia	Serum transaminases
Eosinophilia	
Histopathology	
Lymphoid tissues	
Spleen	
Lymph nodes	
Thymus	
Peyer's patches in gut	
Bone marrow	
Cytology (if needed) ^a	
Prevalence of activated macrophages	
Tissue prevalence and location of lymphocytes	
Evidence of B-cell germinal centers	
Evidence of T-cell germinal centers	
Necrotic or proliferative changes in lymphoid tissues	

^a More comprehensive cytological evaluation of the tissues would not be done unless there is evidence of potential immunotoxicity from the preceding evaluation.

7.3.13 Imaging and Telemetry

In addition to more specific plasma enzyme markers for kidney (KIM-1) and cardiac (troponin) damage, the use of implanted telemetered sensors to measure physiologic functions (blood pressure, heart rate, EKG, respiratory rate, and volume) and body chemistry parameters (blood oxygen, blood sugar, insulin, and glucagen levels) are now available in most larger CROs and already widely used to be able to continuously (or on a predetermined schedule), noninvasively, and nontraumatically monitor these parameters during safety pharmacology and other studies. The range of potential for such measurements (Nikita, 2014) and possibility to reduce animal usage is not yet widely realized, but as it increases in human medicine, it will expand rapidly.

Likewise, the range of imaging technologies that can be employed to capture *in vivo* measurements of physiological function and structured anatomic changes is now well beyond just X-rays and radiopharmaceutical markers. Ultrasounds, MRI, and echocardiographs (Bruggen and Roberts, 2003) are the most commonly used technologies in nonclinical research and testing. All of these promise vast improvements in clinical parameter measurement sensitivity and specificity.

7.4 COMPLICATIONS

A vast number of potential complications can plague the interpretation of general toxicology studies.

Health of the animals and variability of technician procedures and practices in handling of animals are two potentially “lurking” variables not readily visible but quite capable of skewing the results of a study.

Stress as a confounding variable is well recognized but not generally well understood or characterized, but it can have profound effects on animals and alter (or potentially mask) the observation of toxicity, acting primarily by modulating the immune system (both innate and humoral, and noted as such in ICH S8). June 2013 issue of *Toxicologic Pathology* provides an excellent overview in the form of contributed articles.

PILOT TOXICITY TESTING IN DRUG SAFETY EVALUATION: MTD AND DRF

8.1 INTRODUCTION

Acute toxicity testing serves to detect, identify, and assess the dose–response relationship of a single (or single day’s) administered doses of a drug or chemical entity. Such effects are produced by a single or a few doses over the course of a day such as *bid* or *tid* (in the case of continuously infused intravenous formulation, in a 24-h course of treatment) of a drug and expressed in no more than 14 days (though they most commonly are seen within 3–4 days). Historically, the main focus of these tests has been lethality determinations and the identification of overt signs and symptoms of over-dosage. For a complete historical perspective, see Andrew (2009), Gad and Chengelis (1999), Auletta (1998), Piegorsch (1989), or Deichmann and Gerarde (1969). A more enlightened and modern view holds that, especially for pharmaceutical agents, lethality in animals is a relatively poor predictor of hazard (other than lethality) in man (Gad and Chengelis, 1999) and is of limited direct utility for drugs. The current trend is either to generate increasing amounts of more sophisticated data from these tests (“expanded acutes”), usually for “phase 0” studies, or to do only a limited maximum tolerated dose (MTD)¹ study to identify doses for the repeat-dose pilot phase (USFDA, 2006; Chan and Hayes, 2015; Wilson et al., 2015). The various types of acute study designs, their utility in pharmaceutical product testing, their limitation, and the resultant sample data are discussed in this chapter. The most common use of these is as part of a screening program of potential candidates. What is seen in these studies, it must be kept in mind, are route and test species that are formulation-dependent. Results are due to the inherent toxicity of the drug, systemic toxicity of what actu-

ally gets absorbed, and local tissue tolerance effects at the site of administration (Andrew, 2009).

Previously, for new product approvals (and first-in-human clinical trials), single-dose toxicity studies were required by regulatory authorities, though this is no longer a requirement (ICH, 2009; Osterberg, 1983; OECD, 1991; USFDA (CDER), 1996; USFDA, 2006).

Another use, now almost abandoned except for in natural product-derived drugs (Pendergast, 1984), is in quality control testing or batch release testing. The latter was once a mandated part of the standardization process for antibiotics, digoxin, and insulin in the *US Pharmacopeia*. While, perhaps, this type of testing is part of a broad safety picture, it is not typically part of a “preclinical” safety package used to make decisions on whether to further develop a NCE or on what the allowable clinical dosage shall be; therefore, these uses are not discussed here. The emphasis in this volume, rather, is on tests used to elucidate the toxicity of new chemical entities, not the safety of finished drug preparations. These tests fall into three general categories: (i) range-finding studies, used primarily to set dosages for initial subchronic or acute testing; (ii) complete “heavy” or expanded acute toxicity tests, used to thoroughly describe the single-dose toxicity of a chemical or to support the opening of an explanatory or phase zero IND, and (iii) screening tests, used to select candidates for development.

8.2 RANGE-FINDING STUDIES

Dose range finders or pilots (now also commonly called DRFs²) are not required to be or normally conducted completely

²DRF studies are studies which are necessary to set doses for GLP studies required by regulation to be able to initiate initial clinical studies. Their results help to select doses, and also to justify that dose selection and identify need for modification in study design.

¹MTD refers to the highest dose of a drug or treatment that does not cause unacceptable side effects.

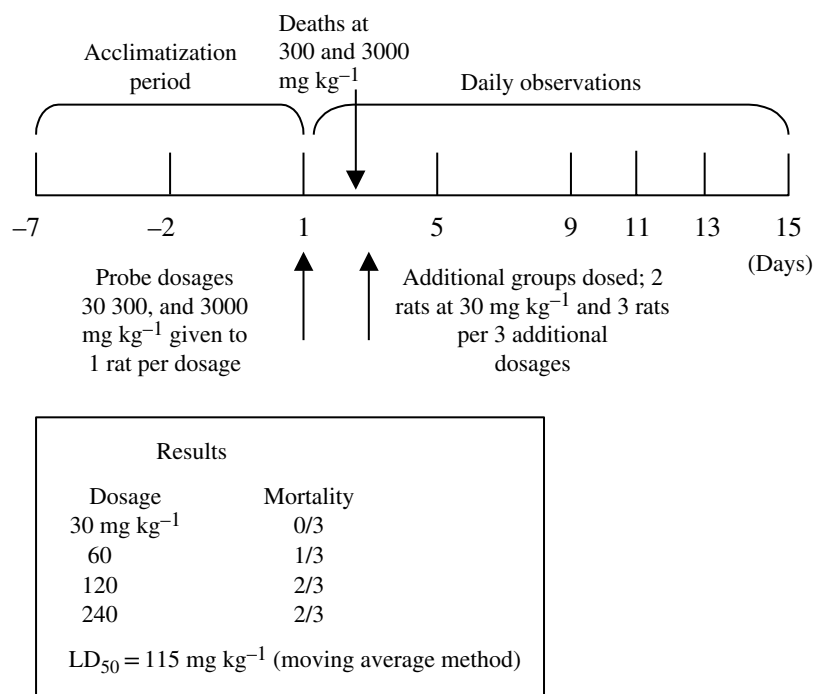

FIGURE 8.1 Example of typical dosage probe protocol.

under the auspices of the Good Laboratory Practice (GLP) Act. They are not used to generate data to support decisions on human safety; rather, they are used to provide sufficient data to allow successful dose selection for definitive (GLP regulatory) toxicity studies. These dosage-level determinations can be for use in acute studies, *in vivo* genotoxicity studies, or subchronic studies. As discussed by Gad and Chengelis (1999), however, there can be a great deal of difference between the single toxic dosage and subchronic repeat-dose toxicity of a drug. Therefore, acute range-finding studies currently and most commonly are the initial component of a two-phase study where a second set (“B” phase) of animals will receive a short-term treatment (up to 7 days) with the drug in question. These studies seek to identify an MTD for dose setting in subsequent studies.

8.2.1 Lethality Testing

Often, in range-finding tests, the end point is simply to determine what the maximum dosage that can be given without killing an animal is for the drug. There are numerous designs available for obtaining this information that minimizes the expenditure of animals and other resources. The minimum lethal dose (MLD), also sometimes called the lowest lethal dose (LDLO), will usually be determined in such studies.

8.2.1.1 Classical LD₅₀ The LD₅₀ test has a rich and controversial history (it is one of a number of tests that raises the ire

of the animal welfare movement) (Trevan, 1927; Rowan, 1981; LeBeau, 1983). In pharmaceutical development, however, there is rarely a need or requirement for an LD₅₀ (Office of Science Coordination, FDA, 1984). In general, a complete, precisely calculated LD₅₀ consumes more resources than is generally required for range-finding purposes. The reader is referred to Gad and Chengelis (1999) for a complete discussion of this test.

8.2.1.2 Dose Probes Dose probe protocols (see Figure 8.1) are of value when one needs the information supplied by a traditional protocol, but they have no preliminary data from which to choose dosages. In this acute protocol, one animal is dosed at each of three widely spaced dosages, where the top dosage is generally the maximum amount deliverable. The method works best if the dosages are separated by constant multiples (e.g., 3000, 300, and 30 mg kg⁻¹—a logarithmic progression). Subsequent dosages are selected on the basis of the results from these probe animals. If none of these animals die, the protocol defaults to a limit test (described later), and two more animals are dosed at the top dosage to confirm the limit.

A dose probe can develop into a more thorough lethality determination. If one or two animals die, then two additional dosages between the lethal and nonlethal dosages are chosen and three animals treated per dosage for defining acute lethality. Selection of these dosages is often a matter of personal judgment. If, for example, one wishes to apply the

TABLE 8.1 Dosage Selection for the Two-Step Dose-Probing Protocol Design

Mortality by Dose ^a			Dosages (mg kg ⁻¹) for the Definitive Experiment as Determined by the Results of the Probe			
10 mg kg ⁻¹	100 mg kg ⁻¹	1000 mg kg ⁻¹

^b The results from the probe are inserted for these doses.

moving average method of calculation, these subsequent dosages can be either even fractions of the top dosage or even multiples of the low dosage. In either case, two to three animals are dosed at the initial dose and three to four animals are dosed at each of the two to three new dosages. The results should be three to four groups of three to four animals each, which should probably provide sufficient data for calculating the LD₅₀ and the slope of the curve. Probing can also be used to define the dosages for subchronic tests. Instead of selecting additional doses for an acute study, one can use the results from the probe to select two dosages for a short (e.g., 5 days) daily dosing regimen (see Section 8.2.1.7).

In a few instances, all the animals may die following the first day of dosing. In that case, the probe activity continues on Day 2 with two more animals dosed at two widely spaced lower dosages (i.e., 3 and 0.3 mg kg⁻¹). This regimen could continue daily until a nonlethal dosage is identified. Unless one has grossly misestimated the toxicity of the test substance, it is unlikely that the probing process would take more than 3 days. Carrying our example into 3 days of dosing would have resulted in probing the 3 μg kg⁻¹ to the 3 g kg⁻¹ range, and it is a rare chemical that is lethal at less than 3 μg kg⁻¹. Once a nonlethal dosage is identified, additional animals and/or dosages can be added, as discussed earlier.

There are two disadvantages to dose probe studies. First, delayed deaths pose difficulties. Hence, all animals should be observed for at least 7 days after dosing (though most deaths occur within 3 and very few after 4 days). Second, if the follow-up dosages are not lethal, the next decision point is ill-defined. Should more animals be dosed at some different dosage? The resulting data sets may be cumbersome and difficult to analyze by traditional statistical methods. Alternatively

(and this is true regardless of protocol design), if no “partial response” (mortality >0 but <100%) dosage is identified, one can simply conclude that the LD₅₀ is between two dosages, but the data do not permit the calculation of the LD₅₀ or the slope of the curve. This can happen if the dosage response is fairly steep.

Lörke (1983) has developed a similar protocol design. His probe (or dose range) experiment consists of three animals per dosage at 10, 100, and 1000 mg kg⁻¹. The results of the experiment dictate the dosages for the second round of dosing, as shown in Table 8.1. Animals were observed for 14 days after dosing. Lörke (1983) compared the results obtained when one to five animals were used per dosage group for the second test. He concluded that using only one animal per group has unreliable results in only 7% of chemicals tested. Hence, the Lörke design can produce reasonable estimates of lethal dosages using 14 or fewer animals. Schultz and Fuchs (1982) have proposed a dose probe protocol that adequately deals with delayed deaths (Figure 8.2). All animals are observed for 7 days before subsequent dosages are given. Dosing is initiated at two widely delivered dosages using one rate for each dosage. A third probe dosage is determined pending the outcome of the first two probes. A fourth may also be used. After that groups of three to four animals are used at subsequent dosages either as part of a “para-acute” dosing regimen to select or confirm dosages for a subchronic study or to continue with the definition of an acute lethality curve.

8.2.1.3 Up/Down Method Using classical or traditional acute lethality protocols, 15–30 animals per curve would be required to calculate a single LD₅₀ (Berkson, 1955). This is because the method relies on the analysis of group responses.

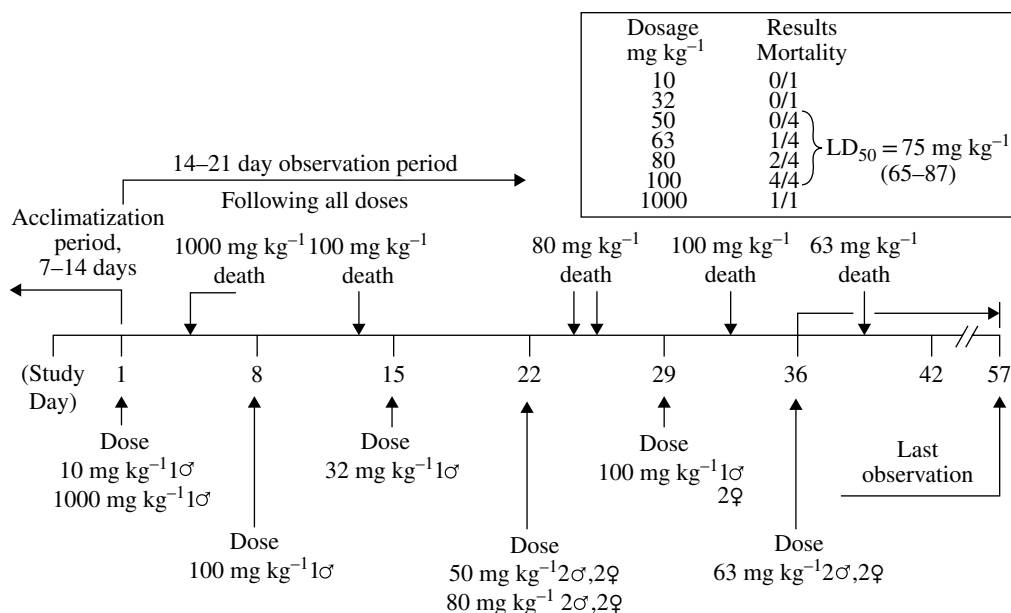

FIGURE 8.2 Example of dose probe method with delayed deaths. Source: Adapted from Schultz and Fuchs (1982).

FIGURE 8.3 Example of typical up/down acute lethality protocol.

The up/down method can provide lethality information by analyzing the responses on an individual animal basis using appropriate statistical maximum likelihood methods (Bruce, 1985). Deichmann and LeBlanc (1943) published an early method that provided an estimate of lethality using no more than six animals. All animals were dosed at the same time. The dosage range was defined as 1.5 × a multiplication factor (e.g., 1.0, 1.5, 2.2, 3.4, 5.1 mL kg⁻¹). The approximate lethal dose (ALD), as they defined it, was the highest dose that did not kill the recipient animal. The resultant ALD differed from the LD₅₀ (as calculated by the probit method from more complete data sets) by -22% to +33%.

The Deichmann method proved to be too imprecise (Muller and Kley, 1982). Later, Dixon and Wood (1948), followed by Brownlee et al. (1953), developed the method in which one animal was exposed per dosage, but subsequent dosages were

adjusted up or down by some constant factor depending on the outcome of the previous dosage. In this method (Figure 8.3), which has been developed more extensively by Bruce (1985), individual animals are dosed at different dosages on successive days. If an animal dies, the dosage for the next animal is decreased by a factor of 1.3. Conversely, if an animal lives, the next dosage is increased by a factor of 1.3. The process is continued until five animals have been dosed after a reversal of the first observation. Alternatively, one can use the tables developed by Dixon (1965). This design can be used not only for range-finding purposes but also to define an LD₅₀ if this value is needed. In general, only six to nine animals are required—unless the initial dosages are grossly high or low. When compared to the LD₅₀ obtained by other more classical protocols, excellent agreement is obtained with the up/down method (Bruce, 1985). As with classical protocols,

sexes should be tested separately. However, a further reduction in the numbers of animals used can be accomplished if one is willing to accept that females are of the same or increased sensitivity as males, as is the case approximately 85–90% of the time (Gad and Chengelis, 1999).

There are three main disadvantages to using the up/down method. The first is regulatory, the second procedural, and the third scientific. First, many regulatory guidelines simply have a requirement for the use of traditional protocols. Some also specify the method of calculation. Second, the sequential dosing design is inappropriate for substances that cause delayed deaths. As reported by various authors (Gad et al., 1984; Bruce, 1985), delayed deaths (beyond 2 days after dosing) are rare but not known. They are most prevalent when animals are dosed by the intraperitoneal route with a chemical that causes peritonitis. Death secondary to severe liver or gastrointestinal damage may also take over 2 days to occur. To guard against possible spurious results, all animals should be maintained and observed for at least 7 days after dosing. If delayed deaths occur, the original data set must be corrected and the LD₅₀ recalculated. A substantial number of delayed deaths could result in a data set from which an LD₅₀ cannot be calculated, in which case the test should be rerun.

8.2.1.4 “Pyramiding” Studies Using this type of design (Figure 8.4), one can obtain information about lethality with the minimum expenditure of animals. A minimum of two animals are dosed throughout the study, usually on alternate days (e.g., Monday, Wednesday, and Friday), but the dosage at session may be 1, 3, 10, 30, 100, 300, 1000, and 3000 mg kg⁻¹ or 10, 20, 40, 80, 160, 320, 640, and 1280 mg kg⁻¹. One is literally stepping up, or pyramiding, the lethality–dosage curve. Dosing continues in this fashion until one or both animals exhibit severe toxicity (a nontolerant dose) or until some practical upper limit is reached. For

drugs, there is no longer a need to go higher than 1000 mg kg⁻¹ for rodents or nonrodents. An alternative, but similar, design is the “leapfrog” study (Figure 8.5). This consists of two groups of two animals each. They are dosed on alternating days (oral 3-day intervals), but the dosages are increased each day. Extending the example of the pyramiding regiment, group 1 would receive 10, 60, and 120 mg kg⁻¹, while group 2 would be given 30, 100, and 120 mg kg⁻¹. This design is of the value when one has to complete the range-finding activity in a short period of time. Because these designs utilize few animals, they are commonly used for assessing severe toxicity in nonrodent species. An exploratory study typically uses an animal of each sex.

There are three conclusions that can be reached on the basis of data from a pyramiding dosage study. First, if none of the animals die or exhibit severe toxicity, then both the threshold or minimum/maximum lethal/toxic dosage (MLD/MTD), and the LD₅₀ are greater than the top or limit dosage. Second, if all animals die at the same dosage, then both the MLD and the LD₅₀ are reported as being between the last two dosages given. This is not an uncommon finding as an indication that the lethality curve has a steep slope. Third, one animal may die at one dosage, and remaining deaths occur at a subsequent dosage. In this case, the MLD is between the lowest nonlethal dosage and the dosage at which the first death occurred, while the LD₅₀ is reported as being between this latter dosage and the dosage at which the last animal dies. A frequently employed variation with nonrodents is if severe toxicity is not observed, the animals are dosed for five or seven consecutive days at the highest observed tolerated dose. This “phase B” study portion serves to provide more confidence in selecting the top dose in subsequent repeat-dose studies.

There are some disadvantages to the pyramiding dose protocol. First, it cannot produce a true lethality or dose–response curve or provide for the calculation of an LD₅₀. Second, this

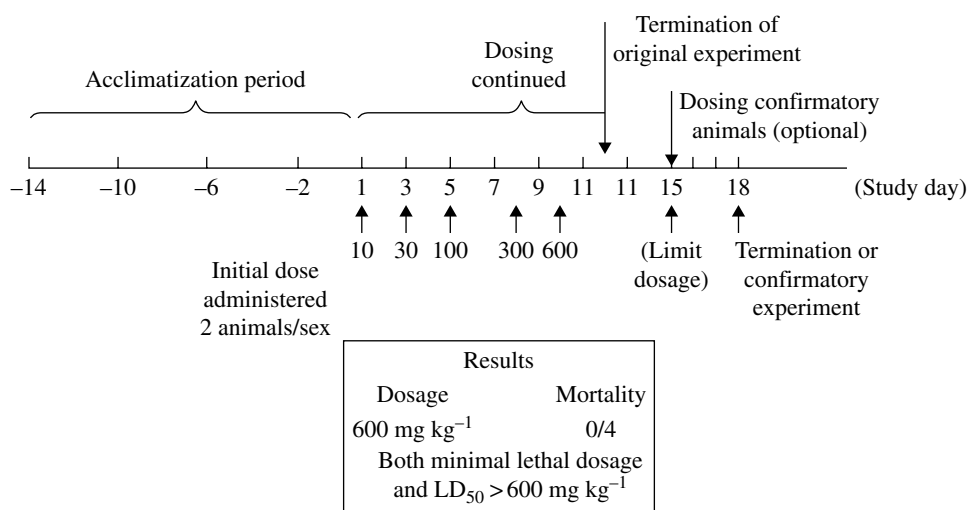

FIGURE 8.4 Example of typical pyramiding dose protocol.

FIGURE 8.5 Example of typical “leapfrog” dosing protocol.

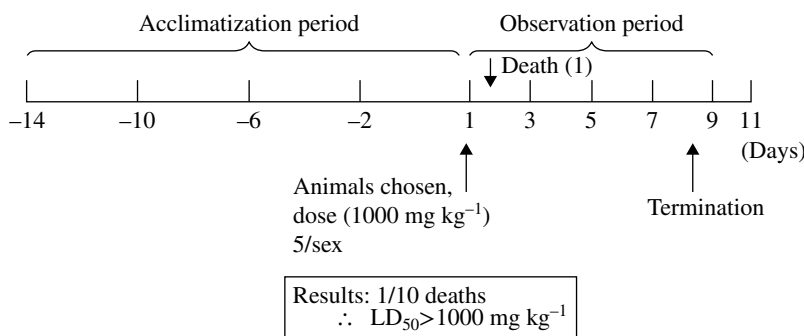

FIGURE 8.6 Example of typical limit test protocol.

method cannot identify delayed deaths. If an animal, for example, dies 1 h after the second dosage, one has no way of determining whether it was the second dosage or a delayed effect of the first. For this reason, it is of little value to observe the animals for any more than a few days after the last dosage. Third, if the test article has an unusually long half-life, bioaccumulation can lead to an underestimation of the acute lethal dosage. By contrast, the pharmacological accommodation can lead to a spuriously high estimate of lethality. Depending on the importance of the finding, one may wish to confirm that the results obtained at the highest dosage administered were obtained while dosing two naive animals at the same dosage. Fortunately, the minimum 48-h period between dosing sessions will minimize such effects. Because of this design feature, it may take as long as 3 weeks to complete the dosing sequence. However, in these types of studies as there is generally no need for a 1–2-week postdosing observation or holding period, the actual study may not take significantly more time than a test of more traditional design.

Keep in mind that the objective of such studies is to gain information about lethality and gross tolerance for use in setting doses in more extensive studies. For nonrodents (especially monkeys), if none of the animals die or demonstrate obvious signs of toxicity, little would be gained by euthanization and necropsy of such animals. They can be saved and used again, following a reasonable “washout” period, to assess the lethality, toxicity, or safety pharmacology of a different chemical. Indeed, given the emphasis on moving smoothly through development, while necropsy and organ weights may provide useful data in an acceptable time frame, the same is not true for histopathology. In the hands of a skilled toxicologist, such adaptive reuse of animals is a cost-effective way to minimize overall usage.

8.2.1.5 Limit Tests There are relatively innocuous drugs that are simply not potently lethal. The limit test (Figure 8.6) provides the simplest protocol for determining the lethality or such substances. The limit test is designed to obtain clearance

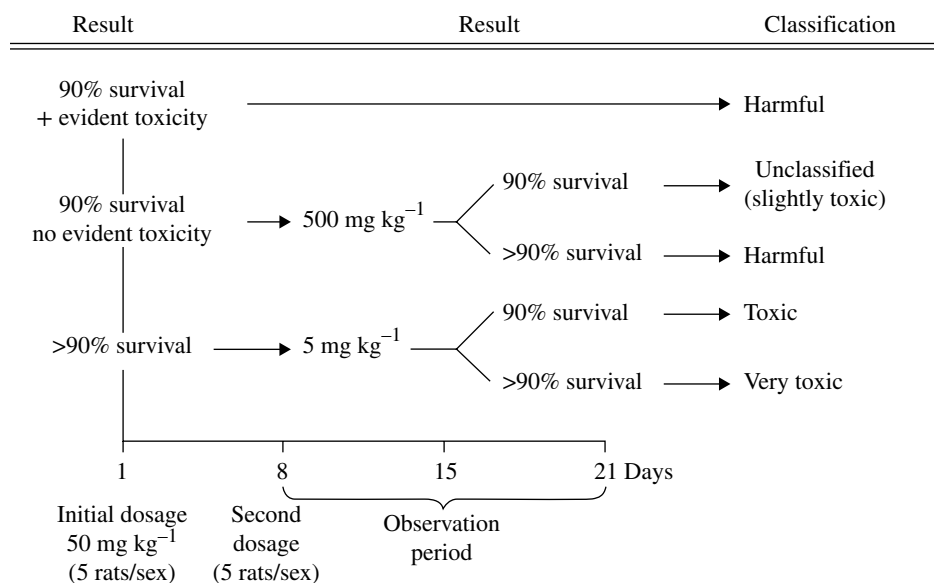

FIGURE 8.7 British Toxicology Society fixed-dose procedure.

at a specific dosage based on the assumption that what may occur at a higher dosage is not of practical relevance. Thus, one dosage only is studied. This limit “dosage” can be set on the basis of the chemical or physical properties of the test article (or vehicle) or on the basis of an upward safety margin. If the preparation is highly acidic ($\text{pH} < 3$), a large intravenous dose would be expected to cause systemic acidosis as well as local irritation but will yield little relevant toxicology information, as such a preparation would never be approved for clinical use. Alternately, if the anticipated human dosage of a drug is 0.3 mg kg^{-1} , there is probably little reason to test dosages in excess of 300 mg kg^{-1} ($1000\times$ the expected human dosage). In general, there is never any reason (or regulatory requirement) to use dosages of more than 1.5 g kg^{-1} .

There are three possible outcomes to a limit test. If none of the animals die, then the conclusion is that the MLD is greater than the limit dosage. If fewer than 50% of the animals die, then the conclusion is that the LD_{50} is greater than the limit dosage. If more than 50% of the animals die, then one has a problem. Depending on the reasons for performing the test, one could reset the limit and repeat the study, or one could assess lethality by a different protocol. Alternatively, the change in the limit could reflect a change in the chemical or biological properties of the test substance that should be evaluated further.

8.2.1.6 Fixed-Dose Procedure The fixed-dose design (Figure 8.7) was proposed by the British Toxicology Society (1984). It is designed to supply the data needed for classification or labeling purposes. It is essentially a three-step limit test.

Five rats per sex are given 50 mg kg^{-1} . If survival is less than 90%, a second group of animals is given 5 mg kg^{-1} . If

survival is again less than 90%, the substance is classified as “very toxic”; otherwise, it is classified as “toxic.”

If, after the 50 mg kg^{-1} dose, survival is 90%, but there is evident toxicity, no further dosages are given, and the substance is classified as “harmful.” If, on the other hand, there is no evident toxicity at 50 mg kg^{-1} , another group of rats is given 500 mg kg^{-1} . If there is again 90% survival and no evident toxicity, the substance is given “unclassified” or “slightly toxic” status.

The fixed-dose procedure is relatively new and apparently results in a large decrease in animal usage. It is also noteworthy in that it utilizes not only lethality but also “evident toxicity,” which, in all likelihood, refers to obvious signs of CNS effects, such as seizures or prostration. It remains to be established whether or not this protocol design becomes widely accepted by various regulatory.

The potential utility of the fixed-dose procedure was demonstrated in an international validation study in which the acute oral toxicity of 20 different chemicals was evaluated using both the fixed-dose and classical LD_{50} procedures. Thirty-three laboratories in eleven different countries were involved in the validation project, and the results have been published (van den Heuvel et al., 1990). The results demonstrated that the fixed-dose procedure produced consistent evaluations of acute toxicity that were not subject to significant interlaboratory variation and provided sufficient information for hazard identification and risk assessment based on signs of toxicity (clinical signs, time to onset, duration, outcome, etc.). The fixed-dose procedure used fewer animals than the classical LD_{50} tests and generally required less time to complete. Because of the emphasis on toxicity (rather than mortality) and the use of fewer animals, the fixed-dose procedure could be considered a more “humane”

TABLE 8.2 Comparison of Toxicity Classification Based on LD₅₀ versus Fixed-Dose Procedure

Test Chemical	Toxicity Classification Based on LD ₅₀	Fixed-Dose: Number of Laboratories Classifying Chemical			
		Very Toxic	Toxic	Harmful	Unclassified
Nicotine	Toxic	—	23	3	—
Sodium pentachlorophenate	Harmful	—	1	25	—
Ferrocene	Harmful/unclassified	—	—	3	—
2-Chloroethyl alcohol	Toxic	—	19	7	—
Sodium arsenite	Toxic	—	25	1	—
Phenyl mercury acetate	Toxic	2	24	—	—
<i>p</i> -Dichlorobenzene	Unclassified	—	—	—	26
Fentin hydroxide	Toxic	—	8	17	1
Acetanilide	Harmful	—	—	4	22
Quercetin dihydrate	Unclassified	—	—	—	26
Tetrachlorvinphos	Unclassified	—	—	1	25
Piperidine	Harmful	—	2	24	—
Mercuric chloride	Toxic	—	25	1	—
1-Phenyl-2-thiourea	Toxic/harmful	12	12	2	—
4-Aminophenol	Harmful	—	—	17	9
Naphthalene	Unclassified	—	—	—	26
Acetonitrile	Harmful	—	—	4	22
Aldicarb (10%)	Very toxic	22	—	—	—
Resorcinol	Harmful	—	—	25	1
Dimethyl formamide	Unclassified	—	—	—	26

or animal-sparing design than the classical LD₅₀ test. When the results of the fixed-dose and LD₅₀ tests were compared for hazard ranking purposes (Table 8.2), comparable results were obtained. Thus, it would appear that the fixed-dose procedure has utility and has been recommended late in 2000 for broad regulatory adaptation by ICCVAM.

8.2.1.7 “Rolling” Acute Test The rolling acute test is a combination protocol that is designed to find a tolerated dose to use for a subchronic toxicity test. The first segment can be either a dose probe or an up/down or pyramiding type of study to define the MLD. In the second segment, three to five animals are dosed for as short period of time—5 to 7 days. The objective of this design is to compensate for the fact that cumulative toxicity can occur at substantial differences in acute and subchronic toxic dosages. One can be easily misled by selecting subchronic dosages based entirely on acute lethality data. An example is a drug tested, where it was found that 360 mg kg⁻¹ was acutely nonlethal and the MLD was 970 mg kg⁻¹. The dosages selected for the four-week subchronic study were 50, 100, 200, and 400 mg kg⁻¹ day⁻¹. The top-dose animals all died within a week. Substantial mortality occurred at 200 mg kg⁻¹ and evident toxicity was present at 50 mg kg⁻¹. A no-effect dosage was not identified, so the entire test had to be repeated with a different dosage structure. The rolling acute structure is a quick and relatively simple “sanity” check that permits one to avoid making such mistakes.

8.2.2 Using Range-Finding Lethality Data in Drug Development: The Minimum Lethal Dose

Range-finding data are often used early in drug development to make preliminary safety estimates. The LD₅₀ is simply a calculated point on a curve. The shape or slope of this curve is also an important characteristic of the test substance. However, unless one does a great deal of acute toxicity testing, the difference between a slope of 1.5 and a slope of 4 has very little meaning. Further, for safety considerations, the dosage that kills 50% of the animals is not as important as the dosage at which lethality first becomes apparent (i.e., the threshold dosage or MLD). For example, if the oral LD₅₀s of two different drugs (A and B) were 0.6 and 2.0 g kg⁻¹, respectively, what would we conclude about the relative safety of these compounds? Further, let us assume that the estimated human dosage of drug A is 0.5 mg kg⁻¹ and of drug B is 5 mg kg⁻¹. Do our conclusions concerning the relative safety of these two drugs change? In fact, the LD₅₀s of both drugs are so high that both are considered only slightly toxic (0.5–5.0 g kg⁻¹). One can also compute the lethality safety margin or index (LSI, equal to LD₅₀/EHD, where EHD = the estimated human dose) for these two drugs; both indices are so large (1200 for A and 400 for B) that there is still no toxicologically relevant difference between the two drugs. Let us now assume that the lethality curve for substance A is very steep, such that 0.4 g kg⁻¹ causes death in a very small percentage of animals—it is, in fact, the lowest dose

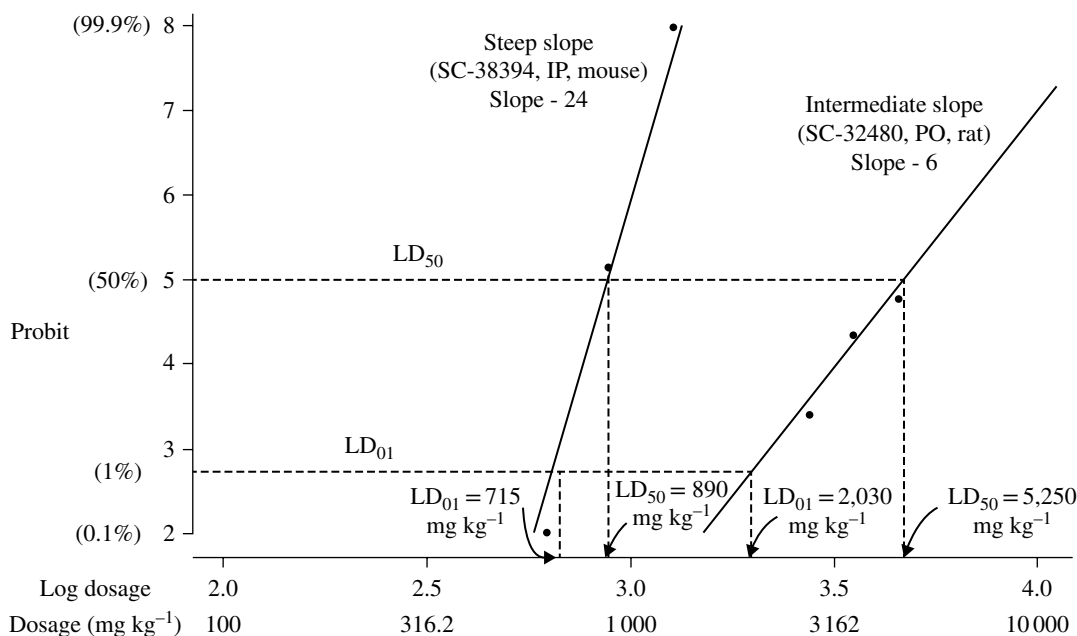

FIGURE 8.8 Examples of probit–log dosage response curves illustrating differences in slope curves and the relationship between the slope, LD_{50} , and LD_{01} .

administered that causes death. This is the MLD or estimated MLD (EMLD). Let us now assume that the lethality curve for B is very shallow, such that its MLD is also 0.4 g kg^{-1} . Does this change our safety considerations of these two drugs? One can calculate a new more conservative safety index (MLD/EHD) of 800 for A and 80 for B. As a very general rule of thumb, an index for lethality of less than 100 is cause for mild concern, one less than 10 is a cause for caution, and one less than 1 should be cause for extreme caution. In the case of our two hypothetical drugs, the development of drug B should be approached with more caution than that of drug A, despite the fact that B has a higher LD_{50} . This is demonstrated in Figure 8.8. There are drugs sold over the counter, however, that have LSI of less than 10. For example, the MLD of indomethacin in rats is 3.7 mg kg^{-1} (from data reported by Schiantarelli and Cadell (1981)), while the maximum recommended human dose is 200 mg (2.9 mg kg^{-1} for a 70-kg person); hence, indomethacin has an LSI of 1.3. Such a finding is only cause for some caution but does not in and of itself justify restricting the use or sale of a drug. Hence, because it results in a more conservative safety factor and also takes into consideration the slope of the lethality curve, the use of the MLD rather than the LD_{50} is recommended in calculating acute safety indices.

A number of different safety factors and therapeutic indices have been proposed in the literature. Despite their similarity, some distinction should be made between these two. A therapeutic index applies only to drugs and is the ratio between a toxic dosage (TD, “toxic dose” or LD, “lethal dose”:

the toxic end point does not always have to be death) and the pharmacologically effective dosage (ED, “effective dose”) in the same species. A safety index can be calculated for all xenobiotics, not just drugs. A safety index is the ratio of likely human exposure (or dosage) and the dosage that causes death or other forms of toxicity in the most-sensitive experimental animal species. The most conservative (L)SI is obtained by dividing the maximum estimated human dosage or exposure by either the MLD or the maximum nonlethal dose (MNL D) (the highest dose tested which does not result in the death of an animal).

8.2.2.1 Minimum Lethal Dose Protocols Stating that the MLD is preferable to the LD_{50} for safety considerations is one thing, trying to determine what a specific MLD may be or could be is another. There are no commonly used experimental designs that have the MLD as an end point. Assuming a log–dose response, the MLD may become a function of group size. Theoretically, if enough animals are dosed, at least one animal could die at any reasonable dosage. There are, however, practical considerations that can and should be applied to determining an MLD. As a practical rule of thumb, we recommend that the estimated LD_{01} —the dose that would be expected to kill 1% of the experimental animals exposed—be used as an estimate of the MLD. If one already has sufficient data to describe a lethality curve, an LD_{01} can be calculated as easily as the LD_{50} . This is often the case with acute toxicity data obtained to support regulatory submission.

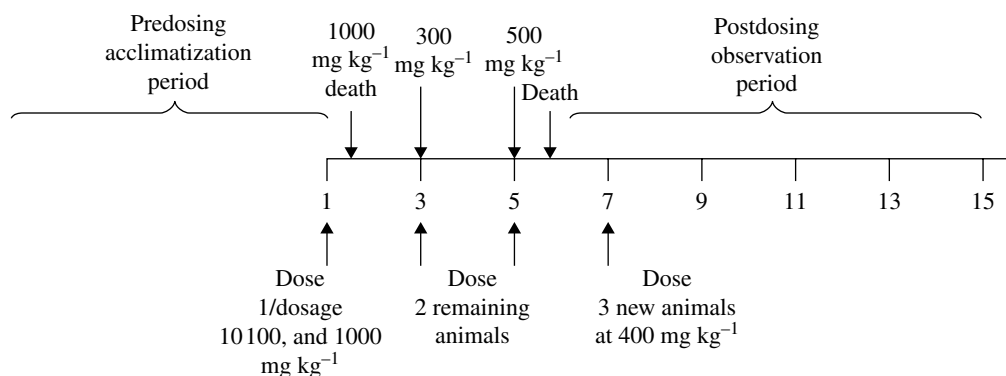

FIGURE 8.9 Example of minimum lethal dose (MLD) pyramiding dose design.

How is the MLD calculated without a complete lethality curve? A modified pyramiding dosage design may be the most appropriate approach. With this design, groups of animals are treated with stepwise increases in dosage until death occurs or a limit dosage is attained. If one has no idea as to what the initial dosage should be or how to graduate the dosages, a dose-probing experiment can be conducted. If the dose-probing experiment produces no deaths, two to three more animals can be dosed at the limit dose to confirm the results; the lethality determination is now complete. If the probe experiment does produce death, then the additional dosages can be graduated between the lowest lethal and the highest nonlethal dosages. A typical progression may proceed as follows (Figure 8.9): on day 1 of the study, three probe animals are dosed at 10, 100, and 1000 mg kg⁻¹. The animal at 100 mg kg⁻¹ dies within a few hours of dosing. The two remaining animals are dosed at 300 mg kg⁻¹ on day 3, neither dies. They are then dosed at 500 mg kg⁻¹ on day 5, one dies. Three additional animals should be dosed on day 7 or 8 at a dosage in between (i.e., 400 mg kg⁻¹ is a good estimate of the maximum nonlethal dose, or MNLD). While different by definition, there is usually not a great deal of distance between the MLD and the MNLD, as this example illustrates. In fact, even for a well-characterized lethality curve, the confidence limits for the LD₀₁ will be quite broad and encompass both the MLD and MNLD.

Malmfors and Teiling (1983) have proposed a similar method for determining what they also termed the MNLD. Rather than initiating the study with probe animals, their design calls for three consecutive pyramiding-type studies with the steps becoming increasingly smaller. For example, two animals will be sequentially dosed at 2, 200, and 2000 mg kg⁻¹. If death occurs at 2000 mg kg⁻¹, a new pair of animals is initiated at 200 mg kg⁻¹, and sequential dosages are increased by a factor of 1.8 until death occurs. Then another pair of animals is initiated at the highest nonlethal dosage, and successive dosages are increased by a factor of 1.15. The result of this exercise will be two dosages, one apparently nonlethal and the other lethal. Six animals are dosed at each dosage. If none dies at the lower dosage and one dies at the higher dose, then the lower dose is

considered to be the MNLD. At least 24 h between dosing rounds are recommended. While this method may have some utility, there are some disadvantages. First, the recommended limiting dosage of 6.5 g kg⁻¹ is too high. Second, 24 h between doses may be too short a period to allow for recovery. Third, even with only 24 h between doses, this is a time-consuming procedure—it may take up to 2 weeks to complete the dosing. Finally, it does not decrease the number of animals needed, since it may use 18–20 animals.

Dose probing is not generally used for nonrodents (rather, the pyramiding dose scheme is), and the initiating dosage is normally in the range of 1–5 times the projected human clinical dosage. The limit is generally in the area of 1 g kg⁻¹ or 100–200 times the human dosage, whichever is less. The normal study will include two animals of each sex treated with the test article. For simple lethality, there is seldom any need to include control animals. If the projected human dosage is 4 mg kg⁻¹, for example, the initial dosage in an MLD range finder in dogs will be 20 mg kg⁻¹, and succeeding dosages will increase stepwise at half-log intervals; thus, 20, 60, 200, and 600 mg kg⁻¹ doses are separated by at least 48 h. The MLD is simply reported as being between the highest observable nonlethal and the lowest lethal dosages, or at greater than the limit dosage—in this case, 600 mg kg⁻¹. Studies should not be done with nonrodents solely for determining lethality, because this would not be an appropriate use of time and animals. Generally, these studies should also include some combination of extensive physical examinations, such as ECGs and rectal temperatures, careful observations of behavior and activity, and extensive clinical laboratory workups after each dose.

The pyramiding dose study is not without disadvantages. First, the small number of animals used can cause simple random variation resulting in misestimation of lethality. It is a well-accepted statistical maxim that the smaller the sample size, the greater the impact of any random variation (error or outlier) on the population characteristic. This may be especially true for a nonrodent species where experimental animals are drawn from an outbred population. Second, the pyramiding dose regimen can permit the development of

tolerance. For example, pyramiding dosage studies were conducted to range-find dosages for a two-week study on a 1,4-benzodiazepine. Lethality in dogs was observed at 600mg kg^{-1} in the pyramiding study. For the subsequent sub-chronic study, the top dose was set at 300mg kg^{-1} ; both dogs died of CNS depression of the first day of dosing.

8.3 ACUTE SYSTEMIC TOXICITY CHARACTERIZATION

Acute systemic toxicity studies are performed to define the acute toxicity of a drug more completely. They are more extensive and time-consuming than range-finding tests or screens and are normally the type of study done to satisfy regulatory requirements or to provide a more thorough early characterization or prediction of toxicity (McClain, 1983). In pharmaceutical development, rarely would an acute test be sufficient to support registration, but it could support an exploratory IND first-in-human single-dose study (USFDA, 2006) or a single human dose study of an imaging agent, and it may be required as part of an overall package. These protocols may resemble range-finding tests, but they call for a collection of more data. A list of the types of data that can be obtained in well-conducted acute toxicity tests is given in Table 8.3. Given that these studies usually include control groups, the classical or traditional design is the most common because it allows for the most straightforward statistical analyses. In addition, while the use of staggered dosing days for different groups is still a fairly common practice, data analyses may be more sensitive if all animals are dosed on the same day, requiring that one have preliminary range-finder data that permit selection of appropriate dosages. Studies of more than one species and/or more than one route should be limited to those instances where they are required by statute.

In general, traditionally designed acute toxicity tests can be divided into three types that can be called the minimal acute toxicity test, the complete acute toxicity test, and the supplemented acute toxicity test. Of these, the minimal protocol is by far the most common and is discussed first. The other two represent increasing orders of complexity as additional parameters of measurement are added to the basic minimal study.

8.3.1 Minimal Acute Toxicity Test

An example of a typical minimal acute toxicity test protocol is shown in Figure 8.10. This study resembles a traditional lethality test in terms of the number of groups and the number of animals per group. Standard protocols consist of three or four groups of treated animals and one group of control animals, each group consisting of five animals per sex per dosage. Traditionally, the emphasis in these types of studies was on determining the LD_{50} , time to death, slope of

Relationship between plasma levels and occurrence of clinical signs

the lethality curve, and the prominent clinical signs, as illustrated by the data reported by Jenner et al. (1964). More recent designs specify, in addition to lethality and clinical observations, that body weights be recorded during the study and gross necropsies performed at the end of the postdosing observation period. For an excellent example of a well-performed acute toxicity evaluation, the reader is referred to the paper by Peterson et al. (1987) of the acute toxicity of the alkaloids of *Lupinus angustifolius*, in which the LD_{50} s, time to death, clinical signs, body weight effect, and gross necropsy findings were all discussed. For pharmaceuticals, where acute toxicity data for more than one species are often required, these studies will be done as batteries on both rats and mice. In addition, because many drugs will be given by

FIGURE 8.10 Example of minimal acute toxicity protocol.

more than one route to human patients, these batteries will include groups treated by two different routes. Thus, an acute study on a pharmaceutical agent will often result in eight “curves”—one per route per species per sex. For tests on nonrodent species, as required for pharmaceuticals, a different design is used (discussed later).

The animals should be acclimated to laboratory conditions for 7–14 days prior to dosing. For acute toxicity tests, this pretreatment period should be more than just a holding period. Animals should be checked daily for signs of ill health and/or abnormal behavior. Body weights may also be determined. These data should be used to exclude abnormal animals from the test. Such data also provide an additional basis for interpreting the data gathered during the postdosing period. Finally, these activities acclimatize the animals to the frequent handling that is a necessary part of an acute toxicity test.

In selecting dosages for an acute systemic toxicity study, the same general guidelines apply as with lethality testing:

1. There is little to be gained from testing dosages that are so high that the physical rather than biological properties become prominent. Generally, little additional information is gained by pushing dosages past 2 g kg⁻¹. The usual regulatory limit for pharmaceuticals is now 1.5 g kg⁻¹.
2. The highest dosage should be no larger than 100–300 times the anticipated human dosage.
3. Widely spaced dosages are better than narrowly spaced dosages.

This latter point is particularly true in an acute toxicity test on a drug, because pharmacologically based clinical signs may occur at dosages considerably lower than those that cause death. Also, as discussed by Sperling (1976) and Gad (1982), the effects at high dosages may mask the effects that would be observed at low dosages. As human beings are more likely to be exposed to lower dosages than experimental animals, these low-dosage effects may be important parameters to define.

Historically, it has been stated in various regulatory communications that a well-conducted acute toxicity test should contain sufficient data to calculate an LD₅₀. This is no longer necessarily the case. Simpler, less resource-intensive range-finding protocols should be used for defining lethality. Because it is rare that an extensive acute protocol would be attempted without preliminary lethality data, the lethality objectives of acute systemic testing are not always critical. Ideally, the highest dosage should elicit marked toxicity (such as lethality), but it does not need to kill all of the animals to satisfy one’s need to show due diligence in stressing the test system. If one already has sufficient preliminary data to suspect that the top dosage will be nonlethal or otherwise innocuous, the test can be conducted as a limit test, consisting of one treated group and one control group.

8.3.1.1 Clinical Signs The nonlethal parameters of acute toxicity testing have been extensively reviewed by Sperling (1976) and Balazs (1970, 1976). Clinical observations or signs of toxicity are perhaps the most important aspect of a minimal acute toxicity test because they are the first indicators of drug- or chemical-related toxicity or morbidity, and they are necessary in the interpretation of other data collected. For example, body weight loss (or a reduction in body weight gain) would be expected if an animal had profound CNS depression lasting several hours.

With regard to clinical signs and observations, there are some basic definitions that should be kept in mind. Symptomatology is the overall manifestation of toxicity. Signs are overt and observable events (Brown, 1983). Symptoms are the subjective impressions of a human patient (e.g., headache) and cannot be described or reported by speechless animals (Balazs, 1970). Clinical signs can be reversible or irreversible. Reversible signs are those that dissipate as the chemical is cleared from the body or tolerance develops (Chan et al., 1982) and are generally not accompanied by permanent organ damage. Irreversible signs are those that do not dissipate and are generally accompanied by organ or tissue damage. Signs can also represent a normal biological or pharmacological

TABLE 8.4 Clinical Observation in Acute Toxicity Tests

Organ System	Observation and Examination	Common Signs of Toxicity
CNS and somatomotor	Behavior	Unusual aggressiveness, unusual vocalization, restlessness, sedation
	Movements	Twitch, tremor, ataxia, catatonia, paralysis, convulsion
	Reactivity to various stimuli	Irritability, passivity, anesthesia, hyperesthesia
	Cerebral and spinal reflexes	Sluggishness, absence of reflex
	Muscle tone	Rigidity, flaccidity
Autonomic nervous system	Pupil size	Miosis, mydriasis
Respiratory	Nostrils	Discharge (color vs. uncolored)
	Character and rate	Bradypnea, dyspnea, Cheyne–Stokes breathing, Kussmaul breathing
Cardiovascular	Palpation of cardiac region	Thrill, bradycardia, arrhythmia, stronger or weaker beat
Gastrointestinal	Events	Diarrhea, constipation
	Abdominal shape	Flatulence, contraction
	Feces consistency and color	Unformed, black or clay colored
Genitourinary	Vulva, mammary glands	Swelling
	Penis	Prolapse
	Perineal region	Soiled
Skin and fur	Color, turgor, integrity	Reddening, flaccid skinfold, eruptions, piloerection
Mucous membranes	Conjunctiva, mouth	Discharge, congestion, hemorrhage, cyanosis, jaundice
Eye	Eyelids	Ptosis
	Eyeball	Exophthalmos, nystagmus
	Transparency	Opacities
Others	Rectal or paw skin temperature	Subnormal, increased
	Injection site	Swelling
	General condition	Abnormal posture, emaciation

response (Chan et al., 1982). For example, an antidepressant would be expected to cause decreased activity and some ataxia. These signs are generally reversible and can lead to secondary, nonspecific signs—nonspecific in that any number of agents or stimuli can evoke the same response and secondary in that they are probably not due (at least, one has no evidence to determine otherwise) to the direct action of the test article. Responses can also be abnormal; in that they are not due to a homeostatic process. The increases in serum urea and creatinine due to kidney damage, for example, are abnormal responses. These are often irreversible, but this is not always the case, depending on the repair capacity or functional reserves of the target organ. These abnormal responses may also be called primary effects because they reflect the direct action of a test article. Agonal signs are those occurring immediately prior to, or concomitantly with, death. They are obviously irreversible but not necessarily reflective of a specific effect of a test article. For example, regardless of the cause, labored breathing will occur in a moribund animal. It is, therefore, important to distinguish between signs that occur in animals that die and those that do not. It should also be kept in mind that agonal signs may mask (make it difficult or impossible) to observe other signs, including those clearly seen at lower doses.

In their simplest form, clinical observations are those done on an animal in its cage or, preferably, in an open plane, such as on the top of a counter or laboratory cart. These are consid-

ered passive observations. One can gain even more information by active examination of the animal, such as the animal's response to stimulation. Fowler and Ruttly (1983) divide their clinical evaluation of toxicity into those signs scored by simple observations (e.g., ataxia), those scored by provocation (e.g., righting reflex), those scored in the hand (e.g., mydriasis), and those scored by monitoring (e.g., rectal temperature). Cage pans should always be examined for unusually large or small amounts of excreta or excreta of abnormal color or consistency. A list of typical observations is summarized in Table 8.4. A more extensive table has been prepared by Chan et al. (1982). Given the fact that the number of different signs displayed is not infinite and that some signs are simply easier to discern than others, most clinical signs are referable to the CNS (e.g., lack of activity), the GI tract (e.g., diarrhea), or the general autonomic nervous system (e.g., increased salivation or lacrimation). This is illustrated by an actual example set of data from acute toxicity studies summarized in Table 8.5.

Other signs can be detected by a well-trained observer but are, nonetheless, less common than those described previously. Respiratory distress can be diagnosed by examining the animal's breathing motions and listening for breathing noises. Cardiovascular signs are generally limited to pallor, cyanosis, delayed capillary refill time, and/or hypothermia. Changes in cardiac function can be difficult to detect in small animals and generally consist of “weak” or “slow” breathing. Arrhythmias

TABLE 8.5 Summary of Clinical Observations from Actual Acute Toxicity Tests

Drug (Route)	Indication	Acute Clinical Signs ^a
SC-37407 (PO)	Analgesic (opiate)	Reduced motor activity, mydriasis, reduced fecal output, hunched posture, convulsions (tonic), ataxia
SC-35135 (PO)	Arrhythmias	Reduced motor activity, lost righting reflex, tremors, dyspnea, ataxia, mydriasis
SC-32840 (PO)	Intravascular thrombosis	Reduced motor activity, ataxia, lost righting reflex, closed eyes, red/clear tears
SC-31828 (PO)	Arrhythmias	Reduced activity, dyspnea, ataxia, lost righting reflex, red/clear tears
SC-25469 (PO)	Analgesic (nonopiate)	Reduced motor activity, ataxia, lost righting reflex, dyspnea, convulsions (clonic)

can be difficult to detect because the normal heart rate in a rodent is quite rapid. ECGs are difficult to meaningfully record from rodents on a routine basis. Therefore, the assessment of potential acute cardiovascular effect of a drug or chemical is usually restricted to a nonrodent species, usually the dog. The DRF studies in nonrodents supply a place to get an initial evaluation of electrophysiological CV effects.

Given the subjective nature of recognizing clinical signs, careful steps must be taken to ensure uniformity (is the animal

depressed or prostrated?) of observation so that the data can be analyzed in a meaningful fashion. There are three ways of achieving this. First, signs should be restricted to a predefined list of simple descriptive terms, such as those listed in Table 8.4 or in Appendix B. Second, if a computerized data acquisition system is unavailable, the use of standardized forms will add uniformity to the observation and recording processes. An example of such a form is shown in Figure 8.11. Third, technicians should be trained in studies (not intended for regulatory

submission) using material of known toxicity so that all personnel involved in such evaluations are using the same terminology to describe the same signs.

Animals should be observed continuously for several hours following dosing. Times of observation should be recorded as well as the actual observations. After the first day of the study, observations generally need only to consist of brief checks for remission or change of any signs and the development of new signs of morbidity. Data should be collected in such a way that the following could be concluded for each sign: (i) estimated times of onset and recovery, (ii) the range of threshold dosages, and (iii) whether signs are directly related (primary) to the test article. An example of clinical signs provoked by a specific drug is given in Table 8.6. Incidences are broken down by dosage group and sex. These data illustrate the fact that mortality can censor (preclude) the occurrence of clinical signs. Note that reduced fecal output was a more frequent observation at the intermediate dosages because most of the animals died at the higher dosages.

Therapeutic ratios are traditionally calculated using the dose of the lowest observed adverse effect. A more sensitive therapeutic ratio could be calculated using the effective dose (ED₅₀) for the most prominent clinical sign. However, while it may be possible to describe a dosage–response curve (which may, in fact, have a different slope than the lethality curve) for a clinical sign and calculate the ED₅₀, in practice, this is rarely done. It is more common for the approximate threshold dosages or no-observable-effect levels (NOELs) to be reported. A typical minimal acute toxicity study can be summarized as shown in Table 8.7.

8.3.2 Complete Acute Toxicity Testing

An example of the next-level test, the complete acute toxicity test, is given in Figure 8.12. As stated by Dayan (1983), the value of doing more than the minimal test will depend on the nature of subsequent testing. The complete protocol is designed to provide for a more in-depth search for target

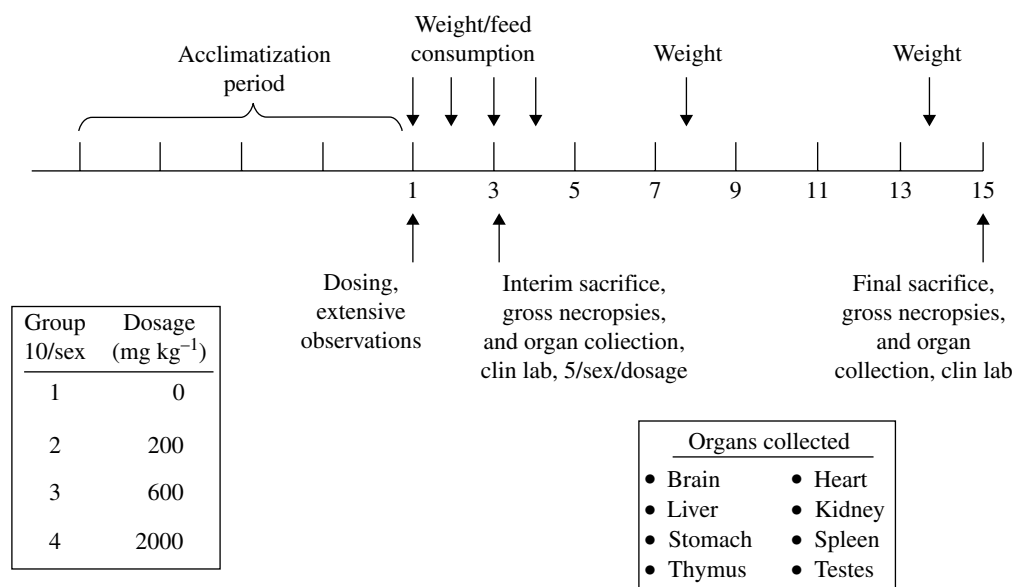

FIGURE 8.12 Example of complete acute toxicity protocol.

organs than the minimal protocol. This type of study, which has been well described by Gad et al. (1984), is similar in design to a minimal acute toxicity study but includes feed consumption data, more frequent body weight determinations, and more detailed and frequent clinical sign assessment. Groups should consist of at least 10 animals per group; 5 per sex per dosage should then be sacrificed 24–48 h for more immediate examination of any pathological changes induced by the test article. Remaining animals will be sacrificed at the end of the two-week period and examined for pathological changes. Blood will be collected at both sacrifices for clinical chemistry and/or hematology determinations. It should be noted that this design bears a striking resemblance to (is indistinguishable from) the design speci-

fied for an “expanded acute” study as required under the exploratory IND guidance (USFDA, 2006), as shown in Figure 8.13.

8.3.2.1 Body Weight Considerations Body weight and feed consumption are frequently determined parameters in toxicity testing. To an extent, the ability of an animal to gain or maintain weight may be considered a sensitive, but non-specific, indicator of health. While this is true in subchronic or chronic studies, its relevance in acute studies must be carefully considered. In most protocols, body weights are determined on day 1 (prior to dosing), day 7, and day 14, which are the days mandated by most regulatory guidelines. Despite being common, the design is not well founded: if an

* Statistically different from control (0 dosage group), *p* ≤ 0.05.

animal has not died within 7 days postdosing, it has probably recovered, and its body weight may not be noticeably different from controls by day 14. A complete protocol addresses this problem by specifying more frequent body weight determinations (daily for the first 3–5 days of the observation period) so that not only can initial decreases (if they occur) be detected but also recovery can also be charted. Feed consumption measurements should be made at the same times because it is difficult to determine the causes behind body weight changes in the absence of feed consumption data. Body weight loss accompanied by normal feed consumption implies something very different than body weight loss (or lack of gain) accompanied by lack of feed consumption. In the absence of feed consumption data, however, changes in body weight should still be considered indicative of a change in an animal's health status.

Yet another reason why body weight determinations are of questionable value in acute studies has to do with the statistical analysis of the data. Deaths may substantially alter group size and complicate analysis. The death of two of five animals

TABLE 8.9 Examples of Gross Necropsy Findings from Acute Toxicity Studies

causes a 40% decrease in group size and a substantial diminution of the power of any statistical test. In addition, the resulting data sets are censored: comparisons will often be between the control group, a dosage group where all the animals survive, and a high-dosage group where less than 50% of the animals survive to the end of the observation period. One must question the utility of body weight changes if they occur at dosages that are acutely lethal. The data in Table 8.8 illustrate this point. Body weight changes tended to occur only at dosages that were acutely lethal. Additionally, one would suspect that the censoring of body weights in groups where death occurs is not random; that is, the animals that die are most likely those that are most sensitive, while those that survive are the most resistant or robust. This problem can be addressed by building exclusionary criteria into a protocol. For example, one could statistically analyze body weight data in groups that only had less than 50% mortality.

Minimal rather than complete protocols tend to be more common in the acute testing of pharmaceutical agents. Drugs will almost always be subjected to at least one subchronic study. Body weight and feed consumption determinations are a standard feature of such studies. Additionally, changes in body weight and feed consumption are more likely in a subchronic than an acute study because the animals are dosed continuously between body weight determinations.

8.3.2.2 Pathology Considerations One of the objectives of any well-conducted toxicity study is to identify target organs. There is some question, however, concerning the utility of extensive pathological assessments as part of an acute study. Gross necropsies are generally the minimum assessments requested by most regulatory bodies. Hence, minimal protocols will include necropsies on all animals found dead and those sacrificed following the postdosing

observation period. An example of necropsy findings is given in Table 8.9. This table illustrates that gross necropsy observations on acute studies rarely predict the toxicity that will be seen when the chemical is given for longer periods of time. This is not surprising, because most drug-related histological lesions are the result of chronicity; that is, discernible lesions tend to result from the cumulative effect of dosages that are acutely well tolerated.

The data in Table 8.9 also demonstrate that substantial gross macroscopic findings are rare in minimal acute studies and seldom suggestive of a specific effect. There are several reasons for the lack of specificity. The first is the rather limited nature of gross observations, in that they are limited to broad descriptive terms (size, shape, color, etc.). The second is for animals found dead, in that it is difficult to separate the chemically associated effects from agonal and/or autolytic changes. Finally, it is difficult to come to a conclusion about the nature of a gross lesion without histological assessment.

If there are any identifiable gross lesions, they often differ between animals that die and those that survive to the end of the observation period. The reason for these differences is very simple. An animal that dies less than 24 h after chemical exposure probably has not had sufficient time to develop a well-defined lesion. As mentioned earlier, most deaths occur within 24 h. Animals that survive for the two-week observation period have probably totally recovered and rarely have apparent lesions. Hence, the animals that provide the best chance to identify test-article-specific lesions are those that die in the region of 24–96 h postdosing. This is, in fact, one of the problems with acute pathology data—that is, comparing animals found dead with those sacrificed at a different time and comparing both to controls. As mentioned, a complete protocol, where groups of animals are sacrificed 24–96 h after dosing, at least partially solves this problem.

Many guidelines suggest microscopic confirmation of gross lesions “when necessary”; however, these are seldom

done because of the autolytic nature of many of the tissues collected from animals found dead. Additionally, the practice of collecting and examining only gross lesions is difficult to justify because it does not permit in-depth comparisons. Pathological findings are most easily interpreted when the same organs are collected and examined from all animals on a test regardless of the circumstances of death. Elsberry (1986) recommends that the GI tract, kidney, heart, brain, liver, and spleen be specifically examined routinely in acute studies. Given the timing issues discussed in the previous paragraph, the amount of effort may not be worth the result. In an attempt to address these problems, Gad et al. (1984) have developed a complete protocol that includes groups of satellite animals that are sacrificed 48 h after exposure and necropsied, and a standardized organ list is collected, weighed, and prepared for histological assessment. This list routinely includes the “first-line” organs: brain, thyroid, liver, kidneys, heart, and adrenals. The same organs are collected from all other animals, that is, those that die as a result of the toxicity as well as control animals. Additional tests can be included if one has a specific concern. For example, the structure of a test article may suggest that it has anticholinesterase potential. Therefore, one could include serum pseudocholinesterase determinations in the clinical laboratory package, as is frequently done for organophosphate and carbamate structures.

8.3.2.3 Supplemented Acute Studies An example of the third-level acute toxicity test, a supplemented study, is given in Figure 8.14. Such tests are rarely performed but are of use when one wishes to obtain data other than descriptive toxicity data, for example, the addition of satellite groups of animals to be dosed with a radiolabeled compound to gain pharmacokinetic information which turns a “complete” study into a “supplemented” one. Another common practice is the addition of other examinations or measurements to gain more information about a potential target organ. An

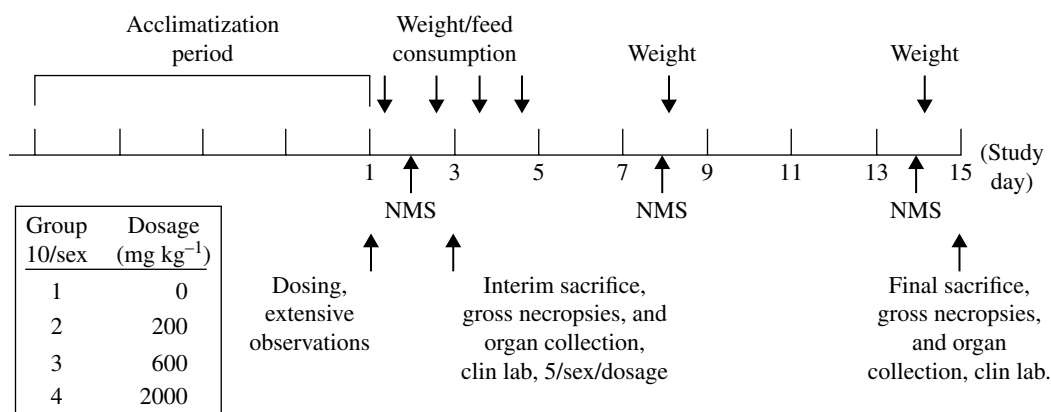

FIGURE 8.14 The design and conduct of a supplemented (or “heavy”) acute systemic toxicity study. The figure illustrates the approach to such a study when it is to serve as the definitive systemic toxicity study for some period of time.

example of this would be recording EKGs in rats, which is too complicated and time-consuming to do on a routine basis but should be considered if the heart is a potential target organ. One way of describing such a study is that it is a complete toxicity study carrying a specific screen “piggyback.”

An excellent example of a supplemented protocol is that described by Gad et al. (1984). A neuromuscular screen was developed (Gad, 1982) and incorporated into their routine acute toxicity protocol for testing nonpharmaceuticals. Doing so allowed for the more systematic and quantifiable examination of effects of the CNS than reliance on simple clinical observations. The neuromuscular screen consists of a battery incorporating standard clinical observations plus some behavioral assessment techniques already described in the literature. These are summarized in Table 8.10. This screen has been further developed to become the now regulatorily required functional observational battery (FOB). An advantage of this screen is that it uses noninvasive techniques and, therefore, will require the use of no additional animals. If an animal is displaying signs of severe CNS depression 2 h postdosing, little useful data will be gathered by examining behavior. In testing a pharmaceutical, it is probably a better practice to apply the neuromuscular screen on days 2, 7, and 14, postdosing in an attempt to identify more subtle or lingering effects and to chart recovery from these effects. For drugs that produce no observable CNS effect following dosing, the neuromuscular screen can be done a few hours postdosing. The more extensive and detailed nature of the data generated by the neuromuscular screen permits more confidence in the conclusion that the test article had no effect on the CNS. As will be discussed in a later chapter, the FOB has been modified for use in rats, mice, dogs, primates, and minipigs. Any suspect target organ can be investigated in a similar fashion. Depending on the invasiveness of the supplementary techniques, satellite groups may or may not need to be added to the study. Care must be taken in this regard to prevent the study from becoming too cumbersome and too complicated to conduct. It may be better to address some questions as separate studies. For this reason, one should not attempt to address more than one supplemental question in any one study.

8.3.3 Acute Toxicity Testing with Nonrodent Species

The designs described thus far for acute toxicity testing generally assume that the test species being used is a rodent. Nonrodent species are also used for acute toxicity testing. Many regulatory bodies require acute testing in at least one nonrodent species. The animals most often used are the dog, pig, or monkey. Veterinary products will also be tested in the target species. For example, a flea collar intended for cats must be tested in cats. While the rabbit is not technically a rodent, it is the species of choice for a variety of tests

^a Data quantal (Q), scalar (S), or interval (N). Quantal data are characterized by being of an either/or variety, such as dead/alive or present/absent. Scalar data allow one to rank something as less than, equal to, or greater than other values, but one cannot exactly quantitate the difference between such rankings. Interval data is continuous data where one can assign (theoretically) an extremely accurate value to a characteristic that can be precisely related to other values in a quantitative fashion.

^b Peripheral (P), sensory (S), muscular (M), or central (c).

for assessing acute oral or intravenous toxicity and is considered a rodent for regulatory purposes. The section is written with the dog and monkey in mind. Clearly, there are some profound differences between these species and rodents with regard to handling, husbandry, and dosing. Here, we focus on the design differences in toxicity testing in large species.

For financial, procurement, and ethical reasons, acute systemic toxicity tests on nonrodents are not performed using traditionally designed animal-intensive protocols. The minimal acute study requires 30–50 animals. Complete and supplemented studies will usually require even more. At a cost of \$15 000.00+ per nonhuman primate, \$2000.00 per minipig, or \$5000.00+ per nonhuman primate, the animal costs alone are enough to make such studies with these species prohibitively

FIGURE 8.15 Example of pyramiding dose study for acute toxicity testing in a nonrodent species.

expensive. Vivarium space and husbandry costs are also much higher with nonrodent species than with rodents. Nonrodents also require a much longer prestudy quarantine period than rodents: at least 6–8 weeks for dogs and pigs and 18–24 weeks for monkeys. Treatment during the quarantine period is more extensive than that given to rodents. The animals should be given frequent physical examinations including complete clinical laboratory panels and appropriate tests for common illnesses and parasites. Special care must be taken with monkeys not only because they can be vectors of human disease, but also because they can contract human diseases and a sick animal can compromise study outcome. All these factors dictate that these animals should be sparingly used. Hence, it is most common to study acute systemic toxicity in nonrodent animals using a pyramiding dosage design. The typical study will consist of two treated animals per sex and two control animals per sex for a total of eight animals. A typical protocol is shown in Figure 8.15.

The use of fewer but larger animals permits more extensive observations of each individual animal. Following each dose, animals can be given complete physical examinations that include palpations, behavioral checks, spinal reflex checks, pupillary light reflexes, respiration rate, ECG recording, and rectal temperature measurement. Blood samples can also be collected following each dose to determine standard clinical chemistry and hematology profiles. Hence, while fewer animals are used with the pyramiding dosage protocol, more information per animal is collected.

The small number of animals used in a pyramiding dosage study makes it difficult to do standard statistical comparisons. This difficulty can be overcome to a certain extent by taking advantage of two design aspects of the pyramiding protocol. First, pretreatment data can and should be obtained on all animals for all parameters examined or determined. In-study comparisons should be made both to pretreatment data and to concurrent control animals. Such comparisons can be made

not only on the basis of absolute numbers but also on the magnitude of any changes from pretreatment values. Second, all animals should be measured repeatedly throughout the study. Hence, to reflect a true drug-related effect, the magnitude of change should increase following each dose (though one must be aware of the potential for the development of tolerance as induction of metabolism). This is, in fact, the only way one can make any dosage–response or threshold conclusions using the pyramiding protocol.

Seldom are drugs tested in nonrodent animals via routes other than the intended or likely routes of human exposure. Hence, the most common routes in these types of protocols are oral, intravenous, and respiratory. Rarely is a test article given to nonrodent species by the intraperitoneal route. Routes are discussed elsewhere in detail (Gad and Chengelis, 1999), but some discussion is appropriate here because of design considerations. Test articles are normally given orally by capsule to dogs and pigs and by gavage to monkeys. Nonrodents have to be restrained if dosed by gavage, making the process very labor-intensive. This is minimized by the small number of animals specified by the pyramiding protocol. In contrast, because of the differences in size, it is much easier to deliver a test article intravenously to nonrodents than to rodents. For topical studies, the rabbit is the nonrodent choice because it is easier to prevent a rabbit from grooming the delivery site and considerably less material is required to deliver a comparable dose to a rabbit than a dog or pig. Acute dermal studies are not, however, usually done with a pyramiding study design but rather as a limit dose study.

The biggest problem with the pyramiding protocol is the development of tolerance. If no toxicity is observed, the chemical could be innocuous or animals could have developed tolerance during the study. The escalating dosage feature of the pyramiding protocol is an excellent vehicle for fostering the development of tolerance. One can check this by dosing additional naive animals at the limit dosage to confirm,

as it were, a negative result. Another problem, which is most peculiar to the dog, is emesis. Oral administration of a large amount of almost any material will cause a dog to vomit. This is always somewhat of a surprise to toxicologists whose prior experience is primarily with rodents, which cannot vomit. One should pay close attention to dogs the first hour after capsule delivery. If the dog vomits up most of the dose, the actual dosage absorbed could be grossly overestimated. This can be a particular problem if one is using the results of a pyramiding dosage study to set the dosages for a repeat-dose study. Dogs can develop tolerance to the emetic effect of a set dosage. When this occurs, absorption and resulting blood concentrations of a test article can increase dramatically, resulting in more florid toxicity than expected on the basis of the pyramiding study. Another problem is that emesis can result in secondary electrolyte changes—especially decreases in chloride—that may be mistaken for a direct effect of the test article. If emesis is a severe problem, one can study toxicity in a different nonrodent species or divide larger dosages into two or three divided dosages on the day of dosing.

As with traditionally designed rodent studies, the pathology component of pyramiding studies usually consists of gross necropsies followed by (when appropriate and necessary) histological assessment of gross lesions. Unfortunately, this study design does not permit the establishment of a dose–response relationship with regard to gross necropsy findings. In addition, the small number of animals makes definitive conclusions difficult. Usually, gross lesions are defined in absolute terms with few comparisons to control animals. Suspected target organs should be further investigated in subsequent subchronic studies or in rigorous and specific mechanistic studies. Because of the limited value of the pathology data generated by the pyramiding protocol, control animals should not be terminated, but rather should be saved for reuse.

8.3.4 Factors that Can Affect Acute Tests

Many investigations into the sources of variability in acute toxicity testing have been conducted, and these have been reviewed by Elsberry (1986). The factors causing the greatest interstudy variation included lack of specifications for sex, strain, age, and weight range. When clearly defined, detailed protocols were used, interlaboratory variation was found to be minimal. Hence, it is equally important that the details of the protocol be well described and followed. It is not appropriate to draw dosage–response conclusion by comparing groups that differ substantially in age or that have been fed, fasted, or otherwise manipulated differently. Guidelines for standardization of acute toxicity testing were proposed by the interagency regulatory liaison group (Interagency Regulatory Liaison Group (IRLG) Office of Consumer Affairs, 1981; Elsberry, 1986). These do not differ markedly

from those mandated by the Toxic Substance Control Act of 1986 (Gad and Chengelis, 1999).

8.3.4.1 Number, Size, and Sex of Dosage Groups The precision with which lethality and signs of toxicity are described will depend on the number of groups (hence, dosages) and the number of animals in each group. Between 1940 and 1980, the standard was to use from four to six dosages with 10 animals per dosage. The current emphasis is on limiting the number of animals used for acute testing, particularly with recognition of the limited value of “precise” lethality data (Gad and Chengelis, 1999). Retrospective analyses by DePass (1989) and Olson et al. (1990) have demonstrated that decreasing group size to two to three animals generally has little impact on overall study results. Hence, the number and size of dosage groups will depend, to an extent, on the methods of statistical analysis. The classic statistical methods for analyzing lethality data (or, indeed, any quantal dosage–response data) were published between 1930 and 1960 and have been extensively reviewed by Armitage and Allen (1959) and Morrison et al. (1968). These methods are mentioned here with regard to the demand they make on protocol design—specifically, the number of dosage groups, the spacing of the dosages, and the number of animals per dosage group. The probit and moving average methods are the most commonly used today. In general, all methods of calculation and computation are more precise if the designs are symmetrical (i.e., the dosages are evenly spaced, and the group sizes are equal). The probit method, first developed by Bliss (1935, 1957) and later refined by Finney (1971, 1985), is considered to be the most precise, but it requires at least two groups of partial responses (i.e., mortality >0 , but $<100\%$). This may require dosing more than three groups until this criterion is met. It also deals ineffectively with groups that had either 0 or 100% mortality. (The most common correction for these groups is to substitute 0.1% for 0 and 99.7% for 100%.) The moving average method, first described by Thompson and Weil (1952), does not require partial responses, deals effectively with complete responses, and, therefore, can produce an acceptable estimate of an LD_{50} with as few as three groups of three to five animals each. The moving average method can also be used to design the experiment. Groups can be dosed in a sequential fashion as in a pyramiding study, with each step dictated by the moving average method. Once evidence of toxicity is observed, further dosing is discontinued. This method requires that the dosages be separated by a constant geometric factor (e.g., 2, 4, and 8 $mg\ kg^{-1}$) and that groups be of equal size. Weil (1952), and later Gad and Chengelis (1999) and Gad (2007) have published tables that allow for the easy calculation of the LD_{50} using $K = 3$ (where $K =$ the number of dosage groups -1). The LD_{50} for $K < 3$ can be easily calculated without the aid of tables. In addition, methods for estimating the confidence limits of this calculated LD_{50} have

also been published (Gad, 2007). Traditionally, the moving average method has not been extensively used because, while it yielded an estimate of the LD₅₀, it did not give the slope of the (probit transformed) lethality curve. However, Weil (1983) also published a method for calculating a slope from the same data. Hence, an estimate of the LD₅₀ and slope can be obtained from as few as three groups of three to five animals per group, provided that at least one group shows a response less than 50% and another shows a response greater than 50%.

The Litchfield and Wilcoxon (1949) plotting method was once commonly used. It is certainly a valid method, and it poses no more restrictions on study design than those imposed by the probit method. The Litchfield–Wilcoxon method has become a victim of technology as modern, handheld calculators and the ready availability of simple computer programs have made other methods more convenient to run. However, at least one software company has adopted the Litchfield–Wilcoxon method for its acute toxicity protocol package.

While much has been written about the influence of gender on acute lethality, most authors now agree that there are seldom any substantial differences in the LD₅₀ due to sex (DePass et al., 1984; Gad and Chengelis, 1999). In those instances, where there is a sex-related difference, females tend to be more sensitive than males (~85% of the time). If one is willing to accept this amount of uncertainty, only one sex needs to be tested. Alternatively, one could use only two to three animals per sex per dosage group. Schultz and Fuchs (1982) have demonstrated that, by pooling sexes, there are seldom any substantial differences in the LD₅₀ calculations between groups consisting of five per sex versus three per sex. If there are no substantial differences between sexes (i.e., 70% mortality for males and 80% for females at a dosage), the results from pooling the sexes can provide a pooled LD₅₀. For most safety considerations, an LD₅₀ derived on this basis will be acceptable and will result in the use of fewer animals.

8.3.5 Selection of Dosages

In setting dosages for acute studies, a few commonsense rules must be applied. First, the intrinsic biological and chemical activity of the test article must be considered. Zbinden and Flury-Roversi (1981) have documented several cases where lethality was of no biological relevance. The oral lethality of tartaric acid, for example, is due to the caustic action of a high concentration of acid in the GI tract. In these instances, limit tests are more appropriate tests. Additionally, it is uncommon that a completely unknown chemical will be tested. Factors such as known pharmacological profile and chemical or physical characteristics including molecular weight, partition coefficient, and the like, and the toxicity of related chemicals should be considered. For example, it is likely that a polymeric, poorly sol-

uble molecule will not be bioavailable at an initial dosage of 100 mg kg⁻¹. A full understanding of all available data will permit one to pick dosages with more confidence and, thereby, save both time and resources.

Second, no protocol will yield high-quality data if all dosages given cause 100% lethality. Therefore, one is best advised to pick widely spaced, rather than closely spaced, dosages. In general, the best dosage regimen includes a dose that will produce a high incidence of severe toxicity, another that will produce marginal toxicity, and one that will produce toxicity in between. If this pattern is obtained, adding more groups does not generally change the results. This point is illustrated by the data in Table 8.11. For two drugs, an LD₅₀ of 300 mg kg⁻¹ was obtained using six groups of 10 mice each. Essentially, the same result was obtained if the second, fourth, and sixth

groups were eliminated and not used in the calculations. Behrens (1929) noted this phenomenon almost 60 years ago.

Widely spaced dosages also decrease the likelihood of nonnormotonic data, where mortality does not necessarily increase with dosage (see Table 8.12). This can occur when the test chemical has a shallow dose–response curve and the group size is small (three to four animals). While it is possible to calculate an LD_{50} from such data, the slope and confidence limits will be inaccurate. Nonnormotonic data can also occur if the lethality is indeed biphasic. If one suspects that this is occurring, additional dosages should be examined. For safety considerations, only the first part of the curve, the lowest LD_{50} , is of importance.

8.3.5.1 Timing The greatest precision in any lethality curve is obtained when the number of experimental variables is kept to a minimum. Hence, it is best if all the animals used for determining a specific curve are dosed on the same day and, if possible, at the same time of day, which limits age-related and diurnal effects. If a total of only 15 animals are being dosed, this is not a difficult task for a single well-trained technician. However, if the test substance is of unknown lethality, it is imprudent to deliver all doses on the same day. It is common practice for a single-dosage group to be treated on the first day of an experiment and the dosages for the second and third groups to be adjusted pending the results of the first group. Generally, most acute deaths will occur within 24 h of dosing. Delayed deaths (those occurring more than 24 h after dosing) are relatively rare and generally restricted to the 72-h period following dosing (Gad et al., 1984; Bruce, 1985). Hence, waiting for 24 h between doses will generally yield sufficient data to allow the choice of the next dosage. For example, if all but one of the animals dosed in the first groups die, there is no doubt that the next dosage should be adjusted downward considerably, whether or not the final animal eventually dies. All the dosing for a single curve can be completed in 3 days. If a test article is being tested in traditional protocols (with two species, two routes, and separate sexes), the two initial groups by a route can be treated on the first day of the dosing period and the second route initiated on the next day. Subsequent dosages can be adjusted on alternate days. Little real impact on the results will occur if there are 2–3 days between dosing sets. After that, however, the increasing age of the animals may result in a change in sensitivity. As reviewed by Balazs (1976), for example, the ratios of the LD_{50} s obtained in adult animals to the LD_{50} s obtained in neonates can vary from 0.002 to 160. One can use longer observation periods between dosing days if separate animal orders are timed for delivery to ensure that all animals dosed are closer in age. As a rule of thumb, the animals should not differ in age by more than 15%; hence, the younger the animals, the smaller the age window.

8.4 SCREENS

Screens are generally not safety studies in the regulatory sense. These are the studies done, as the name implies, to examine several chemicals in order either to select those with the most desirable properties for development or to eliminate those that have undesirable properties. There is nothing novel about screening; the process has been an integral part of pharmaceutical research for decades (Irwin, 1962). In a pioneering paper, Smyth and Carpenter (1944) described a screening process for gathering preliminary toxicity data for a new chemical. In their discussion, they clearly state the underlying rationale for toxicity screening:

Opinions upon the toxicity, hazards of manufacture, and fields for safe use must be expressed regarding many chemicals which will never be produced in quantity. Large expenditures of time and money upon securing these basic conclusions is not justified. Later, when a few of the new compounds are obviously going to be made commercially, more detailed studies can be undertaken.

Screens are designed for speed, simplicity, and minimal resource expenditure. They are designed to answer positive, single-sided questions. For example, the lack of an effect in an initial screen does not mean that toxicity will not be manifested with a different formulation or in a different species. It is for this reason that a screen should not, as stated by Zbinden et al. (1984), be seen as replacements for thorough safety testing. An acute toxicity screen can be the first leg in a decision tree or tier testing process for selecting a chemical or drug candidate for development. An example of this process is given in Figure 8.16.

8.4.1 General Toxicity Screens

There are two types of acute toxicity screens. In the general toxicity screen, animals (often, for economic reasons, mice) are exposed to two or three predefined dosages of chemical. No more than three mice per dosage are necessary, and no control group is required. An example of this type of protocol is shown in Figure 8.17. The animals are carefully observed for mortality and obvious signs of toxicity, such as convulsions, but no attempt should be made to quantify the severity of a response. There is seldom any need to have an observation period of more than 4–5 days. Because of the quantal nature of the data, interpretation is straightforward. There are four possible outcomes: (i) no death or signs of toxicity seen at dosages up to $X \text{ mg kg}^{-1}$, (ii) no deaths but evident signs of toxicity seen at $X \text{ mg kg}^{-1}$, (iii) deaths but no evident signs of toxicity at $X \text{ mg kg}^{-1}$, and (iv) deaths and evident signs of toxicity both occurred at $X \text{ mg kg}^{-1}$. General toxicity screens

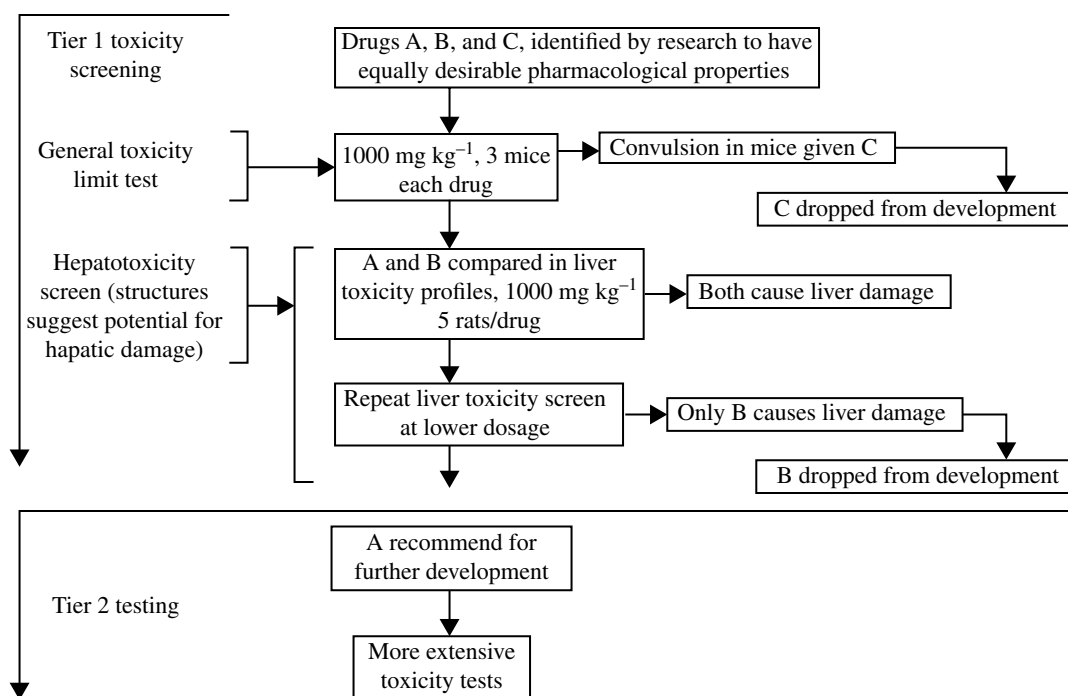

FIGURE 8.16 Example of use of screens in selecting drug candidates for development.

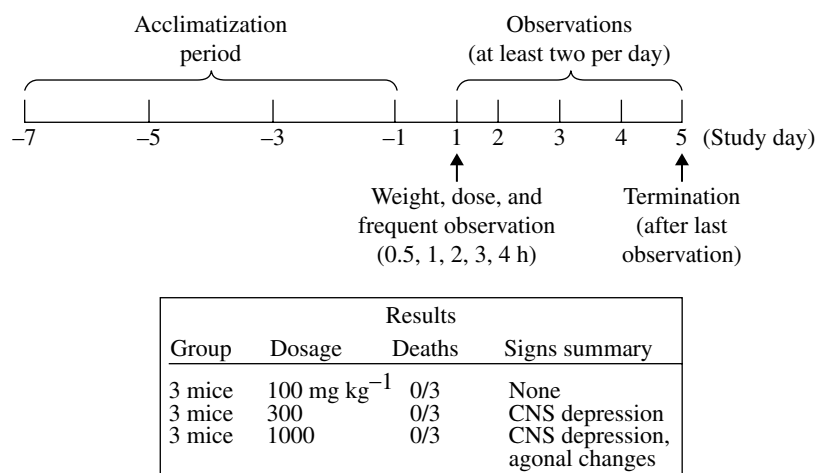

FIGURE 8.17 Example of general toxicity screen.

may also provide the preliminary information for picking the dosages for more definitive acute studies.

There are two ways to apply the data from toxicity screens to the development of a drug or chemical. On a relative basis, the drugs under consideration can be ranked according to screen results, and the one that appears to be the least toxic can be chosen for future development. Alternatively, decisions can be made on an absolute basis. All candidates that are positive below a certain dosage are dropped, and all those that are negative at or above that dosage will continue to the next tier of

testing. If absolute criteria are used, the screen need be done only at the critical dosage. If only one dosage is examined, then the test is a limit test. A limit test of this kind is the simplest form of toxicity screen, and depending on the nature of subsequent testing, it is highly recommended.

Fowler et al. (1979) have described a rat toxicity screen (illustrated in Figure 8.18) that is more extensive and detailed than the one shown in Figure 8.17. It includes two rounds of dosing. In the first round, up to 12 rats are (singly) exposed to six different dosages by two different routes for the purpose of

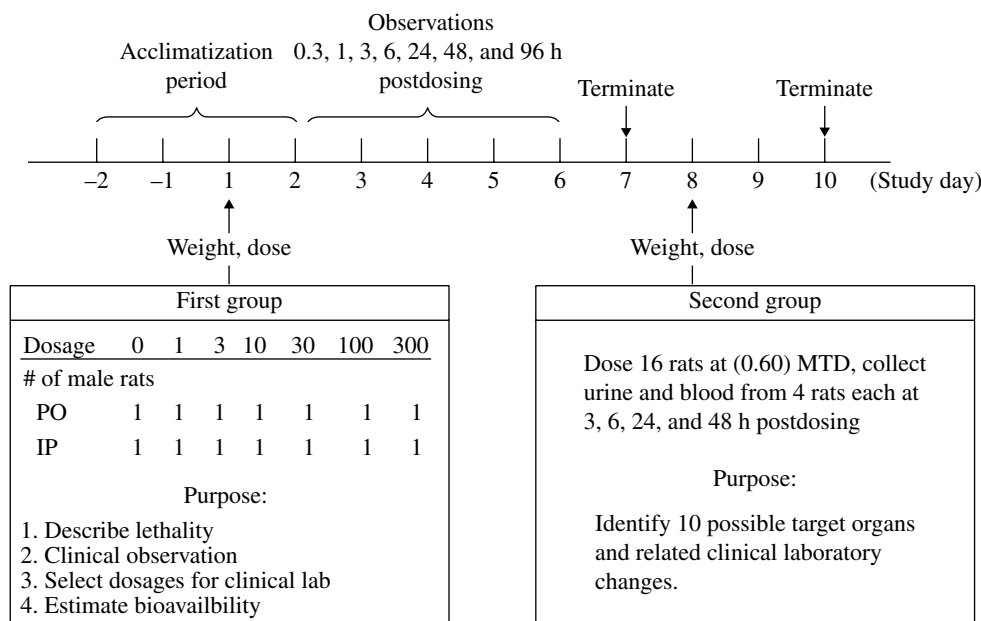

FIGURE 8.18 Example of rat toxicity screen for drugs.

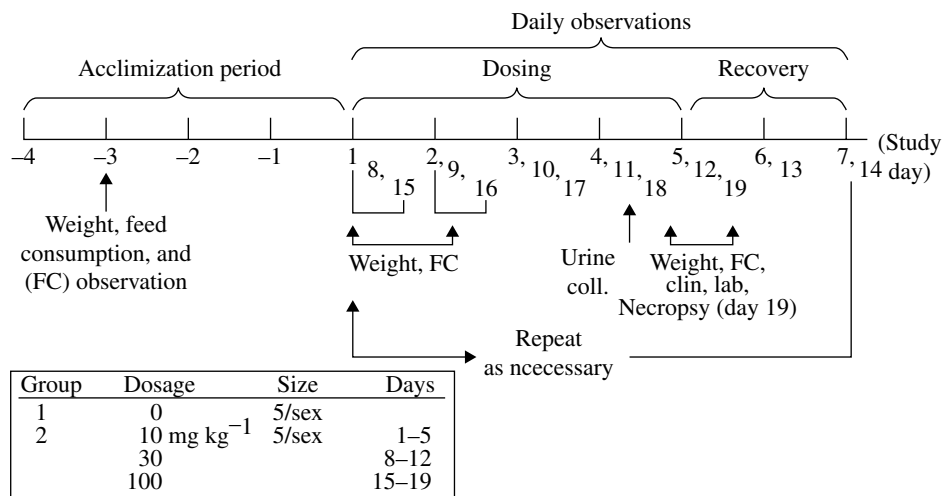

FIGURE 8.19 Example of rising dose tolerance test (no pharmacokinetic (PK) groups).

defining the MTD. In the second round of dosing, 16 rats are dosed at two-thirds (0.66) of the MTD and sacrificed on a serially timed basis for blood sample collections to determine test-article concentrations and for clinical laboratory tests. These features make this design too complicated, time-consuming, and expensive to run as an initial screen. This design is better suited as a second-tier screen to provide a more extensive follow-up study for a more limited screen. Fowler et al. contend that their screen disclosed most toxicity uncovered by more conventional studies. This screen was most successful in defining acute CNS, liver, or kidney toxicity (Fowler et al., 1979). Lesions that require long-term

exposure, such as those generally involving the eyes, may not be detected in this type of screen.

Up/down or pyramiding designs can be used for general toxicity screens, but this is not a common approach because of the time involved. In addition, if several chemicals are being compared, an up/down study where death occurs at different dosages can be complicated to run. It is much easier to test several chemicals at the same time using a limit test design. Because only individual animals are dosed, these designs can be used when there is a very limited amount of test article available and/or there are few prior data on which to base an expected toxic dosage.

Hazelette et al. (1987) have described a rather novel pyramiding dosage screen that they term the rising dose tolerance (RDT) study (illustrated in Figure 8.19). The study, which uses a subacute rather than an acute dosing regimen, can also be used as a range-finding study design. The rats are exposed for 4 days to the initial dosage followed by 3 days of recovery before the next 4-day dosing period at the next highest dosage. This process is repeated for the three dosing cycles. Plasma and urine samples are collected for clinical chemistry and urinalysis, as well as test-article determinations. Necropsies and microscopic examinations are performed. While this study design is novel, it appears to provide considerable acute data. It is also possible that this design could generate sufficient data to plan a pivotal subchronic study and, therefore, replace a traditional two-week study, resulting in considerable savings of time and animals. This is not a simple study and, therefore, inappropriate as an initial screen, but it would appear to be appropriate for a second-tier test.

8.4.2 Specific Toxicity Screening

The second type of acute toxicity screen is the specific toxicity test. This type of test is done when one has a specific toxicological concern, for example, when prior structure–activity data suggest that a family of chemicals can be hepatotoxic. A screen to select the chemical with the least hepatotoxic potential is then in order. These tests are also done, as described by Zbinden (1984), to look for a specific toxicological effect that may be easily overlooked in a route safety study. Zbinden gives, as an example, screens that are designed to detect specific lesions to the hemostatic process. As pointed out by Irwin (1962) over three decades ago, such tests have their greatest power if more than one measure of specific target organ toxicity is used. Dayan (1983) refers to this technique as a matrix of measurements. In a liver toxicity screen, for example, liver weights (both absolute and relative), gross necropsy examinations, and a battery of serum enzyme assays should all be part of the protocol. As a general rule, because of the time and expense involved, screens should be designed to minimize the use of histopathological techniques. The dosages can be standardized or set on the basis of the results of a generalized toxicity screen. Specific toxicity screens can be the next-level test in the decision tree process for selecting a candidate for development (as illustrated in Figure 8.16).

The number of animals and the number of dosages are highly dependent on the type of data gathered. A few rules of thumb should be followed: (i) keep it lean: each additional group, animal, or test article added to a protocol makes the study exponentially more difficult to conduct—simplicity is one of the most important features of a screen; (ii) the more parameters examined, the fewer the number of animals required; and (iii) if normal limits of a test parameter are relatively broad (e.g., serum glucose), more animals will be required than if the parameter is normally tightly controlled (e.g., prothrombin

time). In general, 3 is the minimum and 10 is the maximum number of animals required per group. Further, if a single chemical is examined per study, no more than three groups will be required. If more than one chemical is included in the study, then a single dosage (limit) group per chemical is the best design.

Strictly speaking, an acute toxicity study is conducted to examine the effect of a single dose of a single compound. In designing specific toxicity screens, however, deviation from this principle is permissible if it increases screen sensitivity. For example, the sensitivity of mice to many indirect hepatotoxins will be enhanced by prior treatment with phenobarbital. Hence, the sensitivity of a hepatotoxicity screen will be enhanced if the mice are pretreated for 3 days with phenobarbital.

The screen should be validated for consistency of response with both positive and negative control articles. A positive control article is one that is known to reliably produce the toxic syndrome the screen is designed to detect. Concurrent control groups are not required with each replicate. Rather, control groups should be evaluated on some regular basis to ensure that screen performance is stable. Because a screen relies on a biological system, it is not a bad idea to test the control benchmarks, particularly the positive ones, on a routine period basis. Not only does that give one increased confidence in the screen, but it also provides a historical base against which to compare the results of new test articles. Zbinden et al. refer to the positive control as the reference compound, and they have discussed some of the general criteria to be applied in the selection of these compounds (Zbinden et al., 1984). Any changes to the design should trigger revalidation. Any analytical methods should be subjected to precision, accuracy, sensitivity, and selectivity (PASS) validation.

Interpretation of specific toxicity screen data is not as straightforward as that of a general toxicity screen. This is because the data will often be continuous, following a Gaussian, or normal, distribution. This has two ramifications. First, for results around the threshold, it may be very difficult to differentiate between positive and negative responses. Second, for any one parameter, there is a real chance of false statistical significance (type I errors), especially if small numbers of animals are used. This occurrence is one of the reasons why specific toxicity screens should include the determination of more than one variable, since it is unlikely for multiple false positives to occur in the same group of animals. An undetected false positive could lead to the dropping of a promising candidate in error. False negatives, by contrast, may not be as critical (other than the time lost and the resources spent), because extensive subsequent tests should lead to the more complete description of the test article's toxic properties.

The problems described in the preceding paragraph assume that the screen will include a traditional (“negative,” or vehicle) control group and that the data from the treated groups will be compared to those of the control group by standard methods. These problems will be minimized if no control group and, therefore, no traditional statistical comparisons are

included. In addition, a decrease in the number of animals used simplifies the study. Data can be interpreted by comparison to a historical control data base as described by Zbinden (1984). The threshold, or test criterion X_c , is calculated according to the following formula:

$$X_c = m + (z)s$$

where m is the population mean, s is the standard deviation, and z is an arbitrary constant. This formula is essentially a method of converting continuous data to quantal data: it is used to determine if individual animals are over the test threshold, not if the group mean is over the threshold. Analysis of screening data by comparison to experience (i.e., historical control data) and an activity criterion are discussed in greater detail in Chapter 4 and by Gad (2007). The higher the z value, the lower the probability of a false positive, but the lower the sensitivity of the screen. Again, including multiple parameters in the screen helps alleviate this problem. Zbinden has proposed a ranking procedure in which various levels of suspicion (LOS) or a level of certainty (LOC) is assigned to the result of a toxicity screen. This is simply a formalized fashion of stating that the more animals that respond, and the greater the severity of the response, the more certainty one has in drawing a conclusion. If relative comparisons are being made, this system provides a framework for ranking test articles and selecting those to continue to the next tier of testing.

With regard to specific toxicity screening, behavioral toxicity screening is an area currently generating a great deal of interest. As reviewed by Hopper (1986), there are several reasons for this interest. First, the Toxic Substance Control Act of 1976 legislatively recognized behavioral measures as essential to examining chemicals for neurotoxic potential. Second, the structure and function of the CNS are not amenable to traditional methods of examination, in that profound behavioral changes can be induced in the absence of any detectable morphological lesions. This large and somewhat controversial subject is outside the scope of this chapter. Specific screening strategies are presented and critically discussed by Hopper (1986). Other recommended references to consult for different perspectives on acute toxicity testing are Rhodes (2000), Brown (1980), and Arnold et al. (1990).

8.5 PILOT AND DRF STUDIES

Between acute studies and the repeat-dose (14 or more typically 28 days) studies (described in Chapter 9), there are studies which are necessary to be able to set doses for the GLP studies required by regulation (ICH M3(R2) and its regional modifications) to be able to initiate initial clinical studies. These studies have evolved over time—until the mid-1990s, they were always miniature (usually 14-day) versions

of the 30-day GLP repeat-dose studies that they were meant to enable the design and dose selection. Concerns for animal usage, costs, and pressures of time have changed this.

The DRF-style studies are not required by regulation, but rather by sound scientific practice. As such, it should be noted that while the results must be included in the documents submitted to regulatory authorities, they do not have to be performed in compliance with GLPs. Their results are frequently used not just to select doses but also to justify dose selection, usually by demonstrating either that higher doses would be intolerable or (especially if TK has been performed) that there is a saturation of absorption effect making the use of higher doses meaningless, and to identify any needs for modification in the design of the studies. The studies should be conducted with dosing by the route and regimen (dose frequencies) intended for clinical studies. The formulations used should be those to be employed in the 14- or 28-day studies, but the actual drug substance (API) lot does not need to be the same (especially as the 28-day “pivotal” toxic doses should use clinical lot material).

For nonrodent species (dog, pig, or primate), dose levels are set based on the maximum tolerated dose identified in the acute pyramiding dose study. The design of that study is presented in Table 8.13.

The design for the rodent pilot study is shown in Table 8.14. Dose levels are set based on results seen in the acute study with the mid-dose typically being the maximum tolerated dose seen in that study.

As time and technology permit, as much information as possible should be collected in these studies. The hematology,

TABLE 8.13 Seven-Day Nonrodent Pilot Toxicology Study

Animal: nine males, nine females		
Study Design	Males	Females
Vehicle control	3	3
Low dose	3	3
High dose	3	3
Dosing: once daily all animal for 7 days		
Observations: (mortality/moribundity) twice daily		
Clinical examination: daily after dosing		
Body weights: before start and on days 1, 2, 3, 5, and 7		
Food consumption: before start and on days 1, 2, 3, 5, and 7		
Physical examinations: conducted by a staff veterinarian on all animals prior to initiation of compound administration and at study termination		
Electrocardiograms: all animals prior to initiation of compound administration and at study termination		
Clinical pathology: hematology, clinical chemistry, and urinalysis evaluations on all animals pretest and at study termination		
Necropsy: all animals on day after last dose		
Organ weights: adrenals, brain, heart, kidneys, liver, lungs, ovaries with oviducts, pituitary, prostate, salivary glands, seminal vesicles, spleen, thyroid with parathyroid, thymus, testes, uterus

Detailed clinical observation: daily		
Functional observational battery: after first dose		
Body consumption: weekly		
Clinical pathology: hematology, clinical chemistry, and urinalysis evaluations on all surviving main study animals at termination (see attachment)		
Toxicokinetics: blood may be collected after first and last dose at six time points		
Necropsy: all main study animals, toxicokinetics animals euthanized and discarded		
Organ weights: adrenals, brain, heart, kidneys, liver, lungs, ovaries with oviducts, pituitary, prostate, salivary glands, seminal vesicles, spleen, thyroid with parathyroid, thymus, testes, uterus.		

clinical chemistry, and urinalysis measures are as described in Chapter 7. Toxicokinetic and organ weight data should be collected in these studies (Ballantyne, 2009; Denny and Stewart, 2017). Clinical signs should be obtained by careful observation of the animals over the course of the study, particularly shortly (usually 2h) after the initial dose. Table 8.15 presents a correlation of such clinical signs and highly probable associated target organs.

In rodents, FOB observations are increasingly performed after the initial animal dosing to both add rigor to the collection of clinical signs (Gad, 1982) and to fulfill the safety pharmacology associated requirement. It should be noted that validated forms exist for the mouse, rat, dog, and primate.

Blood samples should be taken and analyzed for toxicokinetic analysis after the first and last dose administration in nonrodents (and potentially in rodents if no such *in vivo* data has previously been collected).

Though separate cardiovascular measurements are required and made in the cardiovascular safety pharmacology studies, these are generally performed at lower (more clinically relevant) doses.

Body weights should be measured prior to study start and throughout the course of the study and food consumption at least subjectively evaluated.

While a gross necropsy is performed and selected organ weights collected (and analyzed), it is not recommended (or required) in most cases to proceed to process tissues to slides and have histopathologic evaluations performed. In addition to cost, the 2 months or more of additional time before such data

is available is rarely warranted. Rather, a careful evaluation of all the available in life data (everything up to and including organ weights and any gross necropsy observations) in an integrated manner serves to identify potential target organs, set GLP study dose levels, and modify designs for such studies.

REPEAT-DOSE TOXICITY STUDIES

In the broadest sense, subacute, subchronic, and chronic studies for pharmaceutical products can utilize any of the routes used to administer a therapeutic agent, initiate a range of dosing regimen, use any of a number of animal models, and conform to a broad range of experimental designs. They can be 2 weeks long (what used to be called “subacute” studies because they were conducted at dose levels below those employed for single-dose or acute studies) or last up to a year. Another name for these studies is repeat-dose studies (Gad, 2008; Ballantyne, 2009; Wilson et al., 2014, Denny and Stewart, 2017)—that is, those studies whereby animals have a therapeutic agent administered to them on a regular and repeated basis by one or more routes over a period of 9 months or less, typically. There is great flexibility and variability in the design of such studies. When the primary driver for testing was occupational exposure, test animal exposure was 5 days a week (simulating the work week). Such designs are almost gone, as environmental, consumer, and potential patient exposures (potentially occurring every day) now dictate 7 days a week dosing or exposure. Currently, the duration of such general repeat-dose toxicity studies ranges from 14 days (long enough for the drug levels in the body to reach steady state and for the adaptive immune response to begin to be active) to 9 months (in nonrodents), or rarely 12 months.

This chapter seeks to provide a firm grasp of the objectives for repeat-dose studies, the regulatory requirements governing them, the key factors in their design and conduct, and the interpretation of their results. The key fundamental concepts in understanding mammalian toxicology are presented in Table 9.1.

TABLE 9.1 Key Concepts in Understanding Toxicity

- Chronicity—the relation of duration of repeat dosing and biologic effects

- Reversibility
- Dose–response
- Time response
- Susceptibility
- Special populations
- Statistical versus biological significance
- Metabolism

9.1 OBJECTIVES

As with any scientific study or experiment (but especially for those in safety assessment), the essential first step is to define and understand the reason(s) for the conduct of the study—that is, its objectives. There are three major (scientific) reasons for conducting subchronic and chronic studies, but a basic characteristic of all but a few subchronic studies needs to be understood. The subchronic study is (as are most other studies in whole animal toxicology) a broad screen. It is not focused on a specific end point; rather, it is a broad exploration of the cumulative biological effects of the administered agent over a range of doses. So broad an exploration, in fact, that it can be called a “shotgun” study.

The objectives of the typical subchronic and chronic studies fall into three categories. The first is to broadly define the toxicity (and, if one is wise, the pharmacology and hyperpharmacology) of repeated doses of a potential therapeutic

agent in an animal model (Traina, 1983; Gad, 2014; Wilson et al., 2014) by the route and dosing regimen performed identically to that which will be used clinically. This definition is both qualitative (what are the target organs and the nature of the effects seen) and quantitative (at what dose levels or, more importantly, at what plasma and tissue levels are effects definitely seen and not seen).

The second objective (and the one that in the pharmaceutical industry testing facilities usually comply in both timing and compromising of design and execution of studies) is to provide support for the initiation of and/or continued conduct of clinical trials in man (Blass, 2021; O’Grady and Linet, 1990; Smith, 1992). As such, subchronic studies should provide not only adequate clearance (therapeutic margin) of initial dose levels and duration of dosing but also guidance for any special measures to be made or precautions to be taken in initial clinical trials. Setting inadequate dose levels (either too low or too high) may lead to the failure of a study. A successful study must both define a safe, or “clean,” dose level (one that is as high as possible to allow as much flexibility as possible in the conduct of clinical studies) and demonstrate and/or characterize signs of toxicity at some higher dose. The duration of dosing issue is driven by a compromise between meeting regulatorily established guidelines (as set out in Table 9.2) and the economic pressure to initiate clinical trials as soon as possible.

The third objective is one of looking forward to later studies. The subchronic study must provide sufficient information to allow a prudent setting of doses for later, longer studies (including, ultimately, carcinogenicity studies). At the same time, the subchronic study must also provide guidance for the other (than dose) design features of longer-term studies (such as what parameters to measure and when to measure them, how many animals to use, and how long to conduct the study).

The Food and Drug Administration (FDA) and other International Conference on Harmonization (ICH) regulating agencies have specific expectations of these general toxicity studies (as now codified in ICHM3(R2), 2009 and FDA, 2000). These include the following:

- a. At least three separate dose groups and concurrent control group.
- b. The high-dose group should, if at all possible, serve to identify one or more target organs (or organs systems) for toxicity at sublethal doses.
- c. The low-dose group should serve to identify a dose level at which there are no adverse effects (a no-observable-adverse-effect level [NOAEL]).
- d. The route and regimen employed should mirror those planned or used for clinical evaluation.
- e. Unless the drug is intended for use in just one sex (say for prostate or uterine cancer), equal numbers of

TABLE 9.2 Recommended Duration of Repeated-Dose Toxicity Studies to Support the Conduct of Clinical Trials

Maximum Duration of Clinical Trial	Recommended Minimum Duration of Repeated-Dose Toxicity Studies to Support Clinical Trials	
	Rodents	Nonrodents
Up to 2 weeks	2 weeks ^a	2 weeks ^a
Between 2 weeks and 6 months	Same duration as clinical trial ^b	Same duration as clinical trial ^b
>6 months	6 months ^{b,c}	9 months ^{b,c,d}

Source: ICH M3 R2 (2009).

^a In the United States, as an alternative to 2-week studies, extended single-dose toxicity studies can support single-dose human trials. Clinical studies of less than 14 days can be supported with toxicity studies of the same duration as the proposed clinical study.

^b In some circumstances clinical trials of longer duration than 3 months can be initiated, provided that the data are available from a 3-month rodent and a 3-month nonrodent study and that complete data from the chronic rodent and nonrodent study are made available, consistent with local clinical trial regulatory procedures, before extending dosing beyond 3 months in the clinical trial. For serious or life-threatening indications or on a case-by-case basis, this extension can be supported by complete chronic rodent data and in-life and necropsy data for the nonrodent study. Complete histopathology data from the nonrodent should be available within an additional 3 months.

^c There can be cases where a pediatric population is the primary population, and existing animal studies (toxicology or pharmacology) have identified potential developmental concerns for target organs. In these cases, long-term toxicity testing starting in juvenile animals can be appropriate in some circumstances.

^d In the EU, studies of 6 months duration in nonrodents are considered acceptable. However, where studies with a longer duration have been conducted, it is not appropriate to conduct an additional study of 6 months. The following are examples where nonrodent studies of up to 6 months duration can also be appropriate for Japan and the United States:

- When immunogenicity or intolerance confounds conduct of longer-term studies.
- Repeated short-term drug exposure even if clinical trial duration exceeds 6 months, such as intermittent treatment of migraine, erectile dysfunction, or herpes simplex.
- Drugs administered on a chronic basis to reduce the risk of recurrence of cancer.
- Drugs for indications for which life expectancy is short.

males and females should be used (see Table 9.3). The data from the two genders is not pooled, and for all practical purposes, two substudies are thus performed—one for males, one for females.

- f. Additional animals (recovery) should be included in (at least) the high-dose and central groups to allow the evaluation of the reversibility of target organ effects.

The use of at least three (but not necessarily only three) separate treatment groups, each receiving a different dose, is

TABLE 9.3 Numbers of Animals for Chronic and Subchronic Study per Test Group

Study Length	Mice or Rats per Sex	Dogs or Minipigs per Sex ^a	Primates per Sex ^a
2–4 weeks	5–10	3–4 (+2/3)	3 (+2/3)
3 months	20	6 (+3)	5 (+3)
6 months	30	8 (+3)	5 (+3)
9 months or 1 year	N/A	10	10

^a Numbers in parenthesis are for animals added to high dose and control to allow assessment of reversibility.

intended to allow the evaluation of dose–response. Table 9.4 presents some important aspects of such dose–response relationships.

These objectives are addressed by the usual subchronic study. Some subchronic studies, however, are unusual in being conceived, designed, and executed to address specific questions raised (or left unanswered) by previous preclinical or early clinical studies. Such a special purpose is addressed separately.

Chronic studies (those that last 6 or 9 months or a year) may also be conducted for the aforementioned purposes but are primarily done to fulfill registration requirements for drugs that are intended for continuous (or frequent intermittent) long-term to lifetime use.

9.2 REGULATORY CONSIDERATIONS

Much of what is done (and how it is done) in repeat-dose studies is a response to a number of regulations. Three of these have very broad impact. These are the Good Laboratory Practices (GLPs) requirements, Animal Welfare Act requirements, and regulatory requirements that actually govern study design.

9.2.1 Good Laboratory Practices

Since 1978, the design and conduct of preclinical safety assessment studies for pharmaceuticals in the United States

TABLE 9.4 The Three Dimensions of Dose–Response

As dose increases. . .
• Incidence of responders in an exposed population increases
• Severity of response in effected individuals increases
• Time to occurrence of response or of progressive stage of response decreases
• An implication is that as duration of dosing increases, NOEL/NOAEL decreases

(and, indeed, internationally) have been governed and significantly influenced by development of GLPs. Strictly speaking, these regulations cover qualifications of staff and facilities, training, record-keeping, documentation, and actions required to ensure compliance with and the effectiveness of these steps. Though the initial regulations were from the US FDA (2021), they have always expanded in content and extended to cover studies performed overseas. Now, most other countries have adopted similar regulations. A discussion of these regulations is beyond the scope of the current chapter, but several aspects are central to this effort. Each technique or methodology to be employed in a study (such as animal identification, weighing and examination, blood collection, and data recording) must be adequately described in a standard operating procedure (SOP) before the study begins. Those who are to perform such procedures must be trained in them beforehand. The actual design of the study, including start date and how it is to be ended and analyzed, plus the principal scientists involved (particularly the study director), must be specified in a protocol that is signed before the study commences. Any changes to these features must be documented in amendments once the study has begun. It is a good idea that the pathologist who is to later perform or oversee histopathology be designated before the start of the study and that the design be a team effort involving the best efforts of the toxicologist, pathologist, and (usually, for subchronic studies) drug metabolism scientist.

9.2.2 Animal Welfare Act

Gone are the days when the pharmaceutical scientist could conduct whatever procedures or studies that were desired using experimental animals. The Animal Welfare Act (APHIS, 1989, amended every 5 years since, most recently in 2020) (and its analogs in other countries) rightfully requires careful consideration of animal usage to ensure that research and testing uses as few animals as possible in as humane a manner as possible. As a start, all protocols must be reviewed by an Institutional Animal Care and Use Committee (IACUC). Such review takes time but should not serve to hinder good science. When designing a study or developing a new procedure or technique, the following points should be kept in mind:

1. Will the number of animals used be sufficient to provide the required data yet not constitute excessive use? (It ultimately does not reduce animal use to utilize too few animals to begin with and then have to repeat the study.)
2. Are the procedures employed the least invasive and traumatic available? This practice is not only required by regulations but is also sound scientific practice, since any induced stress will produce a range of responses in test animals that can mask or confound the chemically induced effects.

9.2.3 Regulatory Requirements for Study Design

The first consideration in the construction of a study is a clear statement of its objectives, which are almost always headed by meeting regulatory requirements to support drug development and registration. Accordingly, the relevant regulatory requirements must be analyzed, which is complicated by the fact that new drugs are no longer developed for registration and sale in a single-market country. The expense is too great, and the potential for broad international sales is too appealing. While each major country has its own requirements as to study designs and studies required (with most of the smaller countries adhering to the regulations of one of the major players), harmonization has done much to smooth these differences (Gad, 2010, 2019). Meeting these regulatory requirements is particularly challenging for several reasons. First, the only official delineation of general requirements in the United States is dated (FDA, 1971), and recently special cases have arisen (agents for the treatment of Covid-19, anti-HIV agents, biotechnologically derived agents, therapeutic agents for neonates and the very elderly, etc.) that try the utility of these requirements. These needs have led to a stream of points to consider which seek to update requirements. Second, the term “guidelines” means different things in different countries (in the United States, it means “requirements,” and in Japan, “suggestions”).

Agents intended to treat or arrest the progress of rapidly spreading life-threatening diseases (such as AIDS) are subject to less stringent safety assessment requirements prior to initial clinical evaluations than are other drugs. However, even though approval (if clinical efficacy is established) for marketing can be granted with preclinical testing still under way, all applicable safety assessments (as with any other class of drugs) must still be completed (FDA, 1988).

Drugs intended for use in either the elderly or the very young have special additional requirements for safety evaluation, in recognition of the special characteristics and potential sensitivities of these populations. For the elderly, these requirements call for special consideration of renal and hepatic effects (Center for Drug Evaluation and Research (CDER), 1989). Likewise, drugs intended for the young require special studies to be performed in neonates and juvenile animals (usually of 2- or 4-weeks’ duration in rats) (CDER, 2006).

In the last 10 years, several potentially important drugs have been produced by recombinant DNA technology. These biomacromolecules, which are primarily endogenously occurring proteins, present a variety of special considerations and concerns, including the following:

- Because they are endogenously occurring molecules, assessing their pharmacokinetics and metabolism presents special problems.
- Is the externally commercially produced molecule biologically equivalent to the naturally occurring one?

- As proteins, are they immunogenic or do they provoke neutralizing antibodies that will limit their usefulness?
- Because they are available only in very small quantities, the use of traditional protocols (such as those that use ever-increasing doses until an adverse effect is achieved) is impractical.
- Agents with such specific activity in man may not be appropriately evaluated in rodents or other model species.

Each of these points must be addressed in any safety testing plan (ICH S6(R1), 2011; Weissinger, 1989). The requirements set out in this chapter are designed to do this (for repeat-dose testing).

9.3 STUDY DESIGN AND CONDUCT

9.3.1 Animals

In all but a few rare cases, for pharmaceutical safety assessment separate studies in at least two species are required. Regulations require that both species be mammalian, and one of these must be a nonrodent; practice and economics dictate that the other species will be a rodent. With extremely rare exception, the rodent species employed is the rat (though the mouse also sees significant use). There is considerably more variability in the nonrodent species, with a range of factors determining whether the dog (most common choice), a primate species (typically the rhesus or cynomolgus, though some others are used in particular cases), the pig (particularly in Europe), or some other animal (e.g., the ferret) is selected. The factors that should and do govern species selection are presented in detail in Gad (2015). The use of multiple species is a regulatory requirement arising from the experience and the belief (going back to 1944, at least) that it will provide a better chance of detecting the full range of biological responses (adverse and otherwise) to the new molecular entity being evaluated. This belief has come under fire in recent years (Prior et al., 2018; Zbinden, 1993) and is not followed for larger molecular entities after initial systemic toxicity studies but is unlikely to be changed soon. Along the same lines, unless an agent is to be used by only one sex or the other of humans, equal numbers of both sexes of an animal species are utilized in the studies, with the sexes being treated as unrelated for purposes of statistical analysis. Also except in rare cases, the animals used are young, healthy adults in the logarithmic phase of their growth curve. (The FDA specifies that rodents be <6 weeks of age at the initiation of dosing.)

Numbers of animals to be used in each dose group of a study are presented in Table 9.3. Though the usual practice is to use three different dose groups and at least one equal

sized control group, this number is not fixed and should be viewed as a minimum (see Section 9.3.4). Use of more groups allows for a reduction in the risk of not clearly defining effects and establishing the highest possible safe dose at a modest increase in cost. There must be as many control animals as are in the largest-size test group to optimize statistical power.

Animals are assigned to groups (test and control) by one or another form of statistical randomization. Prior to assignment, animals are evaluated for some period of time after being received in house (usually at least 1 week for rodents and 2 for nonrodents) to ensure that they are healthy and have no discernible abnormalities. The randomization is never pure; it is always “blocked” in some form or another (by initial body weight, at least) so that each group is not (statistically) significantly different from the others in terms of the “blocked” parameters.

Proper facilities and care for test animals are not only a matter of regulatory compliance (and a legal requirement) but also essential for a scientifically sound and valid study.

Husbandry requires clean cages of sufficient size and continuous availability of clean water and food (unless the protocol requires some restriction on their availability). Environmental conditions (temperature, humidity, and light–dark cycle) must be kept within specified limits. All of these must, in turn, be detailed in the protocols of studies. The limits for these conditions are set forth in relevant National Institutes of Health (NIH) and US Department of Agriculture (USDA) publications.

9.3.2 Routes and Setting Doses

Route (how an agent is administered to a test animal) and dose (how much of and how frequently an agent is administered) are inseparable in safety assessment studies and really cannot be defined independently. The selection of both begins with an understanding of the intended use of the drug in humans. The ideal case is to have the test material administered by the same route, at the same frequency (once a day, three times a day, etc.), and for the same intervals (e.g., continuously, if the drug is an intravenously infused agent) as the drug’s eventual use in people. Practical considerations such as the limitations of animal models (i.e., there are some things you can’t get a rat to do), limitations on technical support¹ and the like, and regulatory requirements (discussed later as part of dose setting) frequently act or interact to preclude this straightforward approach.

¹Many antiviral agents, particularly some anti-HIV agents, have rather short plasma half-lives, which require frequent oral administration of the agent. Thirteen-week studies have been conducted with TID dosing of rats and monkeys, requiring around-the-clock shift work for technical staff of the laboratory.

Almost 30 routes exist for administration of drugs to patients (see Chapter 6), but only a handful of these are commonly used in preclinical safety studies (Gad, 1994; Gad and Spainhour 2018). The most common deviation from what is to be done in clinical trials is the use of parenteral (injected) routes such as intravenous (IV) and subcutaneous (SC) deliveries. Such injections are loosely characterized as bolus (all at once or over a very short period, such as 5 min) and infusion (over a protracted period of hours, days, or even months). The term *continuous infusion* implies a steady rate over a protracted period, requiring some form of setup such as an implanted venous catheter or infusion port.

It is rare that the raw drug itself is suitable (in terms of stability, local tissue tolerance, and optimum systemic absorption and distribution) for direct use as a dosage form. Either it must be taken into a solution or a suspension in a suitable carrier, a more complex formulation (a prototype of the commercial form) must be developed. Gad (2015) should be consulted for a more complete discussion of dose formulation for animals or humans. One formulation or more must be developed (preferably the same one for both animals and humans) based on the specific requirements of preclinical dosage formulation. For many therapeutic agents, limitations on volumes that can be administered and concentrations of active ingredient that can be achieved impact heavily on dose setting.

Setting of doses for initial repeat-dose studies, when little is known as to dose–response and pharmacokinetics, is one of the most difficult tasks in study design. The doses administered must include one that is devoid of any adverse effect (preferably of *any* effect) and yet still high enough to “clear” the projected clinical dose by the traditional (10× for rodents, 5× for nonrodents) or regulatory safety factors (the human equivalent dose [HED] factor times 10 for most therapeutic areas). At the same time, if feasible, at least one of the doses should characterize the toxicity profile associated with the agent (for some biotechnologically derived agents, particularly those derived from endogenous human molecules, it may only be possible to demonstrate biological effects in appropriate disease models and impossible to demonstrate toxicity). Because of limitations on availability of protodrugs, it is generally undesirable to go too high to achieve this second (toxicity) objective.

Traditionally, studies include three or more dose groups to fulfill these two objectives. Based on earlier results (generally, single-dose or 2-week studies), doses are selected. It is, by the way, generally an excellent idea to observe the “decade rule” in extrapolation of results from shorter to longer studies; that is, do not try to project doses for more than an order-of-magnitude-longer study (thus the traditional progression from single-dose to 14-day to 90-day studies). Also, one should not allow the traditional use of three dose groups plus a control to limit designs. If there is a

great deal of uncertainty, it is much cheaper in every way to use four or five dose groups in a single study than to have to repeat the entire study. Finally, remember that different doses may be appropriate for the different sexes.

It should also be kept in mind that formulating materials may have effects of their own, and “vehicle” control groups may be required in addition to a negative control group. Additionally, the limitations on volumes of dose administration should be kept in mind as presented in Table 9.5.

9.3.3 Parameters to Measure

As was stated earlier, repeat-dose general (systemic) toxicity studies are “shotgun” in nature; that is, they are designed to look at a very broad range of end points with the intention of screening as broadly as indications of toxicity. Meaningful findings are rarely limited to a single end point; rather, what typically emerges is a pattern of findings. This broad search for components of toxicity profile is not just a response to regulatory guidelines intended to identify potentially unsafe drugs. An understanding of all the indicators of biological effect can also frequently help one to understand the relevance of findings, to establish some as unrepresentative of a risk to humans, and even to identify new therapeutic uses of an agent.

Parameters of interest in the repeat-dose study can be considered as sets of measures, each with its own history, rationale, and requirements. Chapter 7 sought to present an overview of such parameters. It is critical to remember, however, that the strength of the study design as a scientific evaluation lies in the relationships and patterns of effects that are seen not in simply looking at each of these measures (or groups) as independent findings but rather as integrated profiles of biological effects.

9.3.3.1 Pharmacokinetics and Metabolism All regulatory repeat-dose general toxicity studies now incorporate (either in the study itself or in a parallel or satellite study) evaluation of the basic pharmacokinetics of a compound. This is discussed in detail in Chapter 19.

Pharmaceutical subchronic toxicity studies are always accompanied by a parallel determination of the pharmacokinetics of the material of interest administered by the same route as that used in the safety study. This parallel determination consists of measuring plasma levels of the administered agent and its major metabolites either in animals that are part of the main study or in a separate set of animals (in parallel with the main study) that are dosed and evaluated to determine just these end points. The purpose of these determinations is both to allow a better interpretation of the findings of the study and to encourage the most accurate possible extrapolation to humans. The first data of interest are the absorption, distribution, and elimination of the test material, but a number of other types of information can also be collected (Yacobi et al., 1989; Tse and Jaffe, 1991). For nonparenteral routes, it is essential to demonstrate that systemic absorption and distribution of the test material did occur; otherwise, it is open to question whether the potential safety of the agent in man has been adequately addressed (not to mention the implication for potential human therapeutic efficacy). A complication, however, is that there are limits as to how much blood may be collected from specific species at one time (see Table 9.6) particularly as samples must be drawn to allow evaluation of clinical chemistry, clinical pathology, and pharmacokinetics. This is even worse in the case of biologics, where adequate samples must also be drawn to allow the evaluation of antibody levels. However, low-volume sampling approaches are becoming more popular (Chapman et al., 2014).

TABLE 9.5 Guidance on Volumes of Administration

Species	Routes and Volumes (mL kg ⁻¹ Administration Site)					
	Oral	SC	IP	IM	IV Bolus	IV (Slowing)
Mouse	10 (50)	10 (40)	20 (80)	0.5 ^a (0.1) ^a	5	(25)
Rat	10 (40)	5 (10)	10 (20)	0.1 ^a (0.2) ^a	5	(20)
Rabbit	10 (15)	1 (2)	5 (20)	0.25 (0.5)	2	(10)

9.3.4 Study Designs

The traditional design for a repeat-dose toxicity study is very straightforward. The appropriate numbers of animals of each sex are assigned to each of the designated dose and control groups. Unfortunately, this basic design is taken by many to be dogma, even when it does not suit the purposes of the investigator. There are many possible variations to study design, but four basic factors should be considered: controls, the use of interval and satellite groups, balanced and unbalanced designs, and staggered starts.

Classically, a single control group of the same size as each of the dose groups is incorporated into each study. Some studies incorporate two control groups (each with the same size as the experimental groups) to guard against having a statistically significant effect due to one control group being abnormal for one or more parameters (a much more likely event when laboratory animals were less genetically homogeneous than they are now). The belief is that a “significant” finding that differs from one (but not both) of the concurrent control groups and does not differ from historical control data, can be considered as not biologically significant. This is, however, an indefensible approach. Historical controls have value, but it is the concurrent control group(s) in a study that is of concern.

Interval or satellite groups have been discussed at two earlier points in this chapter. They allow measurement of termination parameters at intervals other than at termination of the study. They are also useful when the manipulation involved in making a measurement (such as the collection of an extensive blood sample), while not terminal, may compromise (relative to other animals) the subject animals. Another common use of

such groups is to evaluate recovery from some observed effect at study termination.

Usually, each of the groups in a study is the same size, with each of the sexes being equally represented. The result is called a balanced design, with statistical power for detection of effects optimized for each of the treatment groups. If one knows little about the dose toxicity profile, this is an entirely sound and rational approach. However, there are situations when one may wish to utilize an unbalanced design—that is, to have one or more dose groups larger than the others. This is usually the case when either greater sensitivity is desired (typically in a low-dose group), or an unusual degree of attrition of test animals is expected (usually due to mortality in a high-dose group), or as a guard against a single animal’s idiopathic response being sufficient to cause “statistical significance.”

As it is the normal practice to have a balanced design, it is also traditional to initiate treatment of all animals at the same time. This may lead to problems at study termination, however. It is a very uncommon toxicology laboratory that can “bring a study down” on a single day. In fact, there are no labs that can collect blood and perform necropsies in a single day on even the 48–80 dogs involved in a study, much less the 160–400+ rats in the rodent version. Starting all animals on study the same day presents a number of less-than-desirable options. The first is to terminate as many animals as can be done each day, continuing to dose (and therefore, further affect) the remaining test animals. Assuming that the animals are being terminated in a random, balanced manner, this means that the last animals terminated will have received from 3 to 10 additional days of treatment. At the least, this is likely to cause some variance inflation (and therefore both decrease the power of the study design and possibly confound interpretation). If the difference in the length of treatment of test animals is greater than 3% of the intended length of the study, one should consider alternative designs.

An alternative approach to study design that addresses this problem employs one of several forms of staggered starts. In these, distinct groups of animals have their dosing initiated at different times. The most meaningful form recognizes that the two sexes are in effect separate studies anyway (they are never compared statistically, with the treatment groups being compared only against the same-sex control group). Thus, if the termination procedure for one sex takes 3–5 days, then one sex should be initiated on dosing 1 week and the other on the following week. This maximizes the benefits of common logistical support (such as dose formulation) and reduces the impact of differential length of dosing on study outcome.

A variation on this is to either stagger the start of different dose groups or of the satellite and main study portions of dose groups. The former is to be avoided (it will completely confound study outcome), while the latter makes sense in some cases (pharmacokinetics and special measures) but not others (recovery and interval sacrifice).

9.4 STUDY INTERPRETATION AND REPORTING

For a successful repeat-dose study, the bottom line is the clear demonstration of a no-effect level, characterization of a toxicity profile (providing guidance for any clinical studies), enough information on pharmacokinetics and metabolism to scale dosages to human applications, and at least a basic understanding of the mechanisms involved in any identified pathogenesis. The report that is produced as a result of the study should clearly communicate these points—along with the study design and experimental procedures, summarized data, and their statistical analysis—and it should be GLP compliant and suitable for FDA submission format.

Interpretation of the results of a study should be truly scientific and integrative. It is elementary to have the report state only each statistically and biologically significant finding in an orderly manner and not just a recitation of all observations. The meaning and significance of each in relation to other findings, as well as the relevance to potential human effects, must be evaluated and addressed.

The author of the report should ensure not only that it is accurate and complete but also that it clearly tells a story and concludes with the relevant (to clinical development) findings. A useful approach is to construct a summary table (such as illustrated in Table 9.7) which gives an overview by dose group, gender, and grouping of observation. The initial use of such a table should be as soon as the “in-life” data (all but the histopathology) from main groups in studies is available, as it can serve as both a tool for early understanding of findings and a guide to what examination may be added or modified in recovery group animals.

There are some common problems encountered in general toxicity studies. The most common of these and their usual causality are presented in Table 9.8.

The usual case is that over the course of drug development, we go from shorter (14 or 28 days) studies in progressive steps to longer studies (90 days/13 weeks) then chronic studies of 6 to 9 months. As we progress through this sequence, the results of earlier studies should modify the design of longer studies.

TABLE 9.7 Summary Integrative Assessment of Study Results

Parameter	Dose Group					
	Low		Middle		High	
	Male	Female	Male	Female	Male	Female
Morbidity						
Body weight						
Clinical signs						
Organ weights						
Clinical chemistry						
Hematology						
Histopathology						

TABLE 9.8 Troubleshooting in General Toxicology

Unexpected toxicity, compared with prior tests	Change in formulation or batch of test chemical. Poor predictability of dose range-finder studies due to factors such as differences in animal age, supplier, or husbandry
Variation in individual response	Metabolic polymorphism or other genetic factor and social factors in group housing, for example, nutrition status
Low systemic concentration or area under the curve (AUC)	Poor absorption or poor formulation; isotonicity is important in parenteral formulations. Extensive first-pass effect. Short half-life
Low toxicity	Low availability; inappropriate route of administration or dose selection
Interspecies differences	Different ADME; different mechanism of effect; species-specific mechanisms such as peroxisome proliferation; enterohepatic recirculation. Different expression of or affinity for pharmacological receptors
Different response in males and females	Especially in rodents; due to different activities of metabolism enzymes in liver particularly but also physiological differences such as α_2 -microglobulin excretion in males

9.5 READ ACROSS FOR PROGRAM WIDE EVALUATION

Repeat-dose studies in pharmaceutical safety assessment are almost always performed as part of a program and as such multiple studies of different lengths (high-dose range finding, 7-day dose range finding) and 14- or 28-day GLP studies to support the opening of an Investigational New Drug (IND), followed by longer 90-day and chronic toxicity studies to support continued clinical development, and in at least two species. All too often, each of these studies is interpreted only as itself.

The term “read-across” is primarily used to cover the consideration of the range of available studies to cover gaps in compounds database. Here the intended use is different and generally overlooked. Rather, here the point is to emphasize that the sum of knowledge from such a program is greater than just that of the individual parts. One can and should look at the patterns across studies, especially to determine first if findings in any one study are matched by those in other studies. Second, to determine if over the course of increased duration of treatment (i) tolerance develops, or (ii) the severity of a specific toxic effect on an organ, or tissue grows worse, or (iii) the exposure level associated with a specific expression of toxicity decreases.

10

GENOTOXICITY

Genotoxicity encompasses all the potential means by which the genetic material of higher organisms may be damaged, with resulting serious consequences to both the organism they occur in and potentially their offspring. With our increasing knowledge of genomics, it needs to be clear that somatic cell genomic changes which are not passed to subsequent generations of cells are not considered genotoxic events. Most forms of genotoxicity are expressions of mutagenicity—the induction of deoxyribonucleic acid (DNA) damage and other genetic alterations, with changes in one or a few of DNA base pairs (gene mutations). Others are clastogenicity, with gross changes in chromosomal structure (i.e., chromosomal aberrations [CAs]) or in chromosome numbers. Clearly, the potential of any pharmaceutical to cause such damage is a concern, though more than half of all currently marketed drugs have shown as genotoxic in one or more test systems (Snyder and Green, 2001).

It has been known for several hundred years that exposure to particular chemicals or complex mixtures can lead to cancer in later life (Doll, 1977), and it has been postulated more recently that chemicals can also induce heritable changes in man, leading to diseases in the next generation (ICEMC, 1983). There has been accumulating evidence that such changes can arise following damage to DNA and resulting mutations (see, e.g., Slater et al., 1971; Bridges, 1976). Therefore, it has become necessary to determine whether widely used drugs or potentially useful new drugs possess the ability to damage DNA (Ishidate, 1988a, b). In pharmaceutical development, such information may be used to discard a new candidate drug from further work, to control or to eliminate human exposure for a mutagenic industrial compound, or, for a drug, to proceed with development if benefits clearly outweigh risks. Data concerning the genotoxicity of a new drug have become part of the safety package, though

the timing of the performance of the tests may vary. They are needed for decision-making and to reduce risks that might otherwise be unforeseen.

The newest revision of the International Conference on Harmonization (ICH) guidance on this subject, ICH S2(R1), sets forth clear guidance in genotoxicity testing requirements in the form of the traditional approach and two optional approaches (as summarized in Table 10.1). This newest revision, which also serves to merge the former S2A and S2B guidelines, is just (2013) into consideration. This revision fundamentally changed many aspects of how candidate drugs are evaluated for potential genotoxicity. The FDA follows the operative ICH guidances (ICH, 2012a, b) and ISO (2012, 2014). The Japanese MAFF guidance was last updated in 2000 (MAFF, 2000).

For impurities and degradants occurring at or below 1 mg day^{-1} of daily exposure, genotoxic concerns can be addressed using two QSAR methodologies (see Chapter 12). For screening of candidate compounds, it is common practice to perform a non-GLP “mini-Ames” that uses only two test strains.

GLP Ames studies require a certificate of analysis for the drug substance, GLP validated analysis of dose solutions and dose solution analyses. These have substantially (3–4×) increased the cost of the studies.

10.1 ICH TEST PROFILE

The ICH recommends a rather different profile of genotoxicity tests for drugs than is used for environmental chemicals. They want to see at least a single relevant *in vivo* test conducted, with subsequent testing performed to allow evaluation of the relevance of test results to potential patient risk (Gad et al., 2015).

TABLE 10.1 Genotoxicity Tests Recommended by ICH (three options)

ICH S2A/B	ICH S2(R1)	
Standard battery	Option 1	Option 2
Ames microbial mutagenesis and repeat <i>In vitro</i> mammalian cell assay: Chromosome aberrations	Ames (one complete assay) <i>In vitro</i> mammalian cell assay: (1 nM top concentration) Chromosome aberrations	Ames (one complete assay) No <i>in vitro</i> mammalian cell assay
Or TK mutations in mouse lymphoma cells	Or TK mutations in mouse lymphoma cells	
<i>In vivo</i> micronucleus (mouse or rat bone marrow, mouse blood) or chromosomal aberration assay (mouse or rat marrow)	Micronucleus assay <i>In vivo</i> micronucleus or chromosome aberration assay (mouse/rat bone marrow or blood) ^a Before phase I if integrated Before phase II if acute study	<i>In vivo</i> Gene-Tox with two tissues ^a : • Micronuclei • Second <i>in vivo</i> end point (comet, DNA breaks, adducts, mutation)

Before phase I.
Before phase II.

^a Can be integrated into repeat dose studies. Micronuclei analysis can be performed by flow cytometry.

While actual study design guidelines are described in the OECD test guidelines (OECD, 1997a, b, c, 2010, 2014a, b), the ICH S9 guideline details which study should be performed. Most recently, FDA has moved to an approach of requiring two *in vitro* studies and if they are negative. Accepting these as sufficient to support opening an IND the (*in vivo* study, such as a micronucleus) is then required before preceding to phase 2 clinical studies.

10.2 DNA STRUCTURE

With the exception of certain viruses, the blueprint for all organisms is contained in a code saved in the form of DNA, a giant macromolecule whose structure allows a vast amount of information to be stored accurately. We have all arisen from a single cell, the fertilized ovum containing two sets of DNA (packaged with protein to form chromatin), one set from our mother, resident in the nucleus of the unfertilized ovum, and the second set from our father via the successful sperm. Every cell in the adult has arisen from this one cell and (with the exception of the germ cell and specialized liver cells) contains one copy of these original chromosome sets.

The genetic code is composed of four “letters”—two pyrimidine nitrogenous bases, thymine and cytosine, and two purine bases, guanine and adenine—which can be regarded functionally as arranged in codons (or triplets). Each codon consists of a combination of three letters; therefore, 4³ (64) different codons are possible. Sixty-one codons code for specific amino acids (three produce stop signals), and as only 20 different amino acids are used to make proteins, one amino acid can be specified by more than one codon.

The bases on one strand are connected together by a sugar (deoxyribose) phosphate backbone. DNA can exist in a single-stranded or double-stranded form. In the latter state, the two strands are held together by hydrogen bonds between the bases. Hydrogen bonds are weak electrostatic forces involving oxygen and nitrogen atoms. As a strict rule, one fundamental to mutagenesis, the adenine bases on one strand always hydrogen bond to the thymine bases on the sister strand. Similarly, guanine bases pair with cytosine bases. Adenine and thymine form two hydrogen bonds, and guanine and cytosine form three.

Double-stranded DNA has a unique property in that it is able to make identical copies of itself when supplied with precursors, relevant enzymes, and cofactors. In simplified terms, two strands begin to unwind and separate as the hydrogen bonds are broken. This produces single-stranded regions. Complementary deoxyribonucleotide triphosphates then pair with the exposed bases under the control of a DNA polymerase enzyme.

A structural gene is a linear sequence of codons which code for a functional polypeptide, that is, a linear sequence of amino acids. Individual polypeptides may have a structural, enzymatic, or regulatory role in the cell. Although the primary structure of DNA is the same in prokaryotes and eukaryotes, there are differences between the genes of these two types of organism, in internal structure, numbers, and mechanism of replication. In bacteria, there is a single chromosome, normally a closed circle, which is not complexed with protein, and replication does not require specialized cellular structures. In plant and animal cells, there are many chromosomes, each present as two copies, as mentioned earlier, and the DNA is complexed with protein. Replication and cell division require the proteinaceous spindle apparatus. The DNA of eukaryotic cells contains repeated sequences of some genes.

Also, eukaryotic genes, unlike prokaryotic genes, have non-coding DNA regions called introns between coding regions called exons. This property means that eukaryotic cells have to use an additional processing step at transcription.

10.2.1 Transcription

The relationship between the DNA in the nucleus and proteins in the cytoplasm is not direct. The information in the DNA molecule is transmitted to the protein-synthesizing machinery of the cell via another informational nucleic acid, called messenger RNA (mRNA), which is synthesized by an enzyme called RNA polymerase. Although similar to DNA, mRNAs are single-stranded and possess the base uracil instead of thymine and the sugar ribose rather than deoxyribose. These molecules act as short-lived copies of the genes being expressed.

In eukaryotic cells, the initial mRNA copy contains homologs of both the intron and exon regions. The intron regions are then removed by enzymes located in the nucleus of the cell. Further enzymes splice the exon regions together to form the active mRNA molecules. In both groups of organisms, mature mRNA molecules then pass out of the nucleus into the cytoplasm.

10.2.2 Translation

The next process is similar in both eukaryotes and prokaryotes and involves the translation of mRNA molecules into polypeptides. This procedure involves many enzymes and two further types of RNA: transfer RNA (tRNA) and ribosomal RNA (rRNA). There is a specific tRNA for each of the amino acids. These molecules are involved in the transportation and coupling of amino acids in to the resulting polypeptide. Each tRNA molecule has two binding sites, one for the specific amino acid and the other containing a triplet of bases (the “anticodon”) which is complementary to the appropriate codon on the mRNA.

rRNA is complexed with protein to form a subcellular globular organelle called a ribosome. Ribosomes can be regarded as the “reading head” which allows the linear array of mRNA codons each to base-pair with an anticodon of an appropriate incoming tRNA/amino acid complex. The polypeptide chain forms as each tRNA/amino acid comes into register with the RNA codon and with specific sites on the ribosome. A peptide bond is formed between each amino acid as it passes through the reading head of the ribosome (Venitt and Parry, 1984).

10.2.3 Gene Regulation

Structural genes are regulated by a special set of codons, in particular “promoter” sequences. The promoter sequence is the initial binding site for RNA polymerase before transcription begins. Different promoter sequences have different affinities for RNA polymerase. Some sets of structural genes

with linked functions have a single promoter, and their coordinate expression is controlled by another regulatory gene called an operator. A group of such genes is called an operon.

The activity of the operator is further controlled by a protein called a repressor, since it stops the expression of the whole operon by binding to the operator sequence, preventing RNA polymerase from binding to the promoter. Repressors can be removed by relevant chemical signals or in a time-related fashion.

In the ways described earlier, only the genes required at a given moment are expressed. This not only helps to conserve the energy of the cell but also is critical for correct cellular differentiation, tissue pattern formation, and formation of the body plan.

10.2.4 DNA Repair

All living cells appear to possess several different major DNA repair processes (reviews: Walker, 1984; Rossman and Klein, 1988). Such processes are needed to protect cells from the lethal and mutating effects of heat-induced DNA hydrolysis, ultraviolet (UV) light, ionizing radiation, DNA reactive chemicals, free radicals, etc. In single-celled eukaryotes such as the yeast *Saccharomyces cerevisiae*, the number of genes known to be involved in DNA repair approaches 100 (Friedberg, 1988). The number in mammalian cells is expected to be at least equal to this and emphasizes the importance of correction of DNA damage.

10.2.4.1 Excision Repair Some groups of enzymes (light independent) are apparently organized to act cooperatively to recognize DNA lesions, remove them, and correctly replace the damaged sections of DNA. The most comprehensively studied of these is the excision repair pathway.

Briefly, the pathway can be described as follows:

1. *Preincision reactions*: UvrA protein dimers are formed which bind to the DNA at a location distant from the damaged site. The UvrB protein then binds to the DNA–UvrA complex to produce an energy requiring topological unwinding of the DNA via DNA gyrase. This area of unwinding is then translocated, again using ATP as an energy source, to the site of the damaged DNA.
2. *Incision reactions*: The UvrC protein binds to the DNA–UvrA/B complex and incises DNA at two sites—seven bases to the 5′ end and three bases to the 3′ end of the damage.
3. *Excision reactions*: UvrD protein and DNA polymerase I excise the damaged bases and then resynthesize the strand, using the sister strand as a template. The Uvr complex then breaks down, leaving a restored, but nicked, strand.
4. *Ligation reaction*: The nick in the phosphate backbone is repaired by DNA ligase.

5. A similar excision repair mechanism exists in mammalian cells (see, e.g., Cleaver, 1983). In both cases, the process is regarded as error-free and does not lead to the generation of mutations. However, this pathway can become saturated with excessive numbers of damaged DNA sites, forcing the cell to fall back on other repair mechanisms.

10.2.5 Error-Prone Repair

Exposure of *Escherichia coli* to agents or conditions that either damage DNA or interfere with DNA replication results in the increased expression of the so-called “SOS” regulatory network (Walker, 1984). Included in this network is a group of at least 17 unlinked DNA damage-inducible (*din*) genes. The *din* gene functions are repressed in undamaged cells by the product of the *lexA* gene (Little and Mount, 1982) and are induced when the LexA protein is cleaved by a process that requires modified RecA protein (RecA*), which then acts as a selective protease (Little, 1984). The *din* genes code for a variety of functions, including filamentation, cessation of respiration, etc. Included are the *umuDC* gene products, which are required for so-called “error-prone” or mutagenic DNA repair (Kato and Shinoura, 1977). The precise biochemical mechanism by which this repair is achieved is still not fully understood. Bacterial polymerase molecules have complex activities, including the ability to “proofread” DNA—that is, to ensure that the base-pairing rules of double-stranded DNA are met. It is hypothesized that Umu proteins may suppress this proofreading activity so that base mismatches are tolerated (Villani et al., 1978). Recent evidence suggests that DNA lesions are bypassed, and this bypass step required UmuDC proteins and RecA* proteins (Bridges et al., 1987). The net result is that random base insertion occurs opposite the lesion which may result in mutation.

Analogues of the *umuDC* genes can be found in locations other than the bacterial chromosome—for example, plasmid pKM101 (Walker and Dobson, 1979), a derivative of the drug resistance plasmid R46 (Mortelmans and Strocker, 1979), which carried *mucAB* genes (Shanabruch and Walker, 1980) (see pp. 879–880). Mutagenic repair, as controlled by *umuDC*, is not universal even among enterobacteria (Sedgwick and Goodwin, 1985). For instance, *Salmonella typhimurium* LT2 does not appear to express mutagenic repair (Walker, 1984). Thus, the usefulness of strains of this species is greatly enhanced by using derivatives containing plasmids with genes coding for error-prone repair (MacPhee, 1973; McCann et al., 1975a, b).

10.2.6 Mismatch Repair

Mismatched pairs that break the normal base-pairing rules can arise spontaneously due to DNA biosynthetic errors,

events associated with genetic recombination and the deamination of methylated cytosine (Modrich, 1987). With the latter, when cytosine deaminates to uracil, an endonuclease enzyme, *N*-uracil-DNA glycosylase (Lindahl, 1979), excises the uracil residue before it can pair with adenine at the next replication. However, 5-methylcytosine deaminates to form thymine and will not be excised by a glycosylase. As a result, thymine exits on one strand paired with guanine on the sister strand, that is, a mismatch. This will result in a spontaneous point mutation if left unrepaired. For this reason, methylated cytosines form spontaneous mutation “hot spots” (Miller, 1985). The cell is able to repair mismatches by being able to distinguish between the DNA strand that exists before replication and a newly synthesized strand.

The mechanism of strand-directed mismatch correction has been demonstrated in *E. coli* (see, e.g., Wagner and Meselson, 1976). In this organism, adenine methylation of d(G-A-T-C) sequences determines the strand on which repair occurs. Thus, parental DNA is fully methylated, while newly synthesized DNA is undermethylated, for a period sufficient for mismatch correction. By this means, the organism preserves the presumed correct sequence—that is, that present on the original DNA strand—and removes the aberrant base on the newly synthesized strand. Adenine methylation is achieved in *E. coli* by the *dam* methylase, which is dependent on *S*-adenosylmethionine. Mutants (*dam*) lacking this methylase are hypermutable, as would be expected by this model (Marinus and Morris, 1974).

10.2.7 The Adaptive Repair Pathway

The mutagenic and carcinogenic effects of alkylating agents such as ethyl methanesulfonate are due to the generation of *O*⁶-alkylguanine residues in DNA, which result in point mutations. Bacterial and mammalian cells can repair a limited number of such lesions before DNA replication, thus preventing mutagenic and potentially lethal events taking place.

If *E. coli* are exposed to low concentrations of simple alkylating agents, a repair mechanism is induced that causes increased resistance to subsequent challenge with a high dose. This adaptation response was first described by Samson and Cairns (1977) and has recently been reviewed by Lindahl et al. (1988). The repair pathway is particularly well understood.

10.2.8 Plasmids

Plasmids are extrachromosomal genetic elements that are composed of circular double-stranded DNA. In bacteria, some can mediate their own transfer from cell to cell by conjugation—that is, they contain a set of *tra* genes coding for tubelike structures, such as pili, through which a copy of plasmid DNA can pass during transfer.

Plasmids range in size from 1.5 to 200 million Da. The number of copies per cell differs from plasmid to plasmid.

Copy number relates to control of replication, and this correlates with size—that is, small plasmids tend to have large copy numbers per cell. This may relate to a lack of replication control genes (Mortelmans and Dousman, 1986).

10.2.9 Plasmids and DNA Repair

Many plasmids are known to possess three properties: (i) increased resistance to the bactericidal effects of UV and chemical mutagens, (ii) increased spontaneous mutagenesis, and (iii) increased susceptibility to UV and chemically induced mutagenesis. Some plasmids possess all three properties; others may possess just one, for example, increased susceptibility to mutagenesis (review: Mortelmans and Dousman, 1986). Often, the profile of activity depends on the DNA repair status of the host cell (Pinney, 1980). Plasmid pKM101 carries DNA repair genes and has been widely used in strains used in bacterial mutagenicity tests.

10.2.10 Nature of Point Mutations

The word “mutation” can be applied to point mutations which are qualitative changes involving one or a few bases in base sequences within genes, as described in the following text, as well as to larger changes involving whole chromosomes (and thus many thousands of genes) and even to changes in whole chromosome sets (described later under cytogenetics).

Point mutations can occur when one base is substituted for another (base substitution). Substitution of another purine for a purine base or of another pyrimidine for pyrimidine is called a transition, while substitutions of purine for pyrimidine or pyrimidine for purine are called transversions. Both types of base substitution have been identified within mutated genes. These changes lead to a codon change which can cause the “wrong” amino acid to be inserted into the relevant polypeptide and are known as missense mutations. Such polypeptides may have dramatically altered the properties if the new amino acid is close to the active center of an enzyme or affects the three-dimensional makeup of an enzyme or a structural protein. These changes, in turn, can lead to change or reduction in function, which can be detected as a change in phenotype of the affected cells.

A base substitution can also result in the formation of a new inappropriate terminator (or nonsense) codon and are thus known as nonsense mutations. The polypeptide formed from such mutated genes will be shorter than normal and is most likely to be inactive. Owing to the redundancy of the genetic code, about a quarter of all possible base substitutions will not result in an amino acid replacement and will be silent mutations.

Bases can be deleted or added to a gene. As each gene is of a precisely defined length, these changes, if they involve a number of bases that is not a multiple of three, result in a

change in the “reading frame” of the DNA sequence and are thus known as frameshift mutations. Such mutations tend to have a dramatic effect on the polypeptide of the affected gene, as most amino acids will differ from the point of the insertion or deletion of bases onward. Very often, a new terminator codon is produced, so, again, short inactive polypeptides will result.

Both types of mutation result in an altered polypeptide, which, in turn, can have a marked effect on the phenotype of the affected cell. Much use of phenotypic changes is made in mutagenicity tests.

Base substitutions and frameshift changes occur spontaneously and can be induced by radiations and chemical mutagens. It is apparent that the molecular mechanisms resulting in these changes are different in each case, but the potential hazards associated with mutagens capable of inducing the different types of mutation are equivalent.

10.2.11 Suppressor Mutations

In some instances, a mutation within one gene can be corrected by a second mutational event at a separate site on the chromosome. As a result, the first defect is suppressed and the second mutation is known as a suppressor mutation. Most suppressor mutations have been found to affect genes encoding for tRNAs. Usually, the mutation causes a change in the sequence of the anticodon of the tRNA. Thus, if a new terminator or nonsense codon is formed as the first mutation, this can be suppressed by a second mutation, forming a tRNA species that now has an anticodon complementary to a termination codon. Thus, the new tRNA species will supply an amino acid at the terminator site on the mRNA and allow translation to proceed. Surprisingly, most suppressors of this type do not adversely affect cell growth, which implies that the cell can tolerate translation proceeding through termination signals, producing abnormal polypeptides. An alternative explanation is that the particular DNA sequences surrounding normal terminator codons result in a reduced efficiency of suppressor tRNAs (Bossi, 1985).

Frameshift suppression is also possible. This can be achieved by a second mutation in a *tRNA* gene such that the anticodon of a tRNA molecule consists of four bases rather than three—for example, an extra C residue in the CCC anticodon sequence of a glycine *tRNA* gene. This change will allow correction of a +1 frameshift involving the GGG codon for glycine (Bossi, 1985).

10.2.12 Adduct Formation

The earlier discussion of adaptive repair made reference to the fact that some unrepaired alkylated bases are lethal, owing to interference with DNA replication, while others such as *O*⁶-methylguanine lead to mutation if unrepaired. These differences indicate that not all DNA adducts (i.e.,

DNA bases with additional chemical groups, not associated with normal DNA physiology) are equivalent. In fact, some adducts appear not to interfere with normal DNA functions or are rapidly repaired, others are mutagenic, and yet others are lethal. Chemicals that form electrophilic species readily form DNA adducts. These pieces of information are hard won, and the reader is recommended to read reviews of the pioneering work of Brooks and Lawley (review: Lawley, 1989) summarizing work identifying the importance of DNA adduct formation with polycyclic hydrocarbons and the importance of “minor” products of base alkylation such as *O*⁶-methylguanine and, in addition, the work of the Millers in linking attack of nucleophilic sites in DNA by electrophiles to mutagenesis and carcinogenesis (Miller and Miller, 1971).

If a DNA adduct involves the nitrogen or oxygen atoms involved in base pairing, and the adducted DNA is not repaired, base substitution can result. Adducts can be small, such as the simple addition of methyl or ethyl groups, or they can be very bulky, owing to reaction with multiringed structures. The most vulnerable base is guanine, which can form adducts at several of its atoms (e.g., N⁷, C⁸, O⁶, and exocyclic N²) (Venitt and Parry, 1984). Adducts can form links between adjacent bases on the same strand (intrastrand cross-links) and can form interstrand cross-links between each strand of double-stranded DNA.

The induction of frameshift mutation does not necessarily require covalent adduct formation. Some compounds that have a flat, planar structure, such as particulate polycyclic hydrocarbons, can intercalate between the DNA strands of the DNA duplex. The intercalated molecules interfere with DNA repair enzymes or replication and cause additions and deletions of base pairs. The precise mechanism is still unclear, although several mechanisms have been proposed. Hot spots for frameshift mutation often involve sections of DNA where there is a run of the same base—for example, the addition of a guanine to a run of six guanine residues. Such information led to a “slipped mispairing” model for frameshift mutation (Streisinger et al., 1966; Roth, 1974). In this scheme single-strand breaks allow one strand to slip and loop out one or more base pairs, the configuration being stabilized by complementary base pairing at the end of the single-stranded region. Subsequent resynthesis results ultimately in additions or deletions of base pairs (Miller, 1985).

10.2.13 Mutations Due to Insertion Sequences

The subject of mutations due to insertion sequences is reviewed in Cullum (1985). Studies of spontaneous mutation in *E. coli* detected a special class of mutations that were strongly polar, reducing the expression of downstream genes (Jordan et al., 1967). These genes mapped as point mutations and reverted like typical point mutations. However, unlike point mutations, mutagens did not increase their reversion

frequency. Further studies showed that these mutations were due to extra pieces of DNA that can be inserted into various places in the genome. They are not just random pieces of DNA but are “insertion sequences” 0.7–1.5 kb long that can “jump” into other DNA sequences. They are related to transposons, which are insertion sequences carrying easily detected markers such as antibiotic resistance genes, and Mu phages (bacterial viruses).

10.2.14 The Link Between Mutation and Cancer

The change in cells undergoing normal, controlled cell division and differentiation to cells that are transformed, dividing without check, and are undifferentiated or abnormally differentiated does not appear to occur as a single step—that is, transformation is multistage. Evidence for this comes from *in vitro* studies, animal models, and clinical observations—in particular, the long latent period between exposure to a carcinogen and the appearance of a tumor in the target tissue. There is much evidence for the sequence of events shown in Figure 10.1 (tumor initiation, promotion, malignant conversion, and progression). Such a scheme provides a useful working model but clearly does not apply to all “carcinogens” in all circumstances.

Study of Figure 10.1 shows that there are several points where genetic change appears to play a role. Such change may occur spontaneously due to rare errors at cell division such as misreplication of DNA or spindle malfunction, or may be induced by exposure to viruses (e.g., acute transforming retroviruses), ionizing and nonionizing radiations absorbed by DNA (e.g., X-rays, UVC), or particular chemical species capable of covalently interacting with DNA (as discussed earlier) or with vital proteins, such as tubulin, that polymerize to form the cell division spindle apparatus.

10.2.15 Genotoxic Versus Nongenotoxic Mechanisms of Carcinogenesis

The previous discussions of oncogene activation and human DNA repair deficiencies provide strong evidence for carcinogenesis via genotoxic mechanisms. However, it has been recognized for many years that cancers can arise without biologically significant direct or indirect interaction between a chemical and cellular DNA (see, e.g., Gatehouse et al., 1988). The distinction between nongenotoxic and genotoxic carcinogens has recently been brought into a sharper focus following the identification of a comparatively large number of “nongenotoxic” carcinogens by the US National Toxicology Program (Tennant et al., 1987). These include a wide range of chemicals acting via a variety of mechanisms, including augmentation of high “spontaneous” tumor yields, disruption of normal hormonal homeostasis in hormone-responsive tissues, peroxisome proliferation, proliferation of urothelial cells following

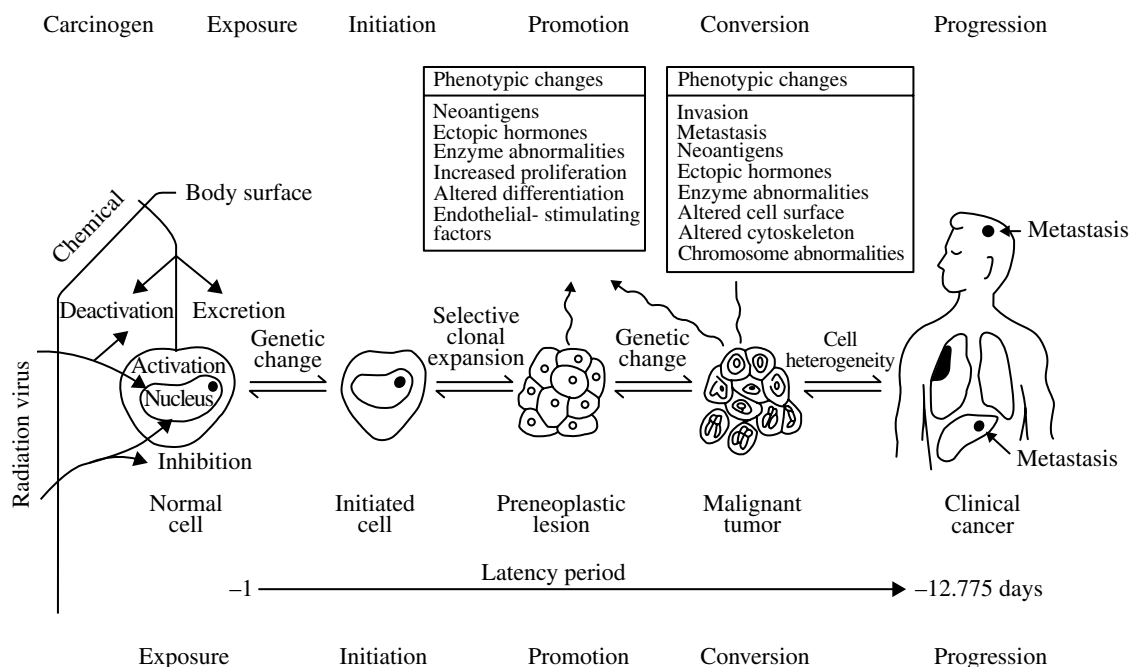

FIGURE 10.1 Schematic representation of events leading to neoplasia. Source: Adapted from Harris et al. (1987).

damage via induced kidney stones, etc. (Clayson, 1989). This author points out that a major effort is under way to determine whether many of these compounds can elicit similar effects in humans.

Ashby and Tennant (1988) and Ashby et al. (1989) stress the significance of their observations that 16 tissues are apparently sensitive to genotoxic carcinogens, while a further 13 tissues are sensitive to both genotoxic and nongenotoxic carcinogens (Table 10.2). Also, genotoxic carcinogens tend to induce tumors in several tissues of both males and females in both rats and mice. This contrasts with nongenotoxic carcinogens, which may induce tumors at high doses, in one tissue of one sex, or of one species. Although it is most unlikely that all nongenotoxic carcinogens will prove to be irrelevant in terms of human risk, it appears from the earlier analysis that a proportion of carcinogens identified by the use of near-toxic levels in rodent bioassays are of dubious relevance to the induction of human cancer. For further discussion, see Butterworth and Slaga (1987).

10.2.16 Genetic Damage and Heritable Defects

Concern about the effects of radiations and chemicals on the human gene pool, and the resulting heritable malformations and syndromes, has steadily risen during this century. The recognition that changes in morphology would result from changes in the hereditary material due to mutations (from the Latin word *mutare*, to change) was adopted by de Vries following observations on the evening primrose, *Oenothera*

(deVries, 1901). Muller went on to demonstrate that X-rays could induce mutations in the germ cells of the fruit fly *Drosophila melanogaster* (Muller, 1927).

The human gene pool is known to carry many deleterious genes acquired from preceding generations which result in numerous genetic diseases. It is clear that these arise as a result of DNA changes affecting particular chromosomes or genes. They can be grouped as follows:

TABLE 10.2 Tissues Sensitive to Genotoxic and/or Nongenotoxic Carcinogens

Tissues Sensitive Primarily to Genotoxins	Tissues Sensitive to Both Genotoxins and Nongenotoxins
Stomach	Nose
Zymbal's gland	Mammary gland
Lung	Pituitary gland
Subcutaneous tissue	Integumentary system
Circulatory system	Kidney
Clitoral gland	Urinary bladder
Skin	Liver
Intestine/colon	Thyroid gland
Uterus	Hematopoietic system
Spleen	Adrenal gland
Tunica vaginalis	Pancreas
Bile duct	Seminal vesicle
Ovary	Urinary tract
Harderian gland	Lymphatic system
Preputial gland	
(Multiple organ sites)	

1. Chromosome abnormalities, small changes in either number or structure.
2. Autosomal dominant gene mutations, in which a change in only one copy of the pair of genes is sufficient for the condition to be expressed.
3. Autosomal recessive gene mutations in which both copies of a gene must be mutated for the trait to become manifest.
4. Sex-linked conditions, which may also be recessive or dominant, where the mutant gene is on an X chromosome and will be expressed at high frequency in males (XY) and at a much lower frequency in females (XX), if the gene acts in a recessive manner.
5. Polygenic mutations, in which the condition results from the interaction of several genes and may include an environmental component.

10.2.17 Reproductive Effects

If a potent genotoxin is able to cross the placental barrier, it is very likely to interfere with differentiation of the developing embryo and thus possess teratogenic potential. Indeed, many of the better-studied teratogens are also mutagenic (Kalter, 1977). However, mutagens form only one class of teratogens, and a large proportion of teratogens are not mutagenic. Alternative mechanisms of teratogenesis include cell death, mitotic delay, retarded differentiation, vascular insufficiency, inhibited cell migration, etc. (Beckman and Brent, 1986).

It is known that more fetal wastage and many spontaneous abortions arise as a result of the presence of dominant lethal mutations in the developing embryo, many of which appear to be due to major chromosomal damage. In addition, impairment of male fertility may also be a consequence of exposure to mutagens.

10.3 CYTOGENETICS

There are various types of cytogenetic changes which can be detected in chromosomes. These are structural CAs, numerical changes which could result in aneuploidy, and sister chromatid exchanges (SCEs). CA assays are used to detect the induction of chromosome breakage (clastogenesis) in somatic or germinal cells by direct observation of chromosomal damage during metaphase analysis or by indirect observation of micronuclei. Chromosomal damage detected in these assays is mostly lethal to the cell during the cell cycle following the induction of the damage. Its presence, however, indicates a potential to induce more subtle chromosomal damages which survive cell division to produce heritable cytogenetic changes. Cytogenetic damage is usually accompanied by other genotoxic damage such as gene mutation.

10.3.1 Cytogenetic Damage and Its Consequences

Structural and numerical CAs in somatic cells may be involved in the etiology of neoplasia and in germ cells which can lead to perinatal mortality, dominant lethality, or congenital malformations in the offspring (Chandley, 1981), and some tumors (Anderson, 1990).

Chromosome defects arise at the level of the individual chromosome or at the level of the chromosomal set, so affecting chromosomal number.

10.3.2 Individual Chromosomal Damage

Damage to individual chromosomes consists of breakage of chromatids, which must result from a discontinuity of both strands of the DNA in a chromatid. How mutagens produce chromosome breakage is not totally understood, but DNA lesions which are not in themselves discontinuities will produce breakage of a chromosome as a consequence of their interference with the normal process of DNA replication. In haploid microorganisms and prokaryotes, chromosome breaks are usually lethal, but not in diploid eukaryotes. According to Bender et al. (1974), in these organisms, chromosome breaks may reconstitute in the same order, probably as a result of an enzyme repair process, resulting in no apparent cytogenetic damage. They may remain unjoined as fragments, which could result in cell death at the next or following mitoses—if, for example, unrejoined fragments are introduced into the zygote via treated germ cells, the embryo may die at a very early stage from a dominant lethal mutation, or they may rejoin in a different order from the original one, producing chromosomal rearrangements. There are various types of chromosomal rearrangements:

Reciprocal translocations can result from the exchange of chromosomal segments between two chromosomes and depending on the position of the centromeres in the rearranged chromosomes, different configurations will result:

1. Asymmetrical exchanges arise when one of the rearranged chromosomes carries both centromeres and is known as dicentric, while the other carries none and is acentric. The cell or zygote carrying this anomaly usually dies, death being caused by segregation difficulties of the dicentric or the loss of the acentric fragment at cell division. Such a translocation contributes to dominant lethality.
2. Symmetrical exchanges occur when each rearranged chromosome carries just one centromere. This allows the zygote to develop normally, but when such heterozygous form germ cells at meiosis, about half of their gametes will be genetically unbalanced, since they have deficiencies and duplications of chromosomal material. The unbalanced gametes which survive produce unbalanced zygotes, which results in death shortly before and after birth or congenital malformations.

Centric fusions involve the joining together of two chromosomes, each of which has a centromere at or near one end, to produce a single metacentric or submetacentric chromosome. When such translocations are produced in a germ cell and resulted from breakage and rejoining in the short arms of the two chromosomes, as a consequence of loss of the derived acentric fragments, a genetic deficiency can result. Some Robertsonian translocations are able to survive, but others pose a risk. In heterozygotes, the two arms of the translocation chromosome may pair with the two separate homologous chromosomes at meiosis but segregate in a disorderly manner. Some of the resultant germ cells lack copies (nullisomy) or carry two copies (disomy) of one or other of the two chromosomes involved, which results in monosomic or trisomic embryos. Monosomics die early, but trisomic embryos, which carry three copies of a chromosome, can survive to birth or beyond. If chromosome 21 is involved in the translocation, it can form a translocation trisomy and produce inherited Down syndrome (this differs from nondisjunctional Down syndrome trisomy).

Deletions and deficiencies are produced when two breaks arise close together in the same chromosome. The two ends of the chromosome join when the fragment between the breaks becomes detached. At the next cell division, the unattached piece of chromosome is likely to be lost. Large deletions may contribute to dominant lethality. Small deletions are difficult to distinguish from point mutations. Deletions may uncover preexisting recessive genes. If one gene that is essential for survival is uncovered, it can act as a lethal in a homozygote and as a partial dominant in a heterozygote.

Inversions occur when two breaks occur in the same chromosome. The portion between them is detached and becomes reinserted in the opposite way to its original position, that is, the gene order is reversed. This need not cause a genetic problem, but imbalanced gametes could result in congenital malformation or fetal death.

10.3.3 Chromosome Set Damage

Accuracy of chromosome replication and segregation of chromosomes to daughter cells requires accurate maintenance of the chromosome complement of a eukaryotic cell. Chromosome segregation in meiosis and mitosis is dependent upon the synthesis and functioning of the proteins of the spindle apparatus and upon the attachment and movement of chromosomes on the spindle. The kinetochores attach the chromosomes to the spindle, and the centrioles are responsible for the polar orientation of the division apparatus. Sometimes such segregation events proceed incorrectly, and homologous chromosomes separate, with deviations from the normal number (aneuploidy) into daughter cells or as a multiple of the complete karyotype (polyploidy). When both copies of a particular chromosome move into a daughter cell

and the other cell receives none, the event is known as nondisjunction.

Aneuploidy in live births and abortions arises from aneuploid gametes during germ cell meiosis. Trisomy or monosomy of large chromosomes leads to early embryonic death. Trisomy of the smaller chromosomes allows survival but is detrimental to the health of an affected person—for example, Down syndrome (trisomy 21), Patau syndrome (trisomy 13), and Edward syndrome (trisomy 18). Sex chromosome trisomies (Klinefelter's and XXX syndromes) and the sex chromosome monosomy (XO), known as the Turner syndrome, are also compatible with survival.

Aneuploidy in somatic cells is involved in the formation of human tumors. Up to 10% of tumors are monosomic and trisomic for a specific chromosome as the single observable cytogenetic change. Most common among such tumors are trisomy 8, 9, 12, and 21, and monosomy for chromosomes 7, 22, and Y.

10.3.4 Test Systems

in vivo and *in vitro* techniques are available to test mutagenic properties to demonstrate presence or lack of ability of the test material to cause mutation or chromosomal damage or cause cancer, as summarized in Table 10.3. The material intended for intimate contact and long exposure should not have any genotoxic properties. The presence of unpolymerized materials and traces of monomers, oligomers, additives, or biodegradation products can cause mutations. Mutation can be a point mutation or chromosomal rearrangement caused by DNA damage. Therefore, the material's ability to cause point mutation, chromosomal change, or evidence of DNA damage is tested. As we have seen, correlations exist between mutagenic and carcinogenic properties. Most carcinogens are mutagens, but not all mutagens are human carcinogens.

The Ames salmonella/microsome test is a principal sensitive mutagen-screening test (McCann et al., 1975a; McCann and Ames, 1976). Compounds are tested on the mutants of *S. typhimurium* for reversion from a histidine requirement back to prototrophy. A positive result is seen by the growth of revertant bacteria (which do not require an external histidine source). A microsomal activation system should be included in this assay. The use of five different bacterial test strains is generally required.

Two mammalian mutagenicity tests (one *in vitro*, one *in vivo*) are generally required to support the lack of mutagenic or carcinogenic potential. Some well-known tests are the following:

- The L5178Y mouse lymphoma assay (MLA) for mutants at the TK locus
- The induction of recessive lethals in *D. melanogaster*

TABLE 10.3 Fifteen Common Assays Described by OECD

	<i>in vitro</i>	<i>in vivo</i>
<i>Salmonella typhimurium</i> reverse mutation assay (Ames test, bacteria) (OECD 471)	✓	
<i>Escherichia coli</i> reverse mutation assay (bacteria) (OECD472)	✓	
Gene mutation in mammalian cells in culture (OECD 476)	✓	
<i>Drosophila</i> sex-linked recessive lethal assay (fruit fly) (OECD 477)		✓
Gene mutation in <i>Saccharomyces cerevisiae</i> (yeast) (OECD 480)	✓	
Mouse spot test (OECD 484)		✓
Assays for chromosomal and genomic mutations <i>in vitro</i> cytogenetic assay (OECD 473)	✓	
<i>in vivo</i> cytogenetic assay (OECD 475)		✓
Micronucleus test (OECD 474)		✓
Dominant lethal assay (OECD 478)		✓
Heritable translocation assay (OECD 485)		✓
Mammalian germ cell cytogenetic assay (OECD 483)		✓
Assays for DNA effects		
DNA damage and repair: unscheduled DNA synthesis <i>in vitro</i> (OECD 482)	✓	
Mitotic recombination in <i>S. cerevisiae</i> (yeast) (OECD 481)	✓	
<i>in vitro</i> sister chromatid exchange assay (OECD 479)	✓	

- Metaphase analysis of cultured mammalian cells and of treated animals
- SCE assay
- Unscheduled DNA synthesis (UDS) assay
- Cell transformation assay
- Comet assay
- Gene mutation in cultured mammalian cells such as Chinese hamster V79 cell/hypoxanthine-guanine phosphoribosyltransferase (HGPRT) mutation system

ICH guidelines specifically require three genotoxicity assays for all devices (see Table 10.1). The assays should preferably evaluate DNA effects, gene mutations, and CAs, and two of the assays should preferably use mammalian cells. Guidance for providing tests for selection to meet these needs is the OECD guidelines, which include eight *in vitro* and seven *in vivo* assays.

10.3.5 *In Vitro* Test Systems

The principal tests can be broadly categorized into microbial and mammalian cell assays. In both cases, the tests are carried out in the presence and absence of *in vitro* metabolic activation enzymes, usually derived from rodent liver.

10.3.5.1 *In Vitro* Metabolic Activation The target cells for *in vitro* mutagenicity tests often possess a limited (often overlooked) capacity for endogenous metabolism of xenobiotics. However, to simulate the complexity of metabolic events that occur in the whole animal, there is a critical need to supplement this activity.

Choice of Species A bewildering variety of exogenous systems have been used for one purpose or another in mutagenicity tests. The choice begins with plant or animal preparations. The attraction of plant systems has stemmed from a desire to avoid the use of animals, where possible, in toxicity testing. In addition, plant systems have relevance when certain chemicals are being tested, for example, herbicides.

If animal systems are chosen, preparations derived from fish (see, e.g., Kada, 1981) and birds (Parry et al., 1985) have been used. However, by far the most widely used and validated are those derived from rodents—in particular the rat. Hamsters may be preferred as a source of metabolizing enzymes when particular chemical classes are being screened—for example, aromatic amines, heterocyclic amines, *N*-nitrosamines, and azo dyes (Prival and Mitchell, 1982; Haworth et al., 1983).

Choice of Tissue The next choice is that of source tissue. Preparations derived from liver are the most useful, as this tissue is a rich source of mixed function oxygenases capable of converting procarcinogens to genetically active electrophiles. However, many extrahepatic tissues (e.g., kidney, lung) are also known to possess important metabolic capacity which may be relevant to the production of mutagenic metabolites in the whole animal.

Cell-Free Versus Cell-Based Systems Most use has been made of cell-free systems—in particular crude homogenates such as 9000 g supernatant (S9 fraction) from rat liver. This fraction is composed of free endoplasmic reticulum, microsomes (membrane-bound packets of “membrane-associated” enzymes), soluble enzymes, and some cofactors. Hepatic S9 fractions do not necessarily completely reflect the metabolism of the whole organ, in that they mainly possess phase I metabolism (e.g., oxygenases) and are deficient in phase II systems (e.g., conjugation enzymes). The latter are often capable of efficient detoxification, while the former are regarded as “activating.” This can be a strength in that S9 fractions are used in screening tests as a surrogate for all tissues in animals, some of which may be exposed to reactive metabolites in the absence of efficient detoxification. Many carcinogens are organ-specific in extrahepatic tissues, yet liver S9 fraction will reveal their mutagenicity. The deficiency of S9 fractions for detoxification can also be a weakness, in that detoxification may predominate in the whole animal, such that the potential carcinogenicity revealed *in vitro* is not realized *in vivo*.

Cell-free systems, when supplemented with relevant cofactors, are remarkably proficient, despite their crudity in generating reactive electrophiles from most procarcinogens. However, they provide at best a broad approximation of *in vivo* metabolism and can fail to produce sufficient quantity of a particular reactive metabolite to be detectable by the indicator cells, or they can produce inappropriate metabolites that do not play a role *in vivo* (see Gatehouse and Tweats (1987) for discussion).

Some of these problems can be overcome by the use of cell-based systems—in particular primary hepatocytes. Hepatocytes closely simulate the metabolic systems found in the intact liver and do not require additional cofactors for optimal enzyme activity. However, apart from greater technical difficulties in obtaining hepatocytes as opposed to S9 fraction, hepatocytes can effectively detoxify particular carcinogens and prevent their detection as mutagens. Despite these difficulties, hepatocytes have a role to play in mutagenicity screening, in both bacterial- and mammalian-based systems (Tweats and Gatehouse 1988).

Inducing Agents The final choice considered here is whether to use “uninduced” liver preparations or those derived from animals pretreated with an enzyme inducer to promote high levels of metabolic activity. If induced preparations are preferred, which inducer should be used?

It appears that uninduced preparations are of limited use in screening assays, as they are deficient in particular important activities such as cytochrome P-450_{1A1} oxygenases. In addition, species and organ differences are most divergent with uninduced enzyme preparations (Brusick, 1987a).

The aforementioned differences disappear when induced microsomal preparations are used. A number of enzyme inducers have been used, the most popular being Aroclor 1254, which is a mixture of polychlorinated biphenyls (as described by Ames et al., 1975). However, concern about the toxicity, carcinogenicity, and persistence of these compounds in the environment has led to the use of alternatives, such as a combination of phenobarbitone (phenobarbital) and β -naphthoflavone (5,6-benzoflavone). This combination results in the induction of a range of monooxygenases similar to that induced by Aroclor 1254 (see e.g., Ong et al., 1980). More selective inducers such as phenobarbitone (cytochrome P-450_{IIa1}, P-450_{IIb1}) or 3-methylcholanthrene (cytochrome P-450_{IA1}) have also been used.

In summary, genetic toxicity tests with both bacterial and mammalian cells are normally carried out with rat liver cell-free systems (S9 fraction) from animals pretreated with enzyme inducers. However, investigations should not slavishly follow this regimen: there may be sound scientifically based reasons for using preparations from different species or different organs or for using whole cells such as hepatocytes.

Standard Method of S9 Fraction Preparation The following method describes the production of hepatic S9 mix from rats induced with a combination of phenobarbitone and β -naphthoflavone and is an adaptation of the method described by Gatehouse and Delow (1979).

Male albino rats within the weight range 150–250 g are treated with phenobarbitone sodium 16 mg mL⁻¹, 2.5 mL kg⁻¹ in sterile saline and β -naphthoflavone 20 mg mL⁻¹ in corn oil. A fine suspension of the latter is achieved by sonicating for 1 h. These solutions are dosed by intraperitoneal injection on days 1, 2, and 3.

Phenobarbitone sodium is normally administered between 0.5 and 2 h prior to β -naphthoflavone.

The animals are killed on day 4 by cervical dislocation and the livers removed as quickly as possible and placed on ice cold KCl buffer (0.01 M Na₂HPO₄ + KCl 1.15%). The liver is cleaned, weighted, minced, and homogenized (in an Ultra-Turrax homogenizer) in the aforementioned buffer to give a 25% (w/v) liver homogenate. The homogenate is stored at 4°C until it can be centrifuged at 9000g for 15 min. The supernatant is decanted, mixed, and divided into 2 mL volumes in cryotubes. These are then snap-frozen in liquid nitrogen. Storage at –196°C for up to 3 months results in no appreciable loss of most P-450 isoenzymes (Ashwood-Smith, 1980).

Quality control of S9 batches is usually monitored by ability to activate compounds known to require metabolism to generate mutagenic metabolites. This is a rather crude approach, and more accurate data can be obtained by measuring biochemical parameters—for example, protein, cytochrome P-450 total activity (from crude S9) and related enzyme activities (from purified microsomes) such as 7-ethoxyresorufin-*O*-deethylase and 7-methoxycoumarin-*O*-demethylase to give an indication of S9 batch-to-batch variation and to set standards for rejecting suboptimal batches (Hubbard et al., 1985). For further details on critical features affecting the use and limitations of S9 fraction, see Gatehouse and Tweats (1987).

S9 Mix The S9 fraction prepared as described earlier is used as a component in “S9 mix” along with buffers and various enzyme cofactors. The amount of S9 fraction in the S9 mix can be varied, but a “standard” level of 0.1 mL mL⁻¹ of S9 mix (or 10% S9) is often recommended for general screening.

No single concentration of S9 fraction in the S9 mix will detect all classes of genotoxic carcinogen with equal efficiency (Gatehouse et al., 1990). Some mutagens, including many polycyclic aromatic hydrocarbons, are activated to mutagens by higher-than-normal levels of S9 fraction in the S9 mix (see, e.g., Carver et al., 1985).

The mixed-function oxidases in the S9 fraction require NADPH, normally generated from the action of glucose-6-phosphate dehydrogenase acting on glucose-6-phosphate and

reducing NADP, both of which are normally supplied as cofactors. As an alternative, isocitrate can be substituted for glucose-6-phosphate (to be used as a substrate by isocitrate dehydrogenase) (Linblad and Jackim, 1982). Additional cofactors may be added (e.g., flavin mononucleotide), when particular classes of compound such as azo dyes are being tested (Prival et al., 1984), or acetyl coenzyme A when aromatic amines such as benzidine are being tested (Kennelly et al., 1984). The composition of a “standard” S9 mix is given in Table 10.4.

10.3.6 Bacterial Mutation Tests

The study of mutation in bacteria (and bacterial viruses) has had a fundamental role in the science of genetics in the twentieth century. In particular, the unraveling of biochemical anabolic and catabolic pathways, the identification of DNA as the hereditary material, the fine structure of the gene, the nature of gene regulation, etc., have all been aided by bacterial mutants.

As an offshoot of studies of genes concerned with the biosynthesis of amino acids, a range of *E. coli* (see, e.g., Yanofsky, 1971) and *S. typhimurium* strains (see e.g., Ames, 1971; Ames et al., 1973; Ames and McCann, 1981) with relatively well-defined mutations in known genes became available. Thus, bacteria already mutant at an easily detectable locus are treated with a range of doses of the test material to determine whether the compound can induce a second mutation that directly reverses or suppresses the original mutations. Thus, for amino acid auxotrophs, the original mutation has resulted in loss of ability to grow in the absence of the required

amino acid. The second mutation restores prototrophy—that is, the affected cell is now able to grow in the absence of the relevant amino acid, if provided with inorganic salts and a carbon source. This simple concept, in fact, underlines the great strength of these assays, for it provides enormous selective power which can identify a small number of the chosen mutants from a population of millions of unmutated cells and cells mutated in other genes. The genetic target—that is, the mutated DNA bases in the gene in question (or bases in the relevant tRNA genes; see the discussion of suppressor mutations)—can thus be very small, just one or a few bases in length.

An alternative approach is to use bacteria to detect “forward mutations.” Genetic systems which detect forward mutations have an apparent advantage, in that a wide variety of genetic changes may lead to a forward mutation—for example, point mutation, deletions, insertions, etc. In addition, forward mutations in a number of different genes may lead to the same change in phenotype; thus, the genetic target is much larger than that seen in most reverse mutation assays. However, if a particular mutagen causes rare specific changes, these changes may be lost against the background of more common events (Gatehouse et al., 1990, 1994). Spontaneous mutation rates tend to be relatively high in forward mutation systems. Acquisition of resistance to a toxic chemical (e.g., an amino acid analog or antibiotic) is a frequently used genetic marker in these systems. For instance, the use of resistance to the antibiotic streptomycin preceded the reversion assays in common use today.

TABLE 10.4 Composition of Standard S9 Mix

Constituent	Final Concentration in Mix (mM)
Glucose-6-phosphate	5
Nicotinamide adenine dinucleotide phosphate	4
MgCl ₂ ·6H ₂ O } salt solution	8
KCl	33
Phosphate buffer (90.2 M)	100
Distilled water to make up to the required volume	
S9 fraction added at 0.1 mL mL ⁻¹ of S9 mix	

For assays using cultured mammalian cells, phosphate buffer and distilled water are replaced by tissue culture medium, as high concentrations of Na and K salts are toxic to such cells. The concentration of S9 fraction in the S9 mix varies, depending on the relevant assay (see individual sections). Once prepared, S9 mix should be used as soon as possible and should be stored on ice until required. S9 fraction, once thawed, should not be refrozen for future use.

10.3.6.1 Reversion Tests: Background There are several excellent references describing the background and use of bacteria for reversion tests (Brusick, 1987a, b; Gatehouse et al., 1990). Three different protocols have been widely used: plate incorporation assays, treat and plate tests, and fluctuation tests. These methods are described in detail in the following sections. Fundamental to the operation of these tests is the genetic compositions of the tester strains selected for use.

10.3.6.2 Genetic Makeup of Tester Strains The most widely used strains are those developed by Bruce Ames and colleagues which are mutant derivatives of the organism *S. typhimurium*. Each strain carries one of a number of mutations in the operon coding for histidine biosynthesis. In each case, the mutation can be reverted either by base change or by frameshift mutations. The genotype of the commonly used strains is shown in Table 10.5.

10.3.6.3 The Use of the Plasmid pKM101 *Salmonella typhimurium* LT2 strains do not appear to possess classical “error-prone” repair as found in *E. coli* strains and some other members of the enterobacteria (Walker, 1984;

TABLE 10.5 Genotype of Commonly Used Strains of *Salmonella typhimurium* LT2 and Their Reversion Events

Strain	Genotype	Reversion Events
TA1535	hisG ₄₆ rfa ○ gal chlD bio uvrB	Subset of base-pair substitution events
TA100	hisG ₄₆ ○ rfa gal chlD bio uvrB (pKM101)	Subset of base-pair substitution events
TA1537	hisC ₃₀₇₆ ○ rfa gal chlD bio uvrB	Frameshifts
TA1538	hisD ₃₀₅₂ ○ rfa gal chlD bio uvrB	Frameshifts
TA98	hisD ₃₀₅₂ ○ rfa gal chlD bio uvrB pKM101	Frameshifts
TA97	hisD ₆₆₁₀ hisO ₁₂₄₂ rfa ○ gal chlD bio uvrB (pKM101)	Frameshifts
TA102	his ○ (G) ₈₄₇₆ rfa galE (pAQ1) (pKM101)	All possible transitions and transversions, small deletions

Sedgwick and Goodwin, 1985). This is due to a deficiency in *umuD* activity in these *Salmonella* strains (Herrera et al., 1988; Thomas and Sedgwick, 1989). One way to overcome this deficiency and to increase sensitivity to mutagens is to use strains containing a plasmid carrying analogs to the *umuDC* genes, such as are present in the pKM101 plasmid.

10.3.6.4 Ames Salmonella/Plate Incorporation Method

The following procedure is based on that described by Ames and colleagues (Kado et al., 1983; Maron and Ames, 1983), with additional modifications:

1. Each selected test strain is grown for 10h at 37°C in nutrient broth (Oxoid No. 2) or supplemented minimal media (Vogel–Bonner) on an orbital shaker. A timing device can be used to ensure that cultures are ready at the beginning of the working day.
2. 2.0mL aliquots of soft agar overlay medium are melted just prior to use and cooled to 50°C, and relevant supplements added—that is, L-histidine, final concentration 9.55 µg mL⁻¹, and D-biotin 12 µg mL⁻¹. (N.B.: If *E. coli* WP2 tester strains are used, the only supplement required is tryptophan 3.6 µg mL⁻¹.) The medium is kept semimolten by holding the tubes containing the medium in a hot aluminum dry block, held at 45°C. It is best to avoid water baths as microbial contamination can cause problems.
3. The following additions are made to each tube of top agar: the test article (or solvent control) in solution (10–200 µL), the test strain (100 µL), and, where necessary, S9 mix (500 µL). The test is carried out in the presence and absence of S9 mix. The exact volume of test article or solvent may depend on toxicity or solubility, as described in the preceding section.
4. There should be at least three replicate plates per treatment with at least five test doses plus untreated controls. Duplicate plates are sufficient for the positive and sterility control treatments. The use of twice as many negative control plates as used in each treatment group will lead to more powerful tests from a statistical standpoint (Mahon et al., 1989).

5. Each tube of top agar is mixed and quickly poured onto dried prelabeled Vogel–Bonner basal agar plates.
6. The soft agar is allowed to set at room temperature, and the plates are inverted and incubated (within 1 h of pouring) at 37°C in the dark. Incubation is continued for 2–3 days.
7. Before scoring the plates for revertant colonies, the presence of a light background lawn of growth (due to limited growth of nonrevertant colonies before the trace of histidine or tryptophan is exhausted) should be confirmed for each concentration of test article by examination of the plate under low power of a light microscope. At concentrations that are toxic to the test strains, such a lawn will be depleted, and colonies may appear that are not true revertants but surviving, nonprototrophic cells. If necessary, the phenotype of any questionable colonies (pseudorevertants) should be checked by plating on histidine- or tryptophan-free medium.
8. Revertant colonies can be counted by hand or with an automatic colony counter. Such machines are relatively accurate in the range of colonies normally observed (although regular calibration against manual counts is a wise precaution). Where accurate quantitative counts of plates with large numbers of colonies are required, only manual counts will give accurate results.

10.3.7 Controls

10.3.7.1 Positive Controls

Where possible, positive controls should be chosen that are structurally related to the test article. This increases the confidence in the results. In the absence of structurally related mutagens, the set of positive controls given in Table 10.6 can be used. The use of such controls validates each test run and helps to confirm the nature of each strain. Pagano and Zeiger (1985) have shown that it is possible to store stock solutions of most routinely used positive controls (sodium azide, 2-aminoanthracene, benzo[*a*]pyrene, 4-nitroquinoline oxide) at –20 to –80°C for several months, without loss of activity. This measure can help reduce potential exposure to laboratory personnel.

TABLE 10.6 Positive Controls for Use in Plate Incorporation Assays

Species	Strain	Mutagen	Concentration (µg plate ⁻¹) ^a
<i>(a) In the absence of S9 mix</i>			
<i>Salmonella typhimurium</i>	TA1535 } TA100 }	Sodium azide	1–5
	TA1538 } TA98 }	Hycanthone methanesulfonate	5–20
	TA1537	ICR 191	1
<i>Escherichia coli</i>	WP2 uvrA	Nifuroxime	5–15
<i>(b) In the presence of S9 mix</i>			
<i>E. coli</i>	WP2 uvraA	2-Aminoanthracene	1–10
<i>S. typhimurium</i>	(pKM101)		
	TA1538 } TA1535 } TA100 } TA90 }		
	TA1537	Neutral red	10–20

^a The concentration given earlier will give relatively small increases in revertant count above the spontaneous level. There is little point in using large concentrations of reference mutagens which invariably give huge increases in revertant counts. This would give little information on the day-to-day performance of the assay.

10.3.7.2 Untreated/Vehicle Controls Untreated controls omit the test article but are made up to volume with buffer. The vehicle control is made up to volume with the solvent used to dissolve the test substance. It is preferable to ensure that each of the treated plates contains the same volume of vehicle throughout.

As detailed by Gatehouse and Tweats (1987), the nature and concentration of solvent may have a marked effect on the test result. Dimethyl sulfoxide (DMSO) is often used as the solvent of choice for hydrophobic compounds. However, there may be unforeseen effects, such as an increase in mutagenicity of some compounds—for example, *p*-phenylenediamine (Burnett et al., 1982)—or a decrease in mutagenicity of others, such as simple aliphatic nitrosamines (Yahagi et al., 1977). It is essential to use fresh batches of the highest purity grade available and to prevent decomposition/oxidation on storage. The products after oxidation are both toxic and can induce base-pair substitutions in both bacterial and mammalian assays. Finally, DMSO and other organic solvents can inhibit the oxidation of different premutagens by microsomal monooxygenases (Wolff, 1977a, b). To reduce the risk of artifactual results, it is essential to use the minimum amount of organic solvent (e.g., <2% w/w) compatible with adequate testing of the test chemical.

It is important to keep a careful check of the number of mutant colonies present on untreated or vehicle control plates. These numbers depend on the following factors:

1. The repair status of the cell—that is, excision repair deficient strains tend to have more “spontaneous mutants” than repair-proficient cells.
2. The presence of mutator plasmids. Excision-deficient strains containing pKM101 have a higher spontaneous mutation rate at both base substitution and frameshift loci than excision-proficient strains.
3. The total number of cell divisions that take place in the supplemented top agar. This is controlled by the supply of nutrients—in particular histidine. Rat liver extracts may also supply trace amounts of limiting nutrients, resulting in a slight increase in the spontaneous yield of mutants in the presence of S9 mix.
4. The size of the initial inoculum. During growth of the starting culture, mutants will arise. Thus, if a larger starting inoculum is used, more of these “preexisting” mutants will be present per plate. In fact, the “plate mutants” arising as described in point (3) predominate.
5. The intrinsic mutability of the mutation in question. In practice, the control mutation values tend to fall within a relatively precise range for each strain. Each laboratory should determine the normal range of revertant colonies per plate for each strain.

Deviations in background reversion counts from the normal range should be investigated. It is possible that cross

contamination, variations in media quality, etc. have occurred that may invalidate particular experiments.

Frequent checks should also be made on the sterility of S9 preparations, media, and test articles. These simple precautions can prevent loss of valuable time and resources.

10.3.7.3 Evaluation of Results At least two independent assays are carried out for each test article. The criterion for positive response is a reproducible and statistically significant result at any concentration for any strain. When positive results are obtained, the test is repeated, using the strain(s) and concentration range with which the initial positive results were observed. This range may be quite narrow for toxic agents.

Several statistical approaches have been applied to the results of plate incorporation assays (Mahon et al., 1989). These authors make a number of important suggestions to maximize the power of statistical analyses; those that relate to the method of analysis are reproduced as follows:

1. Unless it is obvious that the test agent has had no effect, the data should be plotted, to give a visual impression of the form of any dose–response and the pattern of variability.
2. Three methods of analysis—linear regression (Armitage, 1971; Steel and Torrie, 1996; Gad, 2005); a multiple comparison analysis, such as Dunnett's method (Dunnett, 1955); and a nonparametric analysis, such as Kruskal–Wallis (Gad, 2005)—can all be recommended. Each has its strengths and weaknesses, and other methods are not excluded.
3. Linear regression assumes that variance across doses is constant and that the dose–response is linear. If the variance is not approximately constant, then a transformation may be applied, or a weighted analysis may be carried out. If the dose scale tends to a plateau, then the dose scale may be transformed. If counts decline markedly at high doses, then linear regression is inappropriate.
4. Dunnett's method, perhaps with a transformation, is recommended when counts decline markedly at one or two high doses. However, when the dose–response shows no such decline, other methods may be more powerful.
5. Kruskal–Wallis's nonparametric method avoids the complications of transformations of weighting and is about as powerful as any other method. However, it is inappropriate when the response declines markedly at high dose.

10.3.7.4 Preincubation Tests Some mutagens are poorly detected in the standard plate incorporation assay, particularly those that are metabolized to short-lived reactive

electrophiles—for example, short-chain aliphatic *N*-nitroso compounds (Bartsch et al., 1976). It is also possible that some metabolites may bind to components within the agar. Such compounds can be detected by using a preincubation method first described by Yahagi et al. (1975) in which the bacteria, test compound, and S9 mix are incubated together in a small volume at 37°C for a short period (30–60 min) before adding the soft agar and pouring as for the standard assay. In this variation of the test, during the preincubation step, the test compound, S9 mix, and bacteria are incubated in liquid at higher concentrations than in the standard test, and this may account for the increased sensitivity with relevant mutagens. In the standard method, the soluble enzymes in the S9 mix, cofactors, and the test agent may diffuse into the bottom agar. This can interfere with the detection of some mutagens—a problem that is overcome in the preincubation method (Forster et al., 1980; Gatehouse and Wedd, 1984). The test is carried out as follows: plates—for

1. The strains are cultured overnight, and the inocula and S9 mix are prepared as in the standard Ames test.
2. The soft agar overlays are prepared and maintained at 45°C prior to use.
3. To each of 3–5 tubes maintained at 37°C in a Dri-Block are added 0.5 mL of S9 mix, 0.1 mL of the tester strain (10–18 h culture), and a suitable volume of the test compound to yield the desired range of concentrations. The S9 mix is kept on ice prior to use.
4. The reaction mixtures are incubated for use to 1 h at 37°C.
5. 2.0 mL of soft agar is added to each tube. After mixing, the agar and reaction mixture are poured onto previously labeled, dried Vogel–Bonner plates.
6. Once the agar has set, the plates are incubated for 2–3 days before revertant colonies are scored.

The use of controls is as described for the plate incorporation assay. It is crucial to use the minimum amount of organic solvent in this assay, as the total volume of the incubation mixture is small relative to the solvent component.

This procedure can be modified to provide optimum conditions for particular chemical classes. For instance, preincubation times greater than 60 min plus aeration have been found necessary in the detection of allyl compounds (Neudecker and Henschler, 1985).

10.3.7.5 *E. coli* Tester Strains Ames and colleagues have made an impressive contribution to mutagenicity testing by the development of the *Salmonella*/microsome test and, in particular, its application in the study of environmental mutagens. In genetic terms, *Salmonella* strains are, in some ways, not the best choice (see, e.g., Venitt and Crofton-Sleigh, 1981). Unlike the *Salmonella* strains, *E. coli* B strains

such as the WP2 series developed by Bridges, Green, and colleagues (Bridges, 1972; Green and Muriel, 1976) inherently possess the *umuDC*⁺ genes involved in generating mutations; they are also partly rough and thus allow many large molecules to enter the cell.

In addition to being effective general strains for mutagen detection, studies by Wilcox et al. (1990) have shown that a combination of *E. coli* WP2 *trp E* (pKM101), which has a functioning excision repair system for the detection of cross-linking agents, and *E. coli* WP2 *trp E uvrA* (pKM101) can be used as alternatives to *Salmonella* TA102 for the detection of oxidative mutagens. The *E. coli* strains have the advantage of lower spontaneous mutation rate and are somewhat less difficult to use and maintain. The *Salmonella* strains are, however, more commonly employed.

10.3.7.6 Storage and Checking of Tester Strains Detailed instructions for maintenance and confirmation of the phenotypes of the various tester strains are given in Maron and Ames (1983) and Gatehouse et al. (1990). Permanent master cultures of tester strains should be stored in liquid nitrogen or in dry ice. Such cultures are prepared from fresh nutrient broth cultures, to which DMSO is added as a cryopreservative. These cultures are checked for the various characteristics before storage as described in the following text. Cultures for use in individual experiments should be set up by inoculation from the master culture or from a plate made directly from the master culture, not by passage from a previously used culture. Passage in this way will inevitably increase the number of preexisting mutants, leading to unacceptably high spontaneous mutation rates (Gatehouse et al., 1990).

The following characteristics of the tester strains should be confirmed at monthly intervals or if the internal controls of a particular experiment fail to meet the required limits:

- Amino acid requirement
- Sensitivity to the lethal effects of the high molecular weight dye crystal violet for those strains carrying the *rfaE* mutation.
- Increased sensitivity to UV irradiation for those strains carrying the *uvrA* or *uvrB* mutations.
- Resistance to ampicillin for strains carrying pKM101 and resistance to tetracycline for strains carrying pAQ1.
- Sensitivity to diagnostic mutagens. This can be measured very satisfactorily by testing pairs of strains—one giving a strongly positive response and the partner a weak response.

The importance of these checks together with careful experiment-to-experiment controls of spontaneous mutation rates and response to reference mutation rates and response to reference mutagens cannot be overstressed; failure to apply them can result in much wasted effort.

10.3.8 Plate Incorporation Assay

10.3.8.1 Protocol for Dose Ranging and Selection

Before carrying out the main tests, it is necessary to carry out a preliminary toxicity dose-ranging test. This should be carried out following the same basic protocol as the mutation test, except that instead of scoring the number of mutants on, for example, minimal media plates with limiting amounts of a required amino acid, the number of survivors is scored on fully supplemented minimal media. A typical protocol is outlined in the following:

1. Prepare a stock solution of the test compound at a concentration of 50 mg mL⁻¹ in an appropriate solvent. It may be necessary to prepare a lower concentration of stock solution, depending on the solubility of the test compound.
2. Make dilutions of the stock solution.
3. To 2.0 mL aliquots of soft agar overlay medium (0.6% agar and 0.5% sodium chloride in distilled water) containing a trace of histidine and excess biotin and maintained at 45°C in a dry block, add 100 μL of a solution of the test article. Use only one plate per dilution.
4. Mix and pour onto dried Vogel–Bonner minimal medium plates as in an Ames test, including an untreated control and a solvent control, if necessary. The final concentrations of test compound will be 5000, 1500, 500, 150, and 50 μg plate⁻¹.
5. Repeat step (3), using 0.5 mL of 8% S9 mix per 2.0 mL aliquot of soft agar in addition to the test compound and tester strain. The S9 mix is kept on ice during the experiment.
6. Incubate the plates for 2 days at 37°C and examine the background lawn of growth with a microscope (8 eye-piece lens, 10 objective lens). The lowest concentration giving a depleted background lawn is regarded as a toxic dose.

This test will also demonstrate excess growth, which may indicate the presence of histidine or tryptophan or their precursors in the test material, which could make testing for mutagenicity impracticable by this method.

When setting the maximum test concentration, it is important to test into the mg plate⁻¹ range where possible (Gatehouse et al., 1990), as some mutagens are only detectable when tested at high concentrations. However, for nontoxic, soluble mutagens an upper limit of 5 mg plate⁻¹ is recommended (DeSerres and Shelby, 1979). For less soluble compounds, at least one dose exhibiting precipitation should be included.

Complex samples/mixtures can be assayed for component mutagens by using their longer chromatography plates as a basis for Ames assay testing (Bjørseth et al., 1982). Seifried et al. (2006) have compiled and published a

summary of comparative results from the Ames and mouse lymphoma mutagenicity test systems, with the Ames giving a better showing.

10.3.8.2 Forward Mutation Tests Forward mutation is an end point that may arise from various events, including base substitutions, frameshifts, DNA deletions, etc., as mentioned earlier.

10.3.9 Eukaryotic Mutation Tests

Prokaryotic systems, as described, have proved to be quick, versatile, and in many cases surprisingly accurate in identifying potential genetic hazards to man. However, there are intrinsic differences between eukaryotic and prokaryotic cells in the organization of the genome and the processing of the genetic information. Thus, there is a place for test systems based on mammalian cells for fundamental studies to understand the mutation process in higher cells and for the use of such tests for screening for genotoxic effects.

The early work of Muller showed the usefulness of the fruit fly *D. melanogaster* as a higher system for measuring germline mutations in a whole animal. The *Drosophila* sexlinked recessive lethal test has yielded much useful information and in the 1970s was a popular system for screening chemicals for mutation, but this test failed to perform well in international collaborative trials to study the utility of such tests to detect carcinogens and popularity waned. Another *Drosophila* test devised in the 1980s, the somatic mutation and recombination test (SMART), shows much promise and has revived the popularity of *Drosophila* for screening for genotoxic agent.

There are a number of test systems that use cultured mammalian cells, from both established and primary lines, that now have a large database of tested chemicals in the literature, that are relatively rapid, and that are feasible to use for genetic toxicity screening. These are discussed in Section 10.3.10.

10.3.10 *in vitro* Tests for the Detection of Mammalian Mutation

There have been a variety of *in vitro* mutation systems described in the literature, but only a small number have been defined adequately for quantitative studies (Cole et al., 1990). These are based on the detection of forward mutations in a similar manner to the systems described earlier for bacteria. A defined large number of cells are treated with the test agent and then, after a set interval, exposed to a selective toxic agent, so that only cells that have mutated can survive. As cultured mammalian cells are diploid (or near diploid), normally there are two copies of each gene. Recessive mutations can be missed if a normal copy is present on the homologous chromosome. As mutation frequencies for individual genes are normally very low, an impossibly large population of cells would need to be

screened to detect cells in which both copies are inactivated by mutation. This problem is overcome by measuring mutation in genes on the X chromosome in male cells where only one copy of the gene will be present or using heterozygous genes where two copies of a gene may be present, but one copy is already inactive through mutation or deletion.

Many genes are essential for the survival of the cell in culture, and thus mutations in such genes would be difficult to detect. However, use has been made of genes that are not essential for cell survival but allow the cell to salvage nucleotides from the surrounding medium. This saves the cell energy, as it does not have to make these compounds from simpler precursors by energy-expensive catabolism. These enzymes are located at the cell membrane. If the cell is supplied with toxic nucleotides, the “normal” unmutated cells will transport these into the cell and kill the cell. However, if the cells have lost the enzyme as a result of mutation (or chromosomal deletion, rearrangement, etc.), then they will not be able to “salvage” the exogenous toxic nucleotides and will survive. The surviving mutant cells can be detected by the formation of colonies on tissue culture plates or, in some cases, in the wells of microtiter plates.

One factor to take into account with these tests is that of expression time. Although a gene may be inactivated by mutation, the mRNA existing before the mutational event may decay only slowly, so that active enzyme may be present for some time after exposure to the mutagen. Thus, the cells have to be left for a period before challenging with the toxic nucleotide: this is the expression time and differs between systems.

10.3.10.1 Chinese Hamster Lines Chinese hamster cell lines have given much valuable data over the past 15 years, but their use for screening is limited by lack of sensitivity, as only a relatively small target cell population can be used, owing to metabolic cooperation (see Cole et al., 1990); however, they are still in use, so a brief description follows.

Chinese hamster ovary (CHO) and V79 lines have high plating efficiencies and short generation times (<24h). These properties make the lines useful for mutagenicity experiments. Both cell lines have grossly rearranged chromosomal complements, which has an unknown effect on their responsiveness to mutagens (Tweats and Gatehouse, 1988). There is some evidence that Chinese hamster lines are undergoing genetic drift in different culture collections (Kirkland and Garner, 1987).

10.3.10.2 V79 System The Chinese hamster V79 line was established in 1958 (Ford and Yerganian, 1958). Publication of the use of the line for mutation studies (by measuring resistance to purine analogs due to mutation of the *Hgprt* locus) occurred 10 years later (Chu and Malling, 1968). The V79 line was derived from a male Chinese hamster; hence, V79 cells possess only a single X chromosome.

V79 cells grow as a cell sheet or monolayer on glass or plastic surfaces. If large numbers of cells are treated with a mutagen, when plated out, cells in close contact can link via intracellular bridges. These allow the transfer of cellular components between cells such as mRNA. Thus, if a cell carries a mutation in the *hgp* gene resulting in the inactivation of the relevant mRNA, it can receive viable mRNA or intact enzyme from adjacent nonmutated cells. Therefore, when the mutated cell is challenged with a toxic purine, it is lost, owing to the presence of active enzyme derived from the imported mRNA. This phenomenon is termed “metabolic cooperation” and severely limited the sensitivity of lines such as V79 for mutagen detection. This drawback can be overcome to an extent by carrying out the detection of mutant clones in semi-solid agar (see, e.g., Oberly et al., 1987) or by using the “resuspending technique” (Fox, 1981).

The preferred expression time for *Hgp* mutants is 6–8 days, although care needs to be taken when testing chemicals well into the toxic range, where the “expression time” needs to be extended to allow recovery.

10.3.10.3 Preliminary Cytotoxicity Testing An essential first step is to carry out a preliminary study to evaluate the toxicity of the test material to the indicator cells, under the conditions of the main mutagenicity test. When selecting dose levels, the solubility of the test compound, the resulting pH of the media, and the osmolality of the test solutions all need to be considered. The latter two parameters have been known to induce false-positive effects in *in vitro* mammalian tests (Brusick, 1986). The experimental procedure is carried out as follows:

1. Seek T75 plastic tissue culture flasks with a minimum of 2.5×10^6 cells in 120 mL of Eagle’s medium containing 20 mM L-glutamine, 0.88 g L⁻¹ sodium bicarbonate, 20 mM HEPES, 50 μg mL⁻¹ streptomycin sulfate, 50 IU mL⁻¹ benzylpenicillin, and 7.5% of fetal bovine serum. The flasks are incubated for 18–24 h at 37°C in a CO₂ incubator to establish monolayer cultures.
2. Prepare treatment medium containing various concentrations of test compound—for example, 19.7 mL of Eagle’s medium (without serum) plus 300 μL of stock concentration of compound in a preferred solvent (e.g., water, ethanol, DMSO, etc.). The final concentration of solvent other than water should not exceed 1% v/v. Normally a range of 0–5000 μg mL⁻¹ (final concentration) is covered. For a sparingly soluble compound, the highest concentration will be the lowest at which visible precipitation occurs. Similarly, if a compound has a marked effect on osmolality, concentrations should not be used that exceed 500 milliosmoles kilogram⁻¹ (mOsm kg⁻¹). In addition, a pH range of 6.5–7.5 should be maintained.

3. Each cell monolayer is rinsed with a minimum of 20 mL phosphate-buffered saline (PBS), and then 20 mL of treatment medium is carefully added. The flasks are incubated for 3 h at 37°C in a CO₂ incubator.
4. After treatment, carefully discard the medium from each flask and wash each monolayer twice with PBS. Care needs to be taken safely to dispose of contaminated solutions.
5. 10 mL of trypsin solution (0.025% trypsin in PBS) is added to each flask. Once the cells have rounded up, the trypsin is neutralized by the addition of 10 mL of complete medium. A cell suspension is obtained by vigorous pipetting to break up cell clumps.
6. The trypsinized cell suspension is counted and diluted in complete media before assessing for survival. For each treatment, set up five petri dishes containing 200 cells per dish.
7. Incubate at 37°C in a CO₂ incubator for 7–10 days.
8. The medium is removed, and the colonies are fixed and stained, using 5% Giemsa in buffered formalin. Once the colonies are stained, the Giemsa is removed, and the colonies are counted.

The method can be repeated including 20% v/v S9 mix.

To calculate percentage survival, the following formula is used:

$$\frac{\text{Cell titre in treated culture}}{\text{Cell titre in control culture}} \times \frac{\text{mean no. of colonies on treated plates}}{\text{mean no. of colonies on control plates}} \times 100$$

The cloning efficiency (CE) of the control culture is calculated as follows:

$$\text{CE} = \frac{\text{mean no. of colonies per plate}}{\text{no. of cells per plate (i.e., 200)}} \times 100$$

In the absence of precipitation or effects on pH or osmolality, the maximum concentration of the main mutagenicity study is a concentration that reduces survival to approximately 20% of the control value.

Procedure for the Chinese Hamster V79/Hgp Assay The assay usually comprises three test concentrations, each in duplicate, and four vehicle control replicates. Suitable positive controls are ethyl methanesulfonate (–S9) and dimethylbenzanthracene (+S9). V79 cells with a low nominal passage number should be used from frozen stocks to help minimize genetic drift. The procedure described includes a reseeding step for mutation expression.

Steps 1–5 are the same as the cytotoxicity assay. As before, tests can be carried out in the presence and in the absence of S9 mix:

1. The trypsinized cultures are counted and a sample is assessed for survival as for the cytotoxicity assay. In addition, an appropriate number of cells are reseeded for estimation of mutation frequency at the day 8 expression time. The cells are transferred to roller bottles (usually 490 cm²) for this stage. The bottles are gassed with pure CO₂, the tops are tightened, and the bottles are incubated at 37°C on a roller machine (approximate speed 0.5–1.0 rev min⁻¹). Usually 10⁶ viable cells are reseeded in 50 mL of Eagle's medium containing serum, but more cells are required at the toxic dose levels.
2. The bottles are subcultured as necessary throughout the expression period to maintain subconfluency. This involves retrypsinization and determining the cell titer for each treatment. For each culture, a fresh roller bottle is reseeded with a minimum of 10⁶ cells.
3. On day 8, each culture is again trypsinized, counted, and diluted so that a sample cell population can be assessed for cloning efficiency and a second sample can be assessed for the induction of 6TG-resistant cells.
4. The cell suspension is diluted in complete medium and 2 × 10⁵ cells added per petri dish (10 petri dishes per treatment). 6-Thioguanine is added to the medium at a final concentration of 10 μg mL⁻¹.
5. The petri dishes are incubated for 7–10 days, and the medium is then removed. The colonies are fixed and stained as previously. The colonies (>50 cells per clone) are then counted.

Mutation frequency in each culture is calculated as

$$\frac{\text{Mean no. colonies on thioguanine plates}}{1000 \times \text{mean no. colonies on survival plates}}$$

10.3.10.4 Data Analysis A weighted analysis of variance is performed on the mutation frequencies, as the variation in the number of mutations per plate usually increases as the mean increases. Each dose of test compound is compared with the corresponding vehicle control by means of a one-sided Dunnett's test, and, in addition, the mutation frequencies are examined to see whether there is a linear relationship with dose (Arlett et al., 1989).

The criterion employed for a positive response in this assay is a reproducible statistically significant increase in mutation frequency (weighted mean for duplicate treated cultures) over the concurrent vehicle control value (weighted mean for four independent control cultures). Ideally, the response should

show evidence of a dose–response relationship. When a small isolated significant increase in mutation frequency is observed in only one of the two duplicate experiments, then a third test should be carried out. If the third test shows no significant effects, the initial increase is likely to be a chance result. In cases where an apparent treated-related increase is thought to be a result of unusually low variability or a low control frequency, comparison with the laboratory historical control frequency may be justified.

10.3.10.5 Chinese Hamster Ovary (CHO)/Hypoxanthine-Guanine Phosphoribosyltransferase (HGPRT) Assay Chinese hamster ovary (CHO) cells have 21 or 22 chromosomes with one intact X chromosome and a large acrocentric marker chromosome (Natarajan and Obe, 1982). The use of these cells in mammalian mutation experiments was first reported by Hsie et al. (1975) and was refined into a quantitative assay for mutagenicity testing by O'Neill. The target gene is at the HGPRT locus on the X chromosome. The HGPRT enzyme is critical for purine salvaging and will incorporate toxic analogs into DNA. A forward mutation yields cells with an inactive gene product that allows cell survival and reproduction. The performance of this system has been reviewed by the US EPA Gene-Tox Program. The experimental procedure for this assay is similar to the V79/HgpRT system already described, and for more detailed descriptions the reader is referred to O'Neill et al. (1977) and Li et al. (1987). Statistical analysis of results requires some modified methodology (Snee and Irr, 1981).

10.3.10.6 Mouse Lymphoma L5178Y TK^{+/-} Assay Whereas the Chinese hamster cell systems are regarded as relatively insensitive, the mouse lymphoma L5178Y TK^{+/-} test is undoubtedly more sensitive. Unfortunately, there are persistent doubts regarding its specificity—that is, the ability to distinguish between mutagens and nonmutagens (see, e.g., Tennant et al., 1987). However, a great advantage is the ability of these cells to grow in suspension culture in which intracellular bridges do not occur. Thus, the problems of metabolic cooperation are avoided, which allows a large number of cells to be treated for optimum statistical analysis of results.

A candid historical overview of the development of the mouse lymphoma TK^{+/-} mutagenicity assay is given by its originator, Clive (1987). Initially, methodologies were developed for producing the three TK genotypes (TK^{+/+} and TK^{-/-} homozygotes and the TK^{+/-} heterozygotes) (Clive et al., 1972, 1979, 1983, 1995). This first heterozygote was lost; however, it was recognized that subsequent heterozygotes produced distinctly bimodal distributions of mutant-colony sizes, owing to differences in growth rate. These were interpreted in terms of single-gene (large-colony mutants) and

viable chromosomal mutations (small-colony mutants). A period of diversification of the MLA followed with controversy over the significance of small-colony mutants (Amacher et al., 1980; Honma et al., 1999a, b).

Following this, a series of cytogenetic studies confirmed the cytogenetic interpretation for small-colony mutants (see, e.g., Clive and Spector, 1975; Hozier et al., 1982). Molecular studies showed that most mutations resulting in small-colony mutants involve large-scale deletions (Evans et al., 1986). A current theory states that, for many compounds, deletion mutants are induced by binding of the compound to complexes between topoisomerase II and DNA (Clive, 1989). Topoisomerases are enzymes that control supercoiling via breakage and reunion of DNA strands; it is the latter step that is disrupted, which leads to chromosomal damage and deletions. Further molecular studies (Applegate et al., 1990) have shown that a wide variety of genetic events can result in the formation of TK^{+/-} genotype from the heterozygote, including recombinations and mitotic nondisjunction.

The TK^{+/-} line was originally isolated as a spontaneously arising revertant clone from a UV-induced TK^{-/-} clone. The parental TK^{+/+} cell and the heterozygote were then the only TK-competent mouse lymphoma cells that could be maintained in THMG medium (3 μg mL⁻¹ thymidine, 5 μg mL⁻¹ hypoxanthine, 0.1 μg mL⁻¹ methotrexate, and 7.5 μg mL⁻¹ glycine) (Clive, 1987). Thus, like most established lines, these cells are remote from wild-type cells. The karyotype of the TK^{+/-} -3.7.2C line has a modal chromosome number of 40 like the wild type but has a variety of chromosomal rearrangements and centromeric heteromorphisms (Blazak et al., 1986).

Two main protocols have been devised for carrying out mutation assays with mouse lymphoma L5178Y cells—that is, plating the cells in soft agar or a fluctuation test approach. It is the latter that is described in the following section, based on Cole et al. (1986). The reader is referred to Clive et al. (1987) for a full description of the soft agar method. Majeska and Holden (1994) have proposed a modification in test design to reduce test compound requirements.

Preliminary Cytotoxicity Assay The cells are maintained in RPMI 1640 medium containing 2.0 mM glutamine, 20 mM HEPES, 200 μg mL⁻¹ sodium pyruvate, 50 IU mL⁻¹ benzylpenicillin, 50 μg mL⁻¹ streptomycin sulfate, and 10% donor horse serum (heat inactivated for 30 min at 56°C). This medium is designated CM10. Conditioned medium is CM10 in which cells have grown exponentially for at least 1 day. Treatment medium contains 3% horse serum and 30% conditioned media (CM3). Medium without serum is known as incomplete medium (ICM). If treatment time exceeds 3 h, treatment is carried out in CM10. In 2006, it was recommended that treatment be for 24 h (Moore et al., 2000, 2006, 2007).

The method is as follows:

1. The cell titer of an exponentially growing culture of cells in CM10 is determined with a Coulter counter. The cell suspension is centrifuged at 70g for 5 min, and the supernatant is reduced such that 3 mL contains approximately 5 × 10⁶ cells (3 h treatment) or 2 × 10⁶ (treatment >3 h).
2.
 - a. For tests in the absence of S9 mix, treatment groups are prepared by mixing 3 mL of solution of test compound and 6.9 mL of ICM (3 h treatment) or 6.9 mL of CM10 (treatment >3 h).
 - b. Tests in the presence of S9 mix are carried out in the same way, except that the treatment medium contains 10% v/v S9 mix at the expense of ICM—that is, 3 mL cell suspension, 5.9 mL ICM, 1 mL S9 mix, and 0.1 mL test compound solution/vehicle. The composition of the S9 mix is as described earlier. It is prepared immediately before required and kept on ice until it is added to the test system. For the vehicle controls, if an organic solvent is used, it should not exceed 1% v/v.
3. After the treatment period, cells are spun down at 70g for 5 min, and the supernatant is transferred for assessment of pH and osmolality. The cell pellet is washed twice in PBS and then resuspended in 10 mL CM10. (All contaminated material and waste should be disposed of safely.)
4. The cell titer of each culture is counted, and a sample diluted in CM10 for assessment of posttreatment survival. For this, two 96-well microtiter plates are charged with 200 μL of a diluted cell suspension, using a multichannel pipette such that each well contains on average one cell.
5. Plates are incubated for 7–8 days at 37°C and 5% CO₂ in 95 ± 3% relative humidity.
6. The plates are removed from the incubator, and 20 μL of MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] at 5 mg mL⁻¹ (in PBS) is added to each well with a multichannel pipette. The plates are left to stand for 1–4 h and are then scored for the presence of colonies with a Titertek mirror box, which allows direct viewing of the bottom surface of the plates.
7. Cytotoxicity can also be determined posttreatment as follows: T25 flasks are set up after treatment containing 0.75 × 10⁵ cells mL⁻¹ in 5 mL CM10. Flasks are incubated with loose lids at 37°C with 5% CO₂ in 95 ± 3% relative humidity. Two days later, the cell titer of each culture is determined with a Coulter counter.

8. Following this procedure, various calculations are carried out to aid selection of dose levels for the main mutation assay.

a. *Cloning efficiency*: In microtiter assays, calculations are based on the Poisson distribution:

$$p(o) = \frac{\text{No. of wells without a colony}}{\text{total no. of cells}}$$

b. *Relative survival*: Relative survival (*S*) is calculated as follows:

$$s = \frac{\text{CE of treated group}}{\text{CE of control group}}$$

c. *Growth*: Growth in suspension (*SG*) is calculated as follows:

$$SG = \frac{\text{Cell count after 3 days}}{0.75 \times 10^5}$$

Relative suspension growth (*RSG*) is calculated as follows:

$$RSG = \frac{\text{SG of treated group}}{\text{SG of control group}} \times 100\%$$

10.3.10.7 Selection of Dose Levels The highest test concentration is selected from one of the following options, whichever is lowest:

- A concentration which reduces survival to about 10–20% of the control value.
- A concentration which reduces RSG to 10–20% of the control value.
- The lowest concentration at which visible precipitation occurs.
- The highest concentration which does not increase the osmolality of the medium to greater than 400 mmol kg⁻¹ or 100 mmol above the value for the solvent control.
- The highest concentration that does not alter the pH of the treatment medium beyond the range 6.8–7.5.
- If none of these conditions are met, 5 mg mL⁻¹ should be used.

Lower test concentrations are selected as fractions of the highest concentration, usually including one dose which causes 20–70% survival and one dose which causes >70% survival.

10.3.10.8 Main Mutation Assay The assay normally comprises three test concentrations, a positive control, and vehicle control. All treatment groups are set up in duplicate.

The expression time is 2 days, unless there are indications that the test agent inhibits cell proliferation, where an additional or possibly alternative expression time should be employed.

Stock cultures are established from frozen ampoules of cells that have been treated with thymidine, hypoxanthine, methotrexate, and glycine for 24h, which purge the culture of preexisting TK^{-/-} mutants. This cell stock is used for a maximum of 2 months.

Treatment is normally carried out in 50mL centrifuge tubes on a roller machine. During the expression time, the cells are grown in T75 plastic tissue culture flasks. For estimation of cloning efficiency and mutant induction, cells are plated out in 96-well microtiter plates. Flasks and microtiter plates are incubated at 37°C in a CO₂ incubator as in the cytotoxicity assays.

Cell titers are determined by diluting of the cell suspension in Isoton and counting an appropriate volume (usually 0.5 mL) with a Coulter counter. Two counts are made per suspension. The experimental procedure is carried out as follows:

1. On the day of treatment, stock solutions for the positive control and the various concentrations of test compound (selected as per the previous selection) are prepared.
2. Treatment is carried out in 30% conditioned media. The serum concentration is 3% (3h treatment) or 10% (treated >3h).
3. Cell suspensions of exponentially growing cells are prepared as in the cytotoxicity assay, except that 6mL of media required for each treatment culture contains 10⁷ cells (3h treatment) or 3 × 10⁶ cells (>3h treatment). The number of cells per treatment may be increased if marked cytotoxicity is expected, to allow enough cells to survive (e.g., if 20% survival or less is expected, 2 × 10⁷ cells may be treated).
4. For tests in the absence of S9 mix, 6mL of cell suspension, 0.2mL test compound/vehicle, and 13.8mL ICM (3h treatment) or 13.8mL CM10 (treatment >7h) are mixed in the presence of S9 mix, and 0.2mL of test compound/vehicle is prepared.
5. After treatment, the cells are centrifuged at 70g for 5 min, and supernatant is discarded and the cell pellet is resuspended in PBS (pH 7). This washing procedure is repeated twice, and finally, the cell pellet is resuspended in CM10.
6. Each culture is counted so that a sample of cells can be assessed for posttreatment survival and the remaining cell population assessed for estimation of mutation frequency.
7. For survival estimation, cells are placed into 96-well microtiter trays at a cell density of one cell per well as per the cytotoxicity assay.

8. For mutation estimation, the cells are diluted to a cell density of 2×10^5 cells mL⁻¹ with CM10 in tissue culture flasks, and the culture is incubated at 37°C in a CO₂ incubator. On day 1, each culture is counted and diluted with fresh medium to a cell density of 2×10^5 cells mL⁻¹ in a maximum of 100 mL of medium.
9. On day 2 each culture is counted again, and an aliquot of cells taken so that (i) a sample of the cell population can be assessed for cloning efficiency. Plates are incubated at 37°C in a CO₂ incubator for 7 days. (ii) A sample of the cell population can be assessed for the induction of TFT-resistant cells (mutants). For this 2×10^3 cells are plated per well in 200 μL CM10 containing 4 μg mL⁻¹ TFT. TFT and TFT-containing cultures must not be exposed to bright light, as the material is light sensitive. The plates are incubated for 10–12 days at 37°C in a CO₂ incubator.
10. At the end of incubation, 20 μL MTT is added to each well. The plates are left to develop for 1–4 h at 37°C and then scored for colony-bearing wells. Colonies are scored by eye and are classified as small or large.

The calculation for cloning efficiency is made as for the cytotoxicity assay.

Relative total growth (RTG) is a cytotoxicity parameter which considers growth in suspension during the expression time and the cloning efficiency of the end of the expression time as follows:

$$\text{Suspension growth(SG)} = \frac{24 \text{ h cell count}}{2 \times 10^4} \times \frac{48 \text{ h cell count}}{2 \times 10^5}$$

$$\text{RTG} = \frac{\text{SG treated culture}}{\text{SG control culture}} \times \frac{\text{CE of treated culture}}{\text{CE of control culture}}$$

Mutation frequency (MF) is calculated as follows:

$$\text{MF} = \frac{\text{In } p_o \text{ for mutation plates}}{\text{no.of cells per well} \times \text{CE}/100}$$

10.3.10.9 *In Vivo Genotoxicity Tests for the Assessment of Primary DNA Lesions*

Primary DNA lesions are detected with so-called “indicator tests.” These tests do not directly measure consequences of DNA interaction (i.e., mutation) but do detect effects related to the process of mutagenesis, such as DNA damage, recombination, and repair. Results from indicator tests can provide additional useful information in the context of extended genotoxicity testing. However, primary DNA lesions may be repaired error-free and do not necessarily result in formation of mutations. The most commonly utilized assays in pharmaceutical development are the P-postlabeling assay and the comet assay. A comparison of different aspects of the methods described in the text is depicted in Table 10.7. Basic aspects regarding optimal study design for *in vivo* micronucleus assays are largely applicable to the design of supplemental *in vivo* assays. Specific or unique aspects on study protocols are described more extensively where appropriate.

10.3.10.10 The Comet Assay The *in vivo* comet assay (aka single-cell gel electrophoresis assay) is increasingly being used as a supplement genotoxicity test for drug candidates (Hartmann et al., 2001; Brendler-Schwaab et al., 2005) due to its simplicity, speed, and wide acceptance. The assay was first developed by Östling and Johansson (1984). There are general review articles on the comet assay (Tice et al., 2000; Speit and Hartmann, 2005), and a general guideline for test conductance has been published as a result of the International Workshop on Genotoxicity Test Procedures (IWGTP).

More specific recommendations with the goal of gaining more formal regulatory acceptance of the comet assay were published following the 4th International Comet Assay Workshop (Burlinson et al., 2007). An updated position paper on specific aspects of tests conditions and data interpretation was prepared following the IWGT in 2005 (Burlinson et al., 2007) (see Table 10.3).

10.3.10.11 Principle of Method The basic principle of the comet assay is the migration of DNA in an agarose matrix under electrophoretic conditions. When viewed through the microscope, a cell has the appearance of a comet, with a head (the nuclear region) and a tail containing DNA

TABLE 10.7 Alternative Test under ICH

Aspect	Comet Assay	DNA Adducts	UDS Test (Liver)	Transgenic Gene Mutation
Test definition (accepted protocol)	Yes	No	Yes	Yes
Regulatory acceptance/use	Yes	Yes	Yes	Yes
Relevance of end point	Moderate	Moderate	Moderate	High
Technical demands	Low moderate	Moderate high	Moderate	High

Applicable to most tissues	Yes	Yes	No	Yes
Dependence of cell turnover	No	No	No	Yes
Cost	Low moderate	Moderate high	Low	High

fragments or strands migrating in the direction of the anode. Among the various versions of the comet assay, the alkaline (pH of the unwinding and electrophoresis buffer ≥ 13) method enables detection of the broadest spectrum of DNA damage and is therefore urgently recommended (in the first instance) for regulatory purposes (Tice et al., 2000). The alkaline version detects DNA damage such as strand breaks, alkali-labile sites (ALS), and single-strand breaks associated with incomplete excision repair. Under certain conditions, the assay can also detect DNA–DNA and DNA–protein cross-linking, which (in the absence of other kinds of DNA lesions) appears as a relative decrease in DNA migration compared to concurrent controls. In contrast to other DNA alterations, cross-links may stabilize chromosomal DNA and inhibit DNA migration (Merk and Speit, 1998). Thus, reduced DNA migration in comparison to the negative control (which should show some degree of DNA migration) may indicate the induction of cross-links, which are relevant lesions with regard to mutagenesis and should be further investigated. Increased DNA migration indicated the induction of DNA strand breaks and/or ALS. Furthermore, enhanced activity of excision repair may result in increased DNA migration. DNA excision repair can influence comet assay effects in a complex way (Speit and Hartmann, 1995). While DNA repair generally reduces DNA migration by eliminating DNA lesions, ongoing excision repair may increase DNA migration to incision-related DNA strand breaks. Thus, the contribution of excision repair to the DNA effects seen in the comet assay depends on the types of induced primary DNA damage and the time point of analysis (Collins et al., 1993).

Test procedure aspects regarding test animals, test substance, use of concurrent negative and positive control animals, as well as dose selection for the design of a cytogenetic assay, as described in detail previously, are largely applicable to the design of an *in vivo* comet assay. In addition, more specific details can be found in an earlier publication. A single treatment or repeated treatments (generally at 24 h intervals) are equally acceptable. In both experimental designs, the study is acceptable as long as a positive effect has been demonstrated or, for a negative result, as long as an appropriate level of animal or tissue toxicity has been demonstrated or the limit dose with appropriate level tissue exposure has been used. For repeated treatment schedules, dosing must be continued until the day of sampling. Daily, test substances may be administered as a split dose (i.e., two treatments separated by no more than a few hours), to facilitate administering a large volume of material. The test may be performed in two ways. If animals are treated with the test substances once, then tissue/organ samples are obtained at 2–6 and 16–26 h after dosing. The shorter sampling time is considered sufficient to detect rapidly absorbed as well as unstable or direct-acting compounds. In contrast, the late sampling time is intended to detect compounds that are more slowly absorbed,

disturbed, and metabolized. When a positive response is identified at one sampling time, data from the other sample time need not be collected. Alternatively, if multiple treatments at 24 h intervals are used, tissue/organ samples need to be collected only once. The sampling time should be 2–6 h after the last administration of the test substance. Alternative sampling times may be used when justified on the basis of toxicokinetic data.

Selection of Tissues and Cell Preparation In principle, any tissue of the experimental animal, provided that a high-quality single cell/nucleus suspension can be obtained, can be used for a comet assay. Selection of the tissue(s) to be evaluated should be based, wherever possible, on data from absorption, distribution, metabolism, and excretion studies and/or other toxicological information. A tissue should not be evaluated unless there is evidence of, or support for, exposure of the tissue to the test substance and/or its metabolite(s). In the absence of such information and unless scientifically justified, two tissues should be examined. Recommended tissues are liver, which is the major organ for the metabolism of absorbed compounds, and a site of first contact tissue—for example, gastrointestinal for orally administered substances, respiratory tract for substances administered via inhalation, or skin for dermally applied substances. Which tissue is evaluated first is at the discretion of the investigator, and both tissues need not be evaluated if a positive response is obtained in the first tissue evaluated.

Single-cell suspension can be obtained from solid tissue by mincing briefly with a pair of fine scissors (Tice et al., 1991), by incubation with digestive enzymes such as collagenase trypsin (Brendler-Schwaab et al., 1994), or by pushing the tissue sample through a mesh membrane. Cell nuclei can also be obtained by homogenization. During mincing or homogenization, EDTA can be added to the processing solution to chelate calcium/magnesium and prevent endonuclease activation. In addition, radical scavengers (e.g., DMSO) can be added to prevent oxidant-induced DNA damage. Any cell dissociation method is acceptable as long as it can be demonstrated that the process is not associated with inappropriate background levels of DNA damage.

Cytotoxicity: A Potential Confounding Factor A general issue with DNA strand break assays such as the comet is the indirect mechanisms related to cytotoxicity which may lead to enhanced strand break formation. However, since DNA damage in the comet assay is assessed on the level of individual cells, dead or dying cells may be identified on microscopic slide by their specific image. Necrotic or apoptotic cells can result in comets with small or nonexistent head and large diffuse tails as observed *in vitro* upon treatment with cytotoxic and nongenotoxic articles. However, such microscopic images are not uniquely diagnostic for apoptosis

or necrosis since they may also be detected after treatment with high doses of radiation or high concentrations of strong mutagens. For the *in vivo* comet assay, only limited data are available to establish whether cytotoxicity results in increased DNA migration in tissues of experimental animals. Despite necrosis or apoptosis in target organs of rodents such as kidneys, testes, liver, or duodenum, no elevated DNA migration was observed. However, enhanced DNA migration was seen in homogenized liver tissue of mice dosed with carbon tetrachloride when histopathological examination showed evidence of necrosis in the liver. Therefore, to avoid potential false-positive effects resulting from cytotoxicity, recommendations regarding a concurrent assessment of target organ toxicity have been made, including dye viability assays, histopathology, and a neutral diffusion assay (Tice et al., 2000; Hartmann et al., 2001).

Biological Significance of Lesions Detected DNA lesions leading to effects in the comet assay can be strand breaks which may be relevant to the formation of CAs or DNA modifications such as abasic sites (AP sites) with relevance to the induction of gene mutations. However, primary lesions detected by the comet assay may also be correctly repaired without resulting in permanent genetic alterations. Neither the magnitude of DNA migration in the comet assay nor the shape of the comet can reveal the types of DNA damage causing the effect or other biological significance, that is, their mutagenic potential. Therefore, conclusions regarding the mutagenicity of a test compound cannot be made solely on the basis of comet assay effects. There are a few limitations of the comet assay with regard to its application and interpretation of test results. For example, short-lived primary DNA lesions such as single-strand breaks, which may undergo rapid DNA repair, could be missed when using inadequate sampling times. However, an appropriate study design including only early preparation time point (i.e., at 3–6 h) is considered sufficient to ensure that these lesions are captured, in particular at higher dose levels, where DNA repair may be significantly delayed or even overwhelmed. In any case, it should be kept in mind that a negative comet result can be considered as a strong indicator for the absence of a mutagenic potential.

Advantages The advantages of this assay for use in genotoxicity testing of drug candidates include its applicability to various tissues and/or special cell types, its sensitivity for detecting low levels of DNA damage, its requirement for small numbers of cells per sample, the general ease of test performance, the short time needed to complete a study, and its relatively low cost. The comet assay can be applied to any tissue in the given *in vivo* model, provided that a single-cell/nuclei suspension can be obtained. Therefore, the comet assay has potential advantages over other *in vivo* genotoxicity

test methods, which are reliably applicable to rapidly proliferating cells only or have been validated preferentially in a single tissue only. The comet assay may detect a broader spectrum of primary DNA lesions, including single-strand breaks and oxidative base damage, which may not be detected in the UDS test because they are not repaired by nucleotide excision repair. The advantages of the comet assay over the alkaline elution test include the detection of DNA damage on a single-cell level and the requirement for only small numbers of cells per sample. In contrast, when using the alkaline elution assay, large quantities of cells are necessary for the determination of genotoxic effects, and, therefore, only a limited number of organs/tissues can be evaluated using this technique. In particular, this seems important for investigation of suspected tissue-specific genotoxic activity, which includes “site-of-contact” genotoxicity (cases of high local vs. low systemic exposure).

Limitations Experimental variability is an important issue and should be kept to a minimum to ensure reliable interpretation and comparability of the data obtained with other *in vivo* comet experiments. Experimental variability may result from shortcomings with regard to number of doses tested, number of animals per dose, number of slides per animal, number of cells analyzed, lack of sufficient DNA migration in cells of concurrent controls, and deviation from minimum time for treatment of slides with alkaline buffer. Considering these discrepancies, the data of the comprehensive study, as well as other study reports not in agreement with the current recommendations, should be interpreted with caution. This point was highlighted recently in a position paper on the use and status of the *in vivo* comet assay in genotoxicity testing, which critically assessed published data produced under test conditions not fully in agreement with the minimal requirements for an acceptable test. For example, it was noted that positive comet assay data were published for compounds that have been assessed before to be neither genotoxic nor carcinogenic, such as food additives. Such isolated positive comet assay results should be critically evaluated in the light of current recommendations to exclude methodological shortcomings and potential artifacts. In cases where negative carcinogenicity data are already available and the *in vivo* comet assay result represents an isolated positive finding in the context of existing genotoxicity data, the biological significance of the effect seen in the comet assay should be assessed with caution.

Data Analysis Data from the fluctuation test described earlier are analyzed by an appropriate statistical method as described in Robinson et al. (1989). Data from plate assays are analyzed as described in Arlett et al. (1989) for treat and plate tests.

10.3.10.12 Status of Mammalian Mutation Tests At present, the only practical assays for screening new chemical entities for mammalian mutation are the mammalian cell assays described earlier. The protocols are well defined, and mutant selection and counting procedures are simple and easily quantified. In general, the genetic end points are understood and relevant to deleterious genetic events in humans. For these reasons, the assays are still regarded as valuable in safety evaluation (Li et al., 1991). It is, however, recognized that there are still unknown factors and molecular events that influence test results. This can be illustrated by the conclusions of the third UKEMS collaborative trial, which focused on tests with cultured mammalian cells. The following points were made:

- The number of cells to be cultured during expression imposes a severe limitation in the use of surface-attached cells.
- The importance of a careful determination of toxicity.
- That S9 levels may need to be varied.
- That the aromatic amine benzidine is mutagenic only at the TK locus in L5178Y TK^{+/−} cells. The most disturbing finding was that benzidine (detectable without metabolism by S9 mix) did not produce detectable DNA adducts (as shown by ³²P-postlabeling) in L5178Y cells. Thus, in the mechanism for mutagenesis in L5178Y cells, benzidine remains to be elucidated (Arlett and Cole, 1990).

10.3.11 *In Vivo* Mammalian Mutation Tests

Mammalian mutation studies of chemicals in the whole animal have provided fundamental information on mutation parameters in germ cells such as dose–response, dose fractionation, sensitivity of various stages in gametogenesis, etc., just as is known for ionizing radiation (Russell, 1989). This has led to estimations of the possible impact chemical mutagens may have on heritable malformation, inborn errors of metabolism, etc. Today germ cell studies are still required when estimating the heritable damage, a mutagen may inflict on exposed human populations.

The existing tests tend to be cumbersome and are not used for routine genetic toxicology screening, and thus only brief descriptions will follow. Reviews of existing data, particularly by Holden (Holden, 1982; Adler and Ashby, 1989; Glover et al., 1992), have indicated that most if not all germ cell mutagens also induce DNA damage in somatic cells, as detected by well-established assays such as the rodent micronucleus test. The converse is not true—that is, some mutagens/clastogens can induce somatic cell damage but do not induce germ cell changes, which probably reflects the special protection afforded to the germ cells, such as that provided by the blood–testis barrier. In other words, it

appears that germ cell mutagens are a subset of somatic cell mutagens.

In vivo mammalian mutation tests are not restricted to germ cell tests. The mouse spot test described in the following text is, again, a test used first for studying radiation-induced mutation but has also been used for screening chemicals for *in vivo* mutagenic potential. This test has had several proponents, but compared with *in vivo* chromosomal assays is not widely used.

10.3.11.1 The Mouse-Specific Locus Test The mouse somatic spot test is a type of specific locus test. The classical specific locus test was developed independently by Russell at Oak Ridge in the late 1940s (Russell, 1951, 1989) and Carter in Edinburgh (Carter et al., 1956). The test consists of treatment of parental mice homozygous for a wild-type set of marker loci. The targets for mutation are the germ cells in the gonads of the treated mice. These are mated with a tester stock that is homozygous recessive at the marker loci. The F₁ offspring that result are normally heterozygous at the marker loci and thus express the wild-type phenotype. In the event of a mutation from the wild-type allele at any of these loci, the F₁ offspring express the recessive phenotype.

The test marker strain (T) developed by Russell uses seven recessive loci, namely, *a* (nonagouti), *b* (brown), *c^{ch}* (chinchilla), *d* (dilute), *p* (pink-eyed dilution), *s* (piebald), and *se* (short ear). As for the mouse spot test, these genes control coat pigmentation, intensity, or pattern, and, for the *se* gene, the size of the external ear (Russell, 1984).

As the occurrence of mutation is rare even after mutagen treatment, the specific locus test is the ultimate study of mutation, requiring many thousands of offspring to be scored, plus significant resources of time, space, and animal husbandry. Because of these constraints, it is often difficult to define a negative result, as insufficient animals are scored or all stages of spermatogenesis are not covered. Of the 25 compounds tested in the assay, as reviewed by Ehling et al. (1986), 17 were regarded as “inconclusive” and 8 positive. The scale studies can reach is illustrated by the test of ethylene oxide described by Russell et al. (1984), where exposures of 101 000 and 150 000 ppm were used over 16–23 weeks. A total of 71 387 offspring were examined. The spermatogonial stem cell mutation rate in the treated animals did not differ significantly from the historical control frequency!

With regard to the design of the test, mice are mated when 7–8 weeks old. By this age, all germ cell stages are present. The test compound is normally administered by the IP route to maximize the likelihood of germ cell exposure. The preferred dose is just below the toxic level so long as fertility is not compromised. One lower dose should also be included.

In males, spermatogonia are most at risk, but it is also desirable that later stages also be exposed. Thus, the mice are mated immediately after treatment to two to four females. This is continued each week for 7 weeks. Then the first group has completed its rearing of the first set of offspring and is

remated. This cycle can be continued for the lifetime of the males. Tests can also be carried out by dosing females, when treatment is carried out for 3 weeks to cover all stages of oogenesis.

The offspring are examined immediately after birth for identification of malformations (dominant visibles) and then at weaning for the specific locus mutations. Presumptive mutant mice are checked by further crosses to confirm their status (Searle, 1984).

Comparison of mutation frequencies is made with the historical database. For definition of a positive result, the same principles are recommended as for the mouse spot test (Selby and Olson, 1981). A minimum size of 18000 offspring per group is recommended by those authors for definition of a negative result.

10.4 *IN VITRO* CYTOGENETIC ASSAYS

The *in vitro* cytogenetic assay is a short-term mutagenicity test for detecting chromosomal damage in cultured mammalian cells (Fox, 1981).

Cultured cells have a limited ability metabolically to activate some potential clastogens. This can be overcome by adding an exogenous metabolic activation system such as S9 mix to the cells (Ames et al., 1975; Madle and Obe, 1980; Natarajan and Obe, 1982; Maron and Ames, 1983). It is important to accurately measure cytotoxicity in the assays, and a range of methods are available to measure them (Lorge et al., 2008).

Observations are made in metaphase cells arrested with a spindle inhibitor such as colchicine or colcemid to accumulate cells in a metaphase-like stage of mitosis (c-metaphase) before hypotonic treatment to enlarge cells and fixation with alcohol/acetic acid solution. Cells are then dispersed on to microscope slides and stained, and slides are randomized, coded, and analyzed for CAs with high-power light microscopy. Details of the procedure are given in Dean and Danford (1984) and Preston et al. (1981, 1987). The UKEMS guidelines (Scott et al., 1990) recommend that all tests be repeated regardless of the outcome of the first test and that, if a negative or equivocal result is obtained in the first test, the repeat should include an additional sampling time. In the earlier version of the guidelines (Scott et al., 1983), a single sampling at approximately 1.5 normal cycle times (–24h for a 1.5 cell cycle) from the beginning of treatment was recommended, provided that a range of concentrations was used which induced marginal to substantial reductions in mitotic index (MI), usually an indicator of mitotic delay. However, Ishidate (1988a) reported a number of chemicals which gave negative responses with a fixation time of 24h but which were positive at 48h. This was when a Chinese hamster fibroblast line (CHO) with a doubling time of 15h was used. It would appear, therefore, that there are chemicals which can induce extensive mitotic delay at clastogenic doses and may be clastogenic only when cells

have passed through more than one cell cycle since treatment (Thust et al., 1980). A repeat test should include an additional sample at approximately 24h later, but it may only be necessary to score cells from the highest dose at this later fixation time. When the first test gives a clearly positive result, the repeat test need only utilize the same fixation time. The use of other sampling times is in agreement with other guidelines (European Community EEC Directive—OECD, 1983; Japanese Ministry of Health and Welfare and Japanese Ministry of International Trade and Industry, 1987; American Society for Testing and Materials—Preston et al., 1987; Ishidate, 1988b; Japanese Guidelines—Japanese Ministry of Health and Welfare (JMHW), 1989).

10.4.1 Cell Types

Established cell lines, cell strains, or primary cell cultures may be used. The most often used are Chinese hamster cell lines and human peripheral blood lymphocytes. The merits of these two cell lines have been reported (Ishidate and Harnois, 1987; Kirkland and Garner, 1987). The cell system must be validated and consistently sensitive to known clastogens. Rat lymphocytes have also been proposed for use (Sinha et al., 1989), with reports that they offer better specificity than hamster cells.

10.4.2 Chinese Hamster Cell Lines

CHO cells in which there has been an extensive rearrangement of chromosome material and the chromosome number may not be constant from cell to cell are frequently used. Polyploidy, endoreduplication, and high spontaneous CA frequencies can sometimes be found in these established cell lines, but careful cell culture techniques should minimize such effects (Hsie et al., 1981). Cells should be treated in exponential growth when cells are in all stages of the cell cycle. High concentration or low or high osmolarities can lead to false positives (Galloway et al., 1985, 1994).

10.4.3 Human Peripheral Blood Lymphocytes

Blood should be taken from healthy donors not known to be suffering from viral infections or receiving medication. Staff handling blood should be immunized against hepatitis B, and regular donors should be shown to be hepatitis B antigen negative. Donors and staff should be aware of AIDS implications, and blood and cultures should be handled at containment level 2 (Advisory Committee on Dangerous Pathogens, 1984).

Peripheral blood cultures are stimulated to divide by the addition of a T-cell mitogen such as phytohemagglutinin (PHA) to the culture medium. Mitotic activity is at a maximum at about 3 days but begins at about 40h after PHA stimulation, and the chromosome constitution remains diploid during

short-term culture (Evans and O'Riordan, 1975). Treatments should commence at about 44 h after culture initiation. This is when cells are actively proliferating and cells are in all stages of the cell cycle. They should be sampled about 20 h later. In a repeat study, the second sample time should be about 92 h after culture initiation. Morimoto et al. (1983) report that the cycle time for lymphocytes averages about 12–14 h except for the first cycle. The incidence of spontaneous cytogenetic aberrations at 48 and 72 h is reported as markedly lower than in CHO cells (Sinha et al., 1984).

Female donors can give higher yields of chromosomal damage (Anderson et al., 1989).

10.4.4 Positive and Negative Controls

When the solvent is not the culture medium or water, the solvent, liver enzyme activation mixture, and solvent and untreated controls are used as negative controls.

Since cultured cells are normally treated in their usual growth medium, the solubility of the test material in the medium should be ascertained before testing. As pointed out earlier, extremes of pH can be clastogenic (Cifone et al., 1987), so the effect of the test material on pH should also be determined, but buffers can be utilized.

Various organic solvents are used, such as DMSO, dimethylformamide, ethanol, and acetone. The volume added must not be toxic to cells. Greater than 10% water (v/v) can be toxic because of nutrient dilution and osmolality changes.

A known clastogen should always be included as a positive control. When metabolic activation is used, a positive control chemical known to require metabolic activation should also be used to ensure that the system is functioning properly. Without metabolic activation, a direct-acting positive control chemical should be used. A structurally related positive control can also be used. Appropriate safety precautions must be taken in handling clastogens (IARC, 1979; MRC, 1981).

Positive control chemicals should be used to produce relatively low frequencies of aberrations so that the sensitivity of the assay for detecting weak clastogens can be established (Preston et al., 1987).

Aberration yields in negative and positive controls should be used to provide a historical database.

10.4.5 Treatment of Cells

When an exogenous activation system is employed, short treatments (about 2 h) are usually necessary because S9 mix is often cytotoxic when used for extended lengths of time. However, cells may be treated with chemicals either continuously up to harvest time or for a short time followed by washing and addition of fresh medium to allow cell-cycle progression. Continuous treatment avoids centrifugation steps required with washing of cells and optimizes the endogenous metabolic capacity of the lymphocytes.

When metabolic activation is used, S9 mix should not exceed 1–10% of the culture medium by volume. It has been shown that the S9 mix is clastogenic in CHO cells and mouse lymphoma cells (Cifone et al., 1987; Kirkland et al., 1989) but not in human lymphocytes, where blood components can inactivate active oxygen species which could cause chromosomal damage. When S9 mix from animals treated with other enzyme-inducing agents such as phenobarbitone/beta-naphthoflavone is used, clastogenesis may be minimized (Kirkland et al., 1989).

Prior to testing, it is necessary to determine the cytotoxicity of the test material, in order to select a suitable dose range for the chromosome assay both with and without metabolic activation. The range most commonly used determines the effect of the agent on the MI, that is, the percentage of cells in mitoses at the time of cell harvest. The highest dose should inhibit mitotic activity by approximately 50% (EEC Annex V) or 75% (UKEMS: Scott et al., 1990) or exhibit some other indication of cytotoxicity. If the reduction in MI is too great, insufficient cells can be found for chromosome analysis. Cytotoxicity can also be assessed by making cell counts in the CA test when using cell lines. In the lymphocyte assay, total white cell counts can be used in addition to MI. A dose which induces 50–75% toxicity in these assays should be accompanied by a suitable reduction in MI.

If the test material is not toxic, it is recommended that it be tested up to 5 mg mL⁻¹. The UKEMS recommends that chemicals be tested up to their maximum solubility in the treatment medium and not just their maximum solubility in stock solutions.

For highly soluble nontoxic agents, concentrations above 10 mM may produce substantial increases in the osmolality of the culture medium which could be clastogenic by causing ionic imbalance within the cells (Ishidate et al., 1984; Brusick, 1987a). At concentrations exceeding 10 mM, the osmolality of the treatment media should be measured, and if the increase exceeds 50 mmol kg⁻¹, clastogenicity resulting from high osmolality should be suspected and, according to the UKEMS, is unlikely to be of relevance to human risk. The UKEMS also does not recommend the testing of chemicals at concentrations exceeding their solubility limits as suspensions or precipitate.

A minimum of three doses of the test material should be used—the highest chosen as described earlier, the lowest on the borderline of toxicity and an intermediate one. Up to six doses can be managed satisfactorily, and this ensures the detection of any dose–response and that a toxic range is covered. MIs are as required for the preliminary study (at least 1000 cells per culture). It is also useful to score endoreduplication and polyploidy for historical data. Cells from only three doses need to be analyzed.

The range of doses used at the repeat fixation time can be those which induce a suitable degree of mitotic inhibition at the earlier fixation time, but if the highest dose reduces the MI

to an unacceptably low level at the second sampling time, the next highest dose should be chosen for screening.

A complete assay requires the test material to be investigated at a minimum of three doses together with a positive (untreated), and solvent-only control can be omitted if tissue culture medium is used as a solvent. When two fixation times are used in repeat tests, the positive control is necessary at only one time, but the negative or solvent control is necessary at both times.

Duplicates of each test group and quadruplicates of solvent or negative controls should be set up. The sensitivity of the assay is improved with larger numbers scored in the negative controls (Richardson et al., 1989).

10.4.6 Scoring Procedures

Prior to scoring, slides should be coded, randomized, and then scored "blind." Metaphase analysis should only be carried out by an experienced observer. Metaphase cells should be sought under low-power magnification and those with well spread, that is, nonoverlapping, clearly defined non-fuzzy chromosomes examined under high power with oil immersion. It is acceptable to analyze cells with total chromosome numbers or that have lost one or two chromosomes during processing. In human lymphocytes ($2n=46$) 44 or more centromeres and in CHO cells ($2n=22$; range 21–24) 20 or more centromeres can be scored. Chromosome numbers can be recorded for each cell, to give an indication of aneuploidy. Only cells with increases in numbers (above 46 in human lymphocytes and 24 in CHO cells) should be considered in this category, since decreases can occur through processing.

Recording microscope coordinates of cells is necessary and allows verification of abnormal cells. A photographic record is also useful of cells with aberrations. Two hundred cells (100 from each of two replicates) should be scored per treatment group. When ambiguous results are obtained, there may be further "blind" reading of these samples.

10.4.7 Data Recording

The classification and nomenclature of the International System for Human Cytogenetic Nomenclature (ISCN, 1985) as applied to acquired CAs is recommended. Score sheets giving the slide code, microscope scorer's name, date, cell number, number of chromosomes, and aberration types should be used. These should include chromatid and chromosome gaps, deletions, exchanges, and others. A space for the vernier reading for comments and a diagram of the aberration should be available.

From the score sheets, the frequencies of various aberrations should be calculated, and each aberration should be counted only once. To consider a break as one event and an exchange as two events is not acceptable, since unfounded

assumptions are made about mechanisms involved (Revell, 1974).

10.4.8 Presentation of Results

The test material, test cells used, method of treatment, harvesting of cells, cytotoxicity assay, etc. should be clearly stated as well as the statistical methods used. Richardson et al. (1989) recommend that comparison be made between the frequencies in control cells and at each dose level using Fisher's exact test.

In cytogenetic assays, the absence of a clear positive dose-response relationship at a particular time frequently arises. This is because a single common sampling time may be used for all doses of a test compound. CA yields can vary markedly with posttreatment sampling time of an asynchronous population and increasing doses of clastogens can induce increasing degrees of mitotic delay (Scott et al., 1990). Additional fixation times should clarify the relationship between dose and aberration yield.

Gaps are by tradition excluded from quantification of CA yields. Some gaps have been shown to be real discontinuities in DNA (e.g., Heddle and Bodycote, 1970). Where CA yields are on the borderline of statistical significance above control values, the inclusion of gaps could be useful. Further details on this approach may be found in the UKEMS guidelines (Scott et al., 1990).

Since chromosome exchanges are relatively rare events, greater biological significance should be attached to their presence than to gaps and breaks.

Chemicals which are clastogenic *in vitro* at low doses are more likely to be clastogenic *in vivo* than those where clastogenicity is detected only at high concentrations (Ishidate et al., 1988). Negative results in well-conducted *in vitro* tests are a good indication of a lack of potential for *in vivo* clastogenesis, since almost all *in vivo* clastogens have given positive results *in vitro* when adequately tested (Thompson, 1986; Ishidate et al., 1988).

10.5 IN VIVO CYTOGENETIC ASSAYS

Damage induced in whole animals can be detected in *in vivo* chromosome assays in either somatic or germinal cells by examination of metaphases or the formation of micronuclei. The micronucleus test can also detect whole chromosome loss or aneuploidy in the absence of clastogenic activity and is considered comparable in sensitivity to chromosome analysis (Tsuchimoto and Matter, 1979).

Rats and mice are generally used for *in vivo* studies, with the mouse being employed for bone marrow micronucleus analysis and the rat for metaphase analysis, but both can be used for either. Mice are cheaper and easier to handle than rats, and only a qualitative difference in response has been

found between the species (Albanese et al., 1988). Chinese hamsters are also widely used for metaphase analysis because of their low diploid chromosome number of 22. However, there are few other historical toxicological data for this species.

10.5.1 Somatic Cell Assays

10.5.1.1 Metaphase Analysis

Metaphase analysis can be performed in any tissue with actively dividing cells, but bone marrow is the tissue most often examined. Cells are treated with a test compound and are arrested in metaphase by the administration of colcemid or colchicine at various sampling times after treatment. Preparations are examined for structural chromosomal damage. Because the bone marrow has a good blood supply, the cells should be exposed to the test compound or its metabolites in the peripheral blood supply, and the cells are sensitive to S-dependent and S-independent mutagens (Topham et al., 1983).

Peripheral blood cells can be stimulated to divide even though the target cell is relatively insensitive (Newton and Lilly, 1986). It is necessary to stimulate them with a mitogen since the number of lymphocytes which are dividing at any one time is very low. Cells are in G_0 when exposure is taking place, so they may not be sensitive to cell-cycle stage-specific mutagens, and any damage might be repaired before sampling.

10.5.1.2 Micronuclei The assessment of micronuclei is considered simpler than the assessment of metaphase analysis (Heddle, 1973; Schmid, 1975; Heddle et al., 1983; Mavourin et al., 1990). This assay is most often carried out in bone marrow cells, where polychromatic erythrocytes are examined. Damage is induced in the immature erythroblast and results in a micronucleus outside the main nucleus, which is easily detected after staining as a chromatid-containing body. When the erythroblast matures, the micronucleus, whose formation results from chromosome loss during cell division or from chromosome breakage forming centric and acentric fragments, is not extruded with the nucleus. Micronuclei can also be detected in peripheral blood cells (MacGregor et al., 1980; Hayashi et al., 1994, 2007). In addition, they can be detected in the liver (Tates et al., 1980; Braithwaite and Ashby, 1988; Fellows and O'Donovan, 2007; Fenech, 2007; Corvi et al., 2008) after partial hepatectomy or stimulation with 4-acetylaminofluorene, or they can be detected in any proliferating cells. The assays can be performed after single or repeat exposure and not just in rodents but also primates (Hamada et al., 2001). Sex and strain of test animals (mouse) can influence test performance (The Collaborative Study Group for the Micronucleus Test, 1986, 1988). Interpretation requires careful consideration and control of test conditions—some can cause increases in micronuclei due to nongenotoxic mechanisms. The *in vivo*

test system can detect genotoxic responses not seen *in vitro* (Tweats et al., 2007a, b).

10.5.2 Germ Cell Assays

The study of chromosomal damage is highly relevant to the assessment of heritable cytogenetic damage. Many compounds which cause somatic cell damage have not produced germ cell damage (Holden, 1982), and, so far, all germ mutagens have also produced somatic damage.

Germ cell data, however, are needed for genetic risk estimation, and testing can be performed in male or female germ cells. The former are most often used, owing to the systemic effects in females. Testing in the male is performed in mitotically proliferating premeiotic spermatogonia, but chromosomal errors in such cells can result in cell death or prevent the cell from passing through meiosis. Damage produced in postmeiotic cells, the spermatids, or sperm is more likely to be transmitted to the F_1 progeny (Albanese, 1987). In females, it is during early fetal development of the ovary that oocyte stage is the most commonly tested stage in the adult female. To test other stages during the first or second meiotic divisions demands, the use of oocytes undergoing ovulation which occur naturally or are hormone stimulated. It is thus more difficult technically to test female germ cells.

10.5.3 Heritable Chromosome Assays

Damage may be analyzed in the heritable translocation test, which involves the examination in male F_1 animals if diakinesis metaphase I spermatocytes for multivalent association fall within the acceptable range for the laboratory for a substance to be considered positive or negative under the conditions of the study.

10.5.4 Germ Cell Cytogenetic Assays

Either mouse or rat can be used but the mouse is generally the preferred species. Normally such assays are not conducted for routine screening purposes.

Spermatogonial metaphases can be prepared by the air-drying technique of Evans et al. (1964) for the first and second meiotic metaphase (MI and MII) in the male mouse. This method is not so suitable for rat and hamster. The numbers of spermatogonial metaphases can be boosted if, prior to hypotonic treatment, the testicular tubules are dispersed in trypsin solution (0.25%). At least 1 month between treatment, sample should be allowed to pass in the mouse to allow treated cells to reach meiosis. Brook and Chandley (1986) established that 11 days and 4 h was required for spermatogonial cells to reach preleptotene and 8 days and 10 h to reach zygotene. It takes 4 h for cells to move from MI to MII, but test compounds can alter this rate. A search for multivalent formation can be made at MI for the structural rearrangements induced in spermatogonia.

Cawood and Breckon (1983) examined the synaptonemal complex at pachytene, using electron microscopy. Errors of segregation should be searched for at the first meiotic division in the male mouse, MII cells showing 19 (hypoploid) and 21 (hyperploid) chromosomes (Brook and Chandley, 1986). Hansmann and El-Nahass (1979), Brook (1982), and Brook and Chandley (1985) describe assays in the female mouse and procedures used for inducing ovulation by hormones and treatment of specific stages of meiosis.

10.6 SISTER CHROMATID EXCHANGE ASSAYS

SCEs are reciprocal exchanges between sister chromatids. They result in a change in morphology of the chromosome, but breakage and reunion are involved, although the exact mechanism is unclear. They are thought to occur at homologous loci.

In 1958, Taylor demonstrated SCEs using autoradiographic techniques to detect the disposition of labeled DNA following incorporation of [³H]-thymidine (Taylor, 1958). 5-Bromo-2'-deoxyuridine (BrdU) has now replaced [³H]-thymidine, and various staining methods have been used to show the differential incorporation of BrdU between sister chromatids: fluorescent Hoechst 33258 (Latt, 1973), combined fluorescent, and Giemsa (Perry and Wolff, 1974), and Giemsa (Korenberg and Freedlander, 1974). The fluorescent plus Giemsa procedure is recommended in view of the fact that stained slides can be stored, and microscope analysis is simpler.

So that SCEs can be seen at metaphase, cells must pass through S phase (Kato, 1973, 1974; Wolff and Perry, 1974). SCEs appear to occur at the replication point, since SCE induction is maximal at the beginning of DNA synthesis but drops to zero at the end of S phase (Latt and Loveday, 1978).

For SCE analysis *in vitro*, any cell type that is replicating or can be stimulated to divide is suitable. The incorporation of BrdU into cells *in vivo* allows the examination of a variety of tissues (Latt et al., 1980; Sinha et al., 1985, 1988). Edwards et al. (1993) suggest that it is necessary to standardize protocols measuring SCE since different responses can be obtained depending on the extent of simultaneous exposure of test compound and BrdU.

10.6.1 Relevance of SCE in Terms of Genotoxicity

SCEs do not appear to be related to other cytogenetic events, since potent clastogens such as bleomycin and ionizing radiation induce low levels of SCE (Perry and Evans, 1975). The mechanisms involved in CAs and SCE formation are dissimilar (e.g., Galloway and Wolff, 1979). There is no evidence that SCEs are in themselves lethal events, since there is little relationship to cytotoxicity (e.g., Bowden et al., 1979). It was suggested by Wolff (1977a, b) that they relate more to mutational events due to a compatibility with cell survival.

However, there are examples of agents that induce significant SCE increases in the absence of mutation (Bradley et al., 1979) as well as they converse (Connell, 1979; Connell and Medcalf, 1982).

The SCE assay is particularly sensitive for alkylating agents and base analogs, agents causing single-strand breaks in DNA, and compounds acting through DNA binding (Latt et al., 1981). The most potent SCE inducers are S phase dependent. Painter (1980) reports that agents such as X-irradiation, which inhibits replicon initiation, are poor SCE inducers, whereas mitomycin C, which inhibits replication fork progression, is a potent SCE inducer.

10.6.2 Experimental Design

Established cell lines and primary cell cultures of rodents may be used. Detailed information on *in vitro* and *in vivo* assays may be obtained in reviews of SCE methods by Latt et al. (1977, 1981), Perry and Thomson (1984), and Perry et al. (1984). The *in vitro* methods will be briefly explored here.

Either monolayer or suspension cultures can be employed, or human lymphocytes. Human fibroblasts are less suitable because of their long cell-cycle duration.

The concentration of organic solvents for the test compound should not exceed 0.8% v/v, as higher concentrations could lead to slight elevations in the SCE level (Perry et al., 1984).

For monolayer cultures, the cultures are set up the day before BrdU treatment so that the cells will be in exponential growth before the addition of BrdU or the test compound. After BrdU addition, the cells are allowed to undergo the equivalent of two cell cycles before cell harvest. A spindle inhibitor such as colchicine or colcemid is introduced for the final 1–2 h of culture to arrest cells in metaphase, after which the cells are harvested, and chromosome preparations are made by routine cytogenetic techniques.

In the absence of metabolic activation, BrdU and the test agent can be added simultaneously and left for the duration of BrdU labeling. Shorter treatments should be used in the presence of metabolic activation or to avoid synergistic effects with BrdU, when cells can be pulse treated for, for example, 1 h before BrdU addition (see Edwards et al., 1993).

Peripheral blood cultures are established in medium containing BrdU and PHA. Colcemid is added 1–2 h before harvest, and the cells are harvested between 60 and 70 h post-PHA stimulation. Cell harvest and slide preparations are conducted according to routine cytogenetic methods.

Heparinized blood samples may be stored at 4°C for up to 48 h without affecting the SCE response (Lambert et al., 1982). If the test agent is known to react with serum or red blood cells, the mononuclear lymphocytes may be isolated by use of a Ficoll/Hypaque gradient (Boyum, 1968).

If metabolic activation is not required, treatment is best conducted over the whole of the final 24 h of culture, or if

metabolic activation is required, a pulse exposure may be employed to treat cultures at the first S phase at around 24–30 h or at 48 h for an asynchronous population.

Exposure of cells to fluorescent light during the culture period leads to photolysis of BrdU-containing DNA and a concomitant increase in SCE frequency (Wolff and Perry, 1974). Consequently, SCE cultures should be kept in the dark and manipulated under subdued light conditions such as yellow safe light. Furthermore, media used in SCE assays should be stored in the dark, since certain media components produce reactive SCE-inducing intermediates on exposure to fluorescent light (Monticone and Schneider, 1979).

Coded and randomized slides should be read. All experiments should be repeated at least once (Perry et al., 1984) with higher and lower concentrations of S9 mix if a negative response is achieved. Even for an apparently unambiguous positive response with a greater than twofold increase in SCEs over the background level at the highest dose and with at least two consecutive dose levels with an increased SCE response, a repeat study is necessary to show a consistent response.

The quality of differential staining will determine the ease and accuracy of SCE scoring, and, to eliminate variation, results from different observers should occasionally be compared. Furthermore, to avoid observer bias, scorers should have slides from different treatment groups equally distributed among them, as with all cytogenetic studies.

10.7 HOW TO DEAL WITH POSITIVE TEST RESULTS

The reason for consideration of a significant revision to S2 (such as is now under consideration) ties in issues and considerations as to perceived unacceptable error rates in test performance and difficulties in interpreting the relevance of findings.

Supplement *in vivo* genotoxicity studies are used (i) to follow up on positive finding in one or more tests of the standard genotoxicity battery, (ii) to elucidate a potential contribution of genotoxicity to the induction of preneoplastic and/or neoplastic changes detected in long-term tests in rodents, and (iii) to elucidate mechanisms of micronucleus formation to differentiate clastogenic from aneugenic effects since aneugenicity is well accepted to result from mechanisms of action for which thresholds exist, demonstrating that micronucleus formation is a result of chromosome loss should allow an acceptable level of human exposure to be defined. No matter the trigger for conducting supplemental *in vivo* genotoxicity testing, it is critical that the approach utilized—for example, the end point and target tissue assessed—is scientifically valuable, such that the results will aid in interpreting the relevance of the initial finding of concern. Ultimately, the goal of supplemental genotoxicity testing is to determine if a genotoxic risk is posed to patient under intended condition of treatment.

Follow-Up Testing of Drug Candidates Positive in the Standard Genotoxicity Test Battery It has been reported that approximately 30–50% of pharmaceuticals produce positive genotoxicity results *in vitro* (Kirkland and Muller, 2000). In contrast, results from bone marrow cytogenetic assays are frequently negative, even for those compounds that produce positive results *in vitro*. This discrepancy may result from a number of major differences that exist when testing in cultured cells versus intact animals. For example, differing metabolic pathways can exist *in vitro* and *in vivo*, metabolic inactivation can occur in the intact animal, parent compound, or active metabolite and may not reach the target cell *in vivo*, rapid detoxification and elimination may occur, or plasma levels *in vivo* may not be comparable to concentrations that generate positive responses in the *in vitro* assays, which is often accompanied by high levels of cytotoxicity. It is also worth noting that positive results generated *in vitro* may be secondary to effects, such as cytotoxicity, which may never be achieved under *in vivo* exposure conditions (Kirkland et al., 2007). Data from *in vivo* experiments are therefore essential before definitive conclusions are drawn regarding the potential mutagenic hazard to humans from chemicals that produce positive results in one or more *in vitro* tests.

Follow-Up Testing of Tumorigenic Drug Candidates Negative in the Standard Genotoxicity Test Battery (Nicolette, 2017; ICH, 2018) Incarcinogenicity testing of pharmaceutical drug candidates of a tumorigenic response in rodents, the ICH guidance S2B currently stipulates that such tumorigenicity is not clearly based on a nongenotoxic mechanism. Typically, supplemental *in vivo* genotoxicity tests should be performed with cells of the respective tumor target organ to distinguish between genotoxic and nongenotoxic mechanism of tumor induction.

End Points Assessed in Supplemental Assays Commonly applied test systems are described that are used as supplemental genotoxicity assays. These assays differ with respect to the end points assessed:

1. Induction of primary DNA lesions, that is, measurement of exposure, uptake, and reactivity to DNA via the comet assay or P-postlabeling assay.
2. Measurement of the repair of DNA lesion using the UDS test.
3. Measurement of induction of genetic drug transgenic animal assays for point mutations or the mouse spot test.

The comet assay is the most commonly applied of these. This assay (OECD 2016) focuses on assessing results on specific large tissues subsequent to *in vivo* exposure of test animals (usually rats). One can also use the Transgenic Rodent

Somatic and Germ Cell Gene Study (OECD 2020), which evaluates induction of gene mutations in multiple tissues.

The issue of how to assess the relevance of a finding of genotoxicity in a candidate drug is a complex one. If the judgment is that such a finding is not relevant to human risks, there are two approaches to assessing and defending such a finding: the weight of evidence (WOE) or the mode of action (MOA). The human biological relevance of a finding of genotoxicity is subject to some complex considerations (Müller and Kasper, 2000).

In the case of impurities in a marketed or candidate drug, the approach is more straightforward. One must reduce the level to or below the toxicological threshold of concern (TTC), which is such a level that no patient would receive more than $1.5 \mu\text{g day}^{-1}$ (EMA, 2006).

11

QSAR TOOLS FOR DRUG SAFETY

11.1 STRUCTURE–ACTIVITY RELATIONSHIPS

Structure–activity relationship (SAR) methods first became a legitimate and useful part of toxicology in the mid-1970s, though the tools had limited utility. These methods were various forms of mathematical or statistical models which seek to predict the adverse biological effects of chemicals based on their structure. The predictions could be of either a qualitative (mutagenic/not mutagenic, carcinogen/noncarcinogen) or quantitative (LD_{50}) nature, with the second group usually being denoted as quantitative structure–activity relationship (QSAR) models. At the start, the basic techniques are utilized to construct such models combined modeling, extrapolation, and reduction of dimensionality methods. For regulatory requirements, however, QSAR is only considered adequate to address potential safety issues of genotoxicity (mutagenicity).

The concept that the biological activity of a compound is a direct function of its chemical structure is now at least a century and a half old (Crum Brown and Fraser, 1869). During most of the twentieth century, the development and use of SARs were the domain of pharmacology and medicinal chemistry. These two fields are responsible for the beginnings of all the basic approaches in SAR work, usually with the effort being called drug design. An introductory medicinal chemistry text (such as Foye et al., 1995 or Thomas et al., 2012) is strongly recommended as a starting place for SAR. Additionally, Burger's Medicinal Chemistry (Abraham and Rotella, 2010; Selassie and Verma, 2010), with its excellent overview of drug structures and activities, should enhance at least the initial stages of identifying the potential biological actions of de novo compounds using a pattern recognition approach. Most recently, Cronin and Livingston (2004), Helma (2005), Seger-Hartmann (2015), Roy et al. (2015), and Instituto di Ricerche Farmacologiche Mario Negri Milano

(2015a) have published excellent overviews of methods and applications.

Having already classified SAR methods into qualitative and quantitative, it should also be pointed out that both of these can be approached on two different levels. The first is on a local level, where prediction of activity (or lack of activity) is limited to other members of a congeneric series or structural near neighbors. The accuracy of predictions via this approach is generally greater but is of value only if one has sufficient information on some of the structures within a series of interest.

The second approach is a prediction of activity over a wide range, generally based on the presence or absence of particular structural features (functional groups).

For toxicology, SARs had a small but important and increasing number of uses until the last decade, when ICH's incorporation of modern SAR/QSAR methods to identify mutagens and nonmutagens among impurity structures gave a huge boost to their use. These can all be generalized as identifying potentially toxic effects or restated as three main uses:

1. For the selection and design of toxicity tests to address end points of possible concern.
2. If a comprehensive or large testing program is to be conducted, SAR predictions can be used to prioritize the tests so that outlined questions (the answers to which might preclude the need to do further testing) may be addressed first.
3. As an alternative to testing at all. Though in general it is not believed that the state of the art for SAR methods allows such usage, in certain special cases (such as selecting which of several alternative candidate compounds to develop further and then test), this use may be valid and valuable.

It is the regulatory acceptance of QSAR methods in place of actual testing in some cases (ICH, 2006; Kruhlak et al., 2012; OECD, 2014) which has truly “exploded” the use of the methods, and which now drives efforts to both expand their scope and improve their performance.

11.1.1 Basic Assumptions

Starting with the initial assumption that there is a relationship between structure and biological activity, we can proceed to more readily testable assumptions.

First, that the dose of chemical is subject to a number of modifying factors (such as membrane selectivities and selective metabolic actions) which are each related in some manner to chemical structure. Indeed, absorption, metabolism, pharmacologic activity, and excretion are each subject to not just structurally determined actions but also to (in many cases) stereospecific differential handlings.

Given these assumptions, actual elucidation of SARs requires the following:

1. Knowledge of the biological activities of existing structures
2. Knowledge of structural features which serve to predict activity (also called molecular parameters of interest)
3. One or more models which relate two to one with some degree of reliability

There are now extensive sources of information as to both toxic properties of chemicals and, indeed, biological activities. These include books, journals, and manuals and computerized databases. The reader is directed to Chapter 3 of this text and Wexler et al. (1999) as a guide to accessing the different sources of toxicology information but is cautioned to remember that there is also extensive applicable information in the realms of medicinal chemistry and pharmacology, as exemplified by Burger’s (Abraham and Rotella, 2010).

11.1.2 Molecular Parameters of Interest

Which structural and physicochemical properties of chemicals are important in predicting their toxicologic activity are both open to considerable debate (Kaufman et al., 1983; Tamura, 1983; Tute, 1983). Table 11.1 presents a partial list of such parameters. The reader is referred to a biologically oriented physical chemistry text (such as Chang, 1981) both for explanations of these parameters and for references to sources from which specific values may be obtained.

There are now several systems available to study the three-dimensional structural aspects of molecules and their interactions. Various molecular modeling sets, molecular design and analysis packages, and molecular graphics software packages

TABLE 11.1 Molecular Parameters of Interest

Electronic Effects
Ionization constants
Sigma substituent constant
Distribution constant
Resonance effect
Field effect
Molecular orbital indices
Atomic/electron net charge
Nucleophilic superdelocalizability
Electrophilic superdelocalizability
Free radical superdelocalizability
Energy of the lowest empty molecular orbital
Energy of the highest occupied molecular orbital
Frontier atom–atom polarizability
Intermolecular coulombic interaction energy
Electric field created at point (A) by a set of charges on a molecule
Hydrophobic Parameters
Partition coefficients
Pi substituent constants
<i>R_m</i> value in liquid–liquid chromatography
Elution time in high-pressure liquid chromatography (HPLC)
Solubility
Solvent partition coefficients
p <i>K_a</i>
Steric Effects
Intramolecular steric effects
Steric substituent constant
Hyperconjugation correction
Molar volume
Molar refractivity, MR substituent constants
Molecular weight
Van der Waals radii
Interatomic distances
Substructural Effects
Three-dimensional geometry
Fragment and molecular properties (see Kubinyi, 1995 for substituent effects)
Chain lengths

are available for personal computers and larger systems. Use of such forms of graphic structural examination as a tool or a method in SAR analysis has been discussed by Cohen et al. (1974) and Gund et al. (1980). Such methods are generally called topological methods.

11.2 SAR MODELING METHODS

A detailed review of even the major methodologies available for SAR/QSAR modeling in toxicology is beyond the scope of this book. Though we will briefly discuss the major approaches, the reader is directed to one of the several very readable introductory articles (Chang, 1981) or books (Olson

and Christoffersen, 1979; Topliss, 1983; Goldberg, 1983; Mackay et al., 2009; or Venkatapathy et al., 2009) for somewhat detailed presentations.

To begin with, it should be made clear that all the actual techniques involved in the performance of SAR analysis are presented elsewhere in this text (Chapter 3 and statistical methods in Chapter 32). It is only their actual application to data which set such analysis apart from the forms of modeling we have previously looked at.

All the current major SAR methods used in toxicology can be classified based on what kinds of compound-related or structural data they use and what method is used to correlate this structural data with the existing biological data. While most used currently to predict mutagenicity (under ICH M7 or REACH guidances) in lieu of testing, these methods currently offer much additional utility such as predicting carcinogenicity or the potency of carcinogens (see Venkatapathy et al., 2009 and Instituto de Ricerche Farmacologiche Mario Negri Milano, 2015b) or sensitizers or providing an initial screen to support candidate molecule selections.

The more classical approaches use physicochemical data (such as molecular weight, free energies, etc.) as a starting point. The major approaches to this are by manual pattern recognition methods, cluster analysis, or by regression analysis. It is this last in the form of Hansch or linear free energy relationships (LFER) which actually launched all SAR work (other than that on limited congeneric cases) into the realm of being a useful approach. Indeed, still foremost among the QSAR methods is the model proposed by Hansch and his coworkers (Hansch, 1971). It was the major contribution of this group to propose the incorporation of earlier observations of the importance of the relative lipophilicity to biologic activity into the formal LFER approach to provide a general QSAR model for biological effects. As a suitable measure of lipophilicity, the partition coefficient ($\log P$) between 1-octanol and water was proposed, and it was demonstrated that this was an approximately additive and constitutive property and that it was therefore calculable, in principle, from molecular structure. Using a probabilistic model for the Hansch equation, which can be expressed as follows:

$$\log\left(\frac{1}{C}\right) = -k\pi^2 + k'\pi + p\sigma + k''$$

or

$$\log\left(\frac{1}{C}\right) = -k(\log p)^2 + k'(\log p) + p\sigma + k''$$

where C is the dose that elicits a constant biological response (e.g., ED_{50} , LD_{50}), p is the substituent lipophilicity, $\log P$ is the partition coefficient, σ is the substituent electronic effect of Hammett, and k , k' , p , and k'' are the regression coefficients derived from the statistical curve fitting, the partition coefficient ($\log P$) can be calculated as an estimate of lipophilicity.

The reciprocal of the concentration reflects the fact that higher potency is associated with lower dose and the negative sign for the π_0 or $\log P_0$.

The statistical method used to determine the aforementioned coefficients is multiple linear regression. A number of statistics are derived in conjunction with such a calculation, which allows the statistical significance of the resulting correlation to be assessed. The most important of these are s , the standard deviation; r^2 , the coefficient of determination or percentage of data variance accounted for by the model (r , the correlation coefficient is also commonly cited); and F , a statistic for assessing the overall significance of the derived equation, values, and confidence intervals (usually 95%) for the individual regression coefficients in the equation. These must be low to assure true “independence” or orthogonality of the variables, a necessary condition for meaningful results.

In a like manner, there are a number of approaches for using structural and substructural data and correlating these to biological activities. Such approaches are generally classified as regression analysis methods, pattern recognition methods, and miscellaneous others (such as factor analysis, principal components, and probabilistic analysis).

The regression analysis methods which use structural data have been, as we will see when we survey the state-of-the-art in toxicology, the most productive and useful. “Keys”—or fragments of structure—are assigned weights as predictors of an activity, usually in some form of the Free–Wilson model (Free and Wilson, 1964) which was developed at virtually the same time as the Hansch. According to this method, the molecules of a chemical series are structurally decomposed into a common moiety (or core) that may be substituted in multiple positions. A series of linear equations of the form:

$$BA_i = \sum_j^i a_j X_j + \mu$$

are constructed where BA is the biological activity, X_j is the j th substituent with a value of 1 if present and 0 if not, a_j is the contribution of the j th substituent to BA , and μ is the overall average activity. All activity contributions at each position of substitution must sum to zero. The series of linear equations thus generated is solved by the method of least squares for the a_j and μ . There must be several more equations than unknowns, and each substituent should appear more than once at a position in different combinations with substituents at other positions. The favorable aspects of this model are the following:

1. Any set of quantitative biological data may be employed as the dependent variable.
2. No independently determined substituent constants are required.
3. The molecules comprising a sample of interest may be

structurally dismembered in any desired or convenient manner.

- Multiple sites of variable substitution are readily handled by the model.

There are also several limitations: a substantial number of compounds with varying substituent combinations are required for a meaningful analysis; the derived substituent contributions give no reasonable basis for extrapolating predictions from the substituent matrix analyzed; and the model will break down if nonlinear dependence on substituent properties is important or if there are interactions between the substituents.

Pattern recognition methods comprise yet another approach to examining structural features and/or chemical properties for underlying patterns that are associated with differing biological effects (Cronin and Livingston, 2004; Ekins, 2007). Accurate classification of untested molecules is again the primary goal. This is carried out in two stages. First, a set of compounds, designated the training set, is chosen for which the correct classification is known. A set of molecular or property descriptors (features) are generated for each compound. A suitable classification algorithm is then applied to find some combination and weight of the descriptors that allow perfect classification. Many different statistical and geometric techniques for this purpose have been used and were presented in earlier chapters. The derived classification function is then applied in the second step to compounds not included in the training set to test predictability. In published work, these have generally been other compounds of known classification also. Performance is judged by the percentage of correct predictions. Stability of the classification function is usually tested by repeating the procedure several times with slightly altered, but randomly varied, sets or samples.

The main difficulty with these methods is in “decoding” the QSAR in order to identify particular structural fragments responsible for the expression of a particular activity. And even if identified as “responsible” for activity, far harder questions for the model to answer are whether the structural fragment so identified is “sufficient” for activity, whether it is always “necessary” for activity, and to what extent its expression is modified by its molecular environment. Most pattern recognition methods use as weighting factors either the presence or the absence of a particular fragment or feature (coded 1 or 0) or the frequency of occurrence of a feature. They may be made more sophisticated by coding the spatial relationship between features.

Enslein et al. (1984) have published a good brief description of the problems involved in applying these methods in toxicology. His “toxicity prediction by computer-assisted technology” (TOPKAT) program was a program running on early desktop computers that offered utility in predicting acute toxicity end points and mutagenicity. The program is still (in a limited number) commercially available.

11.3 APPLICATIONS IN TOXICOLOGY

True SAR methods have been developed to predict a number of toxicological end points (mutagenesis, carcinogenesis, dermal sensitization, lethality (LD₅₀ values), biological oxygen demands, and teratogenicity) with varying degrees of accuracy, and models for the prediction of other end points continue under development. An earlier “semi-SAR” tool was the Cramer decision tree in the 1970s (Cramer et al., 1978). The purpose of the decision tree was to categorize the mass of chemical structures for which there was limited or no data as either potentially very toxic (and therefore of high priority to test—Category 1) to Category 3 (unlikely to be toxic). The current version of the Cramer Tree (ToxTree) still serves primarily the same purpose. Some of these existing models are presented by category of use in Table 11.2. Additionally, both Environmental Protection Agency (EPA) and Food and Drug Administration (FDA) have models for mutagenicity/carcinogenicity that they utilize to “flag” possible problem compounds.

Reproductive toxicity		X	Bernstein (1984), Enslein et al. (1983)

Note that all models are only as good as the data that they are based on. Issues of data quality and range of possible structural features incorporated into the data set utilized remain an issue (Sahigara et al., 2012).

It should be expected that qualitative models are more “accurate” than quantitative ones and that the more possible mechanisms associated with an end point, the less accurate (or more difficult) a prediction. Table 11.3 contains end points which each of the major programs evaluates.

11.3.1 Metabolism

A central tenet of both toxicology and pharmacology is that any assessment of either adverse or desirable effects of a drug must incorporate an assessment of the absorption, distribution, elimination, and metabolism of the administered drug molecule. While Chapter 18 looks at the generating and evaluation of such ADME data, the prediction of values of absorption (particularly from the skin—see Baba et al., 2015) and of metabolic routes and rates (Kirchmair et al., 2015) are areas of both active technology development and of great interest. Kirchmair presents a table summarizing the aspects and capabilities of 34 different available programs for use in metabolic predictions, including Meteor which will be discussed further later. It should be noted that most of the current toxicology predictive programs do not explicitly incorporate such predictions.

11.3.2 Reproductive

SARs have not been as successful for reproductive and developmental toxicology. Data are available that suggest SARs for certain classes of chemicals (e.g., glycol ethers, phthalate

esters, heavy metals). Yet, for other agents, nothing in their structure would have identified them as male reproductive toxicants (e.g., chlordecone). Bernstein (1984) reviewed the literature and has offered a set of classifications relating structure to reported male reproductive activity. Although limited in scope and in need of rigorous validation, such schemes do provide hypothesis that can be tested. Enslein et al. (1983) have proposed a commercial computer model for this and developmental end points. Comparison of the chemical or physical properties of an agent with those of known male reproductive toxicants may provide some indication of a potential for reproductive toxicity. Such information may be helpful in setting priorities for testing of agents or for the evaluation of potential toxicity when only minimal data are available.

11.3.3 Eye Irritation

QSAR analysis, widely used to predict various physiological and biochemical activities of novel chemicals, also has been used to predict eye irritancy of structurally related chemicals. Using QSAR, Sugai et al. (1990) examined the eye irritancy (opacity and conjunctivitis) of 131 chemically heterogeneous chemicals. The accuracy was 86.3% for classifying irritancy of the chemicals. Overall accuracy rates as high as 91% have been reported. Although this approach may provide useful information on structurally related chemicals, its utility is limited for formulated products.

11.3.4 Lethality

Analysis of the SARs within a class of chemicals can yield valuable information and may reduce the number of bioassays

conducted. QSAR analysis is particularly useful during the discovery stage for selection of chemicals for further development. QSAR also can be used for prioritization of chemicals for various actions related to health and safety and environmental assessment. The elements generally needed for QSAR include a verified bioassay database for the end point to be predicted, a set of chemical–physical parameters which described the chemical structures so that the end point can be modeled in terms of these parameters, statistical techniques, that is, principally multivariate regression and discriminant analysis for weighing these parameters in a near-optimum fashion for the explanation of the end point, and computer technology to make it all practical. Using QSAR, Enslin et al. (1983) has analyzed 2066 chemicals of various chemical structures and found that the oral rat LD₅₀ of almost 50% of the compounds examined was predicted within a factor of 2 and 95% within a factor of 8. Obviously, there are limitations for the QSAR approach to predict a complex toxic response in whole animals. These include limited database on which to base a QSAR model, the temptation to extrapolate beyond the confines of the model, and the noise inherent in the bioassays on which the models are based. The results from QSAR have to be used with caution, and at this stage, QSAR is useful during the discovery stage and for prioritizing chemicals.

11.3.4.1 Oral Rat LD₅₀ Oral Rat LD₅₀ is the administered dose of chemical in milligram per kilogram body weight that causes 50% of rats to die after oral ingestion. The data set for this end point contains 7420 chemicals, and predictions by the EPA Toxicity Estimation Software Tool (TEST) and TOTKAT (both predict oral LD₅₀ values) methods have a good correlation with experimental data. Table 11.4 presents a summary of the Predictive Performance using this data set.

TEST allows you to estimate the value for several toxicity end points using several different advanced QSAR methodologies. For predicting mutagenicity, a data set of 6512 chemicals was compiled from several different sources. The final data set consists of 5743 chemicals (after removing salts, mixtures, ambiguous compounds, and compounds without CAS numbers).

The Ames mutagenicity data set that was used as a statistical tool for external validation (Bercu et al., 2009) has

shown that the consensus method achieved the best prediction accuracy (concordance) and prediction coverage. The consensus method's predicted toxicity is estimated by taking an average of the predicted toxicities from the hierarchical clustering, FDA, and nearest neighbor QSAR methods (provided the predictions are within the respective applicability domains (ADs)):

- *Hierarchical method*: The toxicity for a given query compound is estimated using the weighted average of the predictions from several different cluster models.
- *FDA method*: The prediction for each test chemical is made using a new model that is fitted to the chemicals that are most similar to the test compound.
- *Nearest neighbor method*: The predicted toxicity is estimated by taking an average of the three chemicals in the training set that are most similar to the test chemical.

The prediction accuracy is then evaluated in terms of the fraction of compounds that are predicted accurately. The prediction accuracy is evaluated in terms of three different statistics—concordance, sensitivity, and specificity:

- Concordance is the fraction of all compounds that are predicted correctly (i.e., experimentally active compounds that are predicted to be active and experimentally inactive compounds that are predicted to be inactive).
- Sensitivity is the fraction of experimentally active compounds that are predicted to be active.
- Specificity is the fraction of experimentally inactive compounds that are predicted to be inactive.

11.3.5 Carcinogenicity

Given the 1–2 million dollars in cost and the 3–5 years required to test a single chemical in a lifetime rodent carcinogenicity bioassay, initial decisions on whether to continue the development of a chemical, submit a premanufacturing notice (PMN), or require additional testing may be based largely on SARs and limited short-term assays. A test agent's structure, solubility stability, pH sensitivity, electrophilicity,

TABLE 11.4 Statistical External Validation for Oral LD₅₀ Prediction Using Data Set

Method	R^2	$(R^2 - R_0^2)/R^2$	k	RMSE	MAE	Coverage
Hierarchical	0.568	0.200	0.955	0.652	0.460	0.826
FDA	0.542	0.220	0.950	0.668	0.492	0.980
Nearest neighbor	0.519	0.340	0.954	0.677	0.491	0.994
Consensus	0.604	0.277	0.952	0.604	0.441	1.000

and chemical reactivity can represent important information for hazard identification. Historically, certain key molecular structures have provided regulators with some of the most readily available information on which to assess hazard potential. For example, 8 of the first 14 occupational carcinogens were regulated together by the Occupational Safety and Health Administration (OSHA) as belonging to the aromatic amine chemical class. The EPA Office of Toxic Substances relies on SARs to meet deadlines for responding to PMN for new chemical manufacture under the Toxic Substances Control Act (TSCA). Structural alerts such as *n*-nitroso or aromatic amine groups, amino azo dye structures, and phenanthrene nuclei are clues to prioritizing agents for additional evaluation as potential carcinogens. The limited database of known developmental toxicants limits SARs to only a few chemical classes, including chemicals with structures related to those of valproic acid and retinoic acid.

More than 100 years ago, Richet (1893), Meyer (1899), and Overton (1901) independently found linear relationships between lipophilicity, expressed as solubility or oil–water partition coefficients, and biological effects, like toxicity and narcotic activity (Gad, 2014). From here, the use of predictive models grew to what is now commonly known as QSAR methodology.

The transition from the classic computational approaches and the current more useful methods started with the Cramer rules, which has since evolved into ToxTree.

The Cramer decision tree is one of the best-known approaches used to estimate the thresholds of toxicological concern (TTCs) for an untested compound based on its chemical structure (Cramer et al., 1978; Munro et al., 1996; Kroes et al., 2004). Initially, the TTC approach was developed to protect humans against carcinogenicity and systemic toxicity. The Cramer decision tree (aka Cramer's rules) is intended to help rank and/or exclude compounds from formal testing based on their predicted toxicities.

Computerized implementations of the Cramer decision tree are not representative of traditional (Q)SAR systems because they do not predict the presence or absence of potential bioactivities for specific endpoints.

Cramer decision tree categorizes a compound's potential toxicity based on the presence or absence of structural alerts/expert rules (Cramer et al., 1978). Cramer decision tree consists of 33 “yes” or “no” questions (i.e., rules) (Cramer et al., 1978). The answers to these questions lead to other questions until the decision tree categorizes the compound into one of the three distinct classes (see Table 11.5).

Cramer first tested the decision tree against 81 chemicals (e.g., pharmaceuticals, excipients, and pesticides,) with oral no-observed-effect level (NOEL) reported in the literature (Cramer et al., 1978). Although NOELs between the three classes overlapped, in general, NOELs of Class I compounds were higher than those of Class II, and NOELs of Class II compounds were higher than those of Class III compounds.

TABLE 11.5 Description of Cramer Classes

Cramer Class	Description
Class I	Substances with simple chemical structures and for which efficient modes of metabolism exist, suggesting a low order of oral toxicity
Class II	Substances which possess structures that are less innocuous than Class I substances but do not contain structural features suggestive of toxicity like those substances in Class III
Class III	Substances with chemical structures that permit no strong initial presumption of safety or may even suggest significant toxicity or have reactive functional groups

Most importantly, the decision tree did not underestimate the toxicity of the compounds tested when compared with oral toxicity data obtained from chronic studies (Lapenna and Worth, 2011).

Subsequently, the Cramer decision tree was modified by Munro et al. (1996) to estimate human TTCs for additional toxicity endpoints. The dataset evaluated by Munro et al. contained more than 613 organic chemicals associated with 2941 NOEL values. The noncancer NOEL values were obtained from subchronic, chronic, reproductive, and developmental toxicity studies conducted in rodents and rabbits. Munro et al. classified the dataset compounds based on the Cramer scheme and estimated human TTC limits by taking the lower fifth percentile value of the distribution of NOELs for each three Cramer classes, multiplying by 60 to convert the values expressed as mg/kg/day into mg/day, and then dividing by a factor of 100 to ensure a margin of safety. Using these methods, Munro et al. proposed oral TTC limits for Class I, II, and III compounds, respectively. (Table 11.6)

The TTC levels proposed by Munro et al. are widely used in the food safety industry. Additionally, three independent nonfood committees (SCCP, SCHER, and SCHENIHR) evaluated the potential applications of the TTC and concluded that the TTC approach is scientifically acceptable for human health risk assessment.

Thus, to promote a consistent application of the Cramer decision tree as defined by Cramer et al. (1978) with TTC limits defined by Munro et al. (1996), the JRC commissioned the development of Toxtree, an open-source software, for use by professionals. In principle, Toxtree's implementation of the

TABLE 11.6 TTC Values of Cramer Classes

Cramer Class	TTC values (µg/day)
Class I	1800
Class II	540
Class III	90

Cramer decision tree may be applied to organic molecules, organic salts, organometallics, oligomers, and polymers.

SARs are useful in assessing the relative toxicity of chemically related compounds. The EPA's (1994) reassessment of the risk of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin and related chlorinated and brominated dibenzo-*p*-dioxins, dibenzofurans, and planar biphenyls might have relied too heavily on toxicity equivalence factors (TEFs) based on induction of the Ah receptor (EPA, 1994). The estimated toxicity of environmental mixtures containing those chemicals is a product of the concentration of each chemical times its TEF value. However, it is difficult to predict activity across chemical classes and especially across multiple toxic end points by using a single biological response. Many complex chemical–physical interactions are not easily understood and may be oversimplified by researchers. Several computerized SAR methods gave disappointing results in the National Toxicology Program's (NTP) 44-chemical rodent carcinogenicity prediction challenge (Ashby and Tennant, 1994).

If we take a series of chemicals and attempt to form a quantitative relationship between the biological effects (i.e., the activity) and the chemistry (i.e., the structure) of each of the chemicals, then we are able to form a QSAR. Less complex, or quantitative, understanding of the role of structure to govern effects, that is, that a fragment or substructure could result in a certain activity, is often simply termed an SAR. Together SARs and QSARs can be referred to as QSARs and fall within a range of techniques known as *in silico* approaches (Puzyn, 2010; Fjodorova and Novič, 2012; Pfannkuch and Suter-Dick, 2015).

QSAR predictions use both statistically based and knowledge-based methods. The statistically based methods rely on techniques such as multivariate analysis, rule induction, cluster analysis, and pattern recognition. They use limited or no prior chemical or biological classification according to mechanism of carcinogenicity. The knowledge-based (or rule-based) methods include toxicological knowledge, expert judgment, and fuzzy logic which considers toxicokinetics, toxicodynamics, and metabolism related to processes with cellular macromolecules or receptors (Serafimova et al., 2010).

11.4 GENOTOXICITY

According to EMA and ICH guidelines on genotoxic impurities, substances which show “alerting structure” in terms of genotoxicity which are not shared with the active substance should be considered and discussed (CHMP, 2008; EMEA, 2006). EMA states that the absence of a structural alert based on a well-performed assessment will be sufficient to conclude that the impurity is of no concern with respect to genotoxicity and no further “qualification” studies or justification will be required. When an impurity is found above the ICH identification threshold, but below the qualification

threshold, and the structure gives rise to a structural alert, this can be negated by carrying out an Ames test on the active ingredient containing the impurity as long as the impurity is present at a minimum concentration of 250 mg plate⁻¹.

11.4.1 QSAR for Mutagenicity

As part of a hazard assessment, database and literature searches should be performed for carcinogenicity and bacterial mutagenicity data. To limit a possible human cancer risk associated with the exposure to potentially mutagenic impurities, the bacterial mutagenicity assay is used to assess mutagenic potential and the need for controls. Other types of genotoxicants that are nonmutagenic typically have threshold mechanisms and usually do not pose carcinogenic risk in humans at the level ordinarily present as impurities (ICH M7).

One simple and well-known approach to predict genotoxicity and carcinogenicity for chemicals is based on the use of structure alerts (SAs). SAs for carcinogenicity are molecular functional groups or substructures known to be linked to the carcinogenic activity of chemicals. Benigni and Bossa authored one of the most recent and complete lists of SAs, 33 in all (Benigni, 2000; Benigni et al., 2008).

Current regulatory guidance on mutagenic impurities in pharmaceuticals states that the absence of structural alerts from two complementary QSAR methodologies, one expert or rule based and one statistical based, is sufficient to conclude that an impurity is of no concern and no further testing is required (ICH, 2017). This guideline is not intended to be used for leachables and extractables but the idea can also be extended to cover these compounds as a first step in risk management. The ICH M7 guideline calls for using QSAR results and any available associated data to classify impurities as belonging to one of five categories, as summarized in Table 11.7.

If a compound/impurity is predicted to be mutagenic, then further testing may be necessary in order to determine the safety of the drug substance or product. If the compound does not elicit a positive prediction for mutagenicity, then further steps should be taken to determine its safety.

When carcinogenic and mutagenic structural alerts are present for an impurity, it is necessary that the levels of this impurity be kept to less than 1.5 mg daily intake, an amount that

TABLE 11.7 ICH M7 Classification of Genotoxic/Mutagenic Risk of Impurity

Class 1	Known mutagenic carcinogen
Class 2	Known mutagen with unknown carcinogenic potential
Class 3	Alerting structure, unrelated to the structure of the drug substance; no mutagenicity data
Class 4	Alerting structure, same alert in drug substance which has been tested and is nonmutagenic
Class 5	No structural alerts, or alerting structure with sufficient data to demonstrate lack of mutagenicity

poses less than one in 100000 risks to patients. Exposure at or above this level may require additional testing in the appropriate species (Ames *in vitro* mutagenicity would be quite effective).

When more than one genotoxic impurity is present in the drug substance, the relevant TTC can be applied to each individual impurity if the impurities are structurally unrelated.

Three additional specific areas of potential toxicity in drug development are (i) adverse immune system responses (sensitization and anaphylaxis, though only the former—as dermal sensitization) is addressed in current QSAR models; (ii) hepatic toxicity (frequently called delayed liver toxicity or DLT); and (iii) cardiotoxicity (both arrhythmias and significant changes in blood pressure). Some of both the expert and statistical-based system address these, as summarized in Table 11.8.

11.4.1.1 Sensitization There are four classes of hypersensitivity responses in the Coombs and Gell scale, but two of these (I, delayed contact hypersensitivity, usually a dermal response, and IV, most seriously expressed as anaphylaxis) are generally significant concerns.

Derek, Leadscope modeler, and TOPKAT predict the potential type I responses well, but no model currently predicts the type IV.

11.4.1.2 Hepatotoxicity For the last two decades, post-marketing occurrences of DLT have been the single most common cause of postmarket drug withdrawal due to

safety—a wider range of available commercial models predict the potential for these responses moderately well, which given the widespread belief that such are idiosyncratic and not predicted well is a promising situation.

11.4.1.3 Cardiotoxicity Cardiotoxicity is second only to hepatic toxicity as a cause of safety concern withdrawal of drugs post market. While the concern is usually expressed as being due to potential arrhythmia (many associated with disruption of the hERG channel), this is the case less than half the time. hERG channel effects are, however, what QSAR models currently seek to predict.

11.5 COMPARISON OF AVAILABLE MODELS/ APPLICATIONS

As a start it should be noted that the current available toxicity prediction programs have two areas of limitation—not currently differentiated stereoisomers and all struggle with predictions involving organometallic ions due to issues associated with metal ions having multiple possible valence states (Walker et al., 2012).

11.5.1 QSAR of Metabolism

As predictive use of QSAR for toxicology end points has matured, the prediction of metabolism is an area of rapidly increasing sophistication (Kirchmair et al., 2015).

TABLE 11.8 Available QSAR Predictive Modeling Systems

	Derek ^a	Leadscope Modeler ^a	Multicase ^a	EPA TEST	TOPKAT	VEGA (REACH Tool)	OECD Toolbox	ToxTree	CAESAR	Read Across

^a Leadscope and Multicase now offers expert rule systems. Similarly, Lhasa (Derek) now offers a statistical system.

11.5.2 Meteor

Meteor is a computer program that helps scientists who need information about the metabolic fate of chemicals and want to be more efficient, be more effective, and make better decisions.

The program uses expert knowledge rules in metabolism to predict the metabolic fate of chemicals, and the predictions are presented in metabolic trees. The only information needed by the program to make its prediction is the molecular structure of the chemical.

Meteor provides comments and literature citations as evidence to support its predictions and is used by scientists with an interest in understanding the metabolic fate of chemicals. Meteor can be used

- To provide information for decision-making when there is little or no experimental metabolism data available
- To help interpret data from mass spectrometry metabolism studies more speedily and accurately

Meteor also

- Predicts the metabolic fate of chemicals, displays results as a metabolic tree, and allows you to filter results and see only “likely” metabolites
- Covers phase I and phase II biotransformations
- Links directly to MetaboLynx to speed up analysis of mass spectrometry data from metabolism studies
- Evaluates the metabolic fate of potential new chemical products, existing products, and impurities to identify potentially harmful metabolites
- Makes decisions about which chemicals are likely to have “more favorable” metabolic profiles when you do not have all the experimental information you would like to have about the metabolism of each chemical
- Carries out metabolism experiments where you could save time by knowing in advance what metabolites are likely to be observed
- Improves the properties of a chemical in the R&D pipeline by slightly redesigning its molecular structure

Meteor is used to provide information about the metabolic fate of a chemical when there is no experimental data available and to help analyze mass spectrometry data from metabolism studies:

- Meteor can be used to suggest the most likely molecular structure of a metabolite, or group of metabolites, when only empirical formula data is available.

Within Meteor, you can predict the likely chemical structures and metabolic pathways of metabolites detected by a

mass spectrometer. Simply input the masses or formulae of your identified metabolites along with the molecular structure of the parent compound to obtain a Meteor prediction.

Meteor bases its decisions on metabolism on a mechanism very similar to Derek:

- Substructures of the molecule that are the known or suspected points of metabolism, enzymatic or chemical action, or conjugation are identified.
- The likelihood of the reaction taking place is estimated and metabolites or resulting compounds are identified.
- The resulting compounds are then compared under the same rules to generate second-order metabolites. This process is repeated up to the level the user specifies.
- The metabolite tree is created along with an indicator of how likely/prevalent the metabolite is.

Similar to Derek, rules for Meteor are proposed both by the users and experts hired by Lhasa, and the rules are implemented only after being reviewed by a panel of experts. Therefore, there is research and documentation available for each Meteor prediction. For the same reason, idiosyncratic reactions will not be anticipated unless they have been reported in research, proposed to Lhasa, and reviewed by the Lhasa experts.

It is always recommended that a thorough search of available data on a compound is performed and to remember that data itself, when good, is always better than a prediction.

11.5.3 Derek

Derek is the premier expert rule-based QSAR model system, and both cover a wide (and expanding) range of end points and undergo regular updates. Current revision predicts the probability of an end point (called an alert) being operative in a classification rating scale, shown in Table 11.9. “Negatives”—no alerts—are called (Lhasa, 2022).

Derek predicts genotoxicity based on substructure toxicity and a complex structure of decision rules. It will predict a positive if a particular substructure in the compound has reported genotoxic effects. The individual substructures in Derek predictions are chosen based on a review by a panel of experts, and the results are not numerical but instead are hierarchical: probable is more serious than plausible, plausible is more serious than doubted, etc. The identification of “alerting” structures adds a valuable aspect to interpreting the results. Lhasa, Ltd., the developer of Derek, does now also offer a complementary statistical-based system so that the two-method requirement for impurity evaluation under ICH M7 is met.

Pricing for Derek evaluations is for assessment (all end points), unlike Leadscope and multiple computer-automated structural evaluation (Multicase) where each end point has an additional cost.

TABLE 11.9 Terminology Used in the Outputs Provided by Derek for Each End Point

Terminology	Description
Certain	There is proof that the proposition is true
Probable	There is at least one strong argument that the proposition is true and there are no arguments against it
Plausible	The weight of evidence supports the proposition
Equivocal	There is an equal weight for and against the proposition
Doubted	The weight of evidence opposes the proposition
Improbable	There is at least one strong argument that the proposition is false and there are no arguments that it is true
Impossible	There is proof that the proposition is false
Open	There is no evidence that supports or opposes that proposition
Contradicted	There is proof both that the proposition is true and that it is false

11.5.4 Leadscope

Leadscope arose from the CAS/RTEC database and performs a nonlinear multiple regression against a group of agents, some classified as genotoxic, and some classified as nongenotoxic. The regression is based on structural similarity but does not use specific substructures. The known agents were selected for their predictive ability against a larger database of agents whose genotoxicity is known (Leadscope, 2022).

The genetic toxicity modeler provides either a probability of an alert being relevant or an error message of “not in domain” for evaluated structures. If the prediction indicates “not in domain,” compound was not within the domain of applicability (compounds/structures currently used in the prediction model) and no prediction can thus be calculated. The domain of applicability determines whether the test compound can be predicted by the model. If the test structure is not at least 30% similar to one of the training set compounds using a fingerprint of Leadscope structural features and at least one model feature is present in the test structure, it is not in the domain. Most use a criterion of 60% in taking an alert as relevant.

11.5.4.1 Multiple Computer-Automated Structural Evaluation Multicase arose out of an effort, funded by EPA, by Klopman (1992) and Klopman and Rosenkranz (1994) to develop a QSAR model for prediction of potential genotoxicity and carcinogenicity associated with chemical structures. It uses a multivariate model to predict proximity to positive structures, expressed as a probability of an alert being relevant (here a value of 0.6 is usually employed). The system has (or has added) additional end points beyond the original two (mutagenicity and carcinogenicity). Structures

need to be submitted as Mole files. FDA uses a modified version. Structures that are organometallic or with molecular weights above 5000 Da cannot be evaluated by Multicase.

11.5.4.2 Toxicity Prediction by Computer-Assisted Technology Developed by Kurt Enslein in the 1970s (Enslein and Craig, 1982; Enslein et al., 1983, 1984; Enslein, 1984), TOPKAT is a hybrid between a traditional system using calculations based on physical chemical aspects of structures and a multivariate statistical system. Unlike Derek, Leadscope, and Multicase, in addition to mutagenicity, it also predicts rat oral LD₅₀ values, developmental toxicity, skin sensitization, skin and ocular irritation, octanol–water partition coefficients, and aerobic biodegradability. It is a PC-based program owned by Accelrys since 2001. Structures must be entered in simplified molecular-input line-entry system (SMILES—Weininger, 1988).

Cramer Rule (ToxTree) Also an older system, originally intended to help prioritize chemical for testing, ToxTree is not actually a QSAR system in that it does not predict the presence or absence of potential activity for specific end points. Rather, it classifies chemicals (based on the presence or absence of substructural features) as to relative toxicity, ranging from class I (highly toxic) to class III (practically nontoxic) (Cramer et al., 1978; Curios-IT, 2009).

Toxicity Estimation Software Tool TEST was developed by EPA (EPA, 2020). While it predicts end points of concern for candidate drugs (Ames mutagenicity, rat oral LD₅₀, and developmental toxicity), many of its end points (such as 96 h fat-head minnow LC₅₀) are more of environmental concern.

11.5.5 VEGA

The model provides a qualitative prediction of mutagenicity on *Salmonella typhimurium* (Ames test). VEGA combines QSAR models and read across tools. The models have been taken from CAESAR or TEST or have been developed later by the contributors to VEGA.

A completely independent algorithm is at the basis of the evaluation for read across. This algorithm shows similar compounds, assesses the QSAR results on the similar compounds, and analyzes some relevant chemical features in the target compound and its related compounds. The QSAR models available for regulatory purposes have been optimized in accordance with the REACH requirements.

The AD of predictions is assessed using an Allowable Daily Intake (ADI) that has values from 0 (worst case) to 1 (best case). The ADI is calculated by grouping several other indices, each one considering a particular issue of the AD.

Most of the indices are based on the calculation of the most similar compounds found in the training and test set of the model, calculated by a similarity index that considers molecule’s fingerprint and structural aspects (count of atoms, rings, and relevant fragments).

11.5.5.1 Global AD Index The global index takes into account all other indices in order to give a general global assessment on the AD for the predicted compound. Defined intervals are the following:

$1 \geq \text{index} \geq 0.9$ predicted substance is into the AD of the model.

$0.9 > \text{index} \geq 0.7$ predicted substance could be out of the AD of the model.

$\text{index} < 0.7$ predicted substance is out of the AD of the model.

In the following, all AD components are reported along with their explanation and the intervals used.

11.5.5.2 Similar Molecules with Known Experimental Value This index considers how similar are the first three most similar compounds found. Values near 1 mean that the predicted compound is well represented in the data set used to build the model; otherwise, the prediction could be an extrapolation.

11.5.5.3 Accuracy of Prediction for Similar Molecules This index takes into account the error in prediction for the three most similar compounds found. Values near 0 mean that the predicted compound falls in an area of the model's space where the model gives reliable predictions.

11.5.5.4 Concordance for Similar Molecules This index takes into account the difference between the predicted value and the experimental values of the three most similar compounds. Values near 0 mean that the prediction made disagrees with the values found in the model's space; thus the prediction could be unreliable.

11.5.5.5 Atom-Centered Fragments Similarity Check This index takes into account the presence of one or more fragments that aren't found in the training set or that are rare fragments.

11.5.5.6 Model Descriptors Range Check This index checks if the descriptors calculated for the predicted compound are inside the range of descriptors of the training and test set. The index has value 1 if all descriptors are inside the range, 0 if at least one descriptor is out of the range.

The model goes through a first step in which a set of 12 SAs related to mutagenicity is checked. If one or more fragments are found, compound is predicted as "mutagen."

Statistics obtained applying the model to its original data set:

- Training set: $n = 3275$; accuracy = 0.92; specificity = 0.87; sensitivity = 0.96
- Test set: $n = 805$; accuracy = 0.82; specificity = 0.74; sensitivity = 0.89

Furthermore, the statistics for the test set considering the ADI is here reported; the ADI is used, as in the final model's assessment, in order to divide results in three groups (into AD, possibly out of AD, out of AD), showing that compounds considered into AD have better performance than the others:

- Test set with ADI greater than 0.9 (compounds into the AD):
 $n = 338$; accuracy = 0.94; specificity = 0.85; sensitivity = 0.98
- Test set with ADI between 0.9 and 0.7 (compounds could be out of AD):
 $n = 320$; accuracy = 0.82; specificity = 0.80; sensitivity = 0.84
- Test set with ADI lower than 0.7 (compounds out of the AD):
 $n = 147$; accuracy = 0.56; specificity = 0.48; sensitivity = 0.66

Results given as PDF file consist of a PDF document containing all the information about the prediction. Several pages are dedicated to each molecule, in the following order:

1. *Prediction*: Here it is reported as a depiction of the compound and the final assessment of the prediction (i.e., the prediction made together with the analysis of the AD). In the following, all information related to the prediction are reported. Note that if some problems were encountered while processing the molecule structure, some warnings are reported in the last field (Remarks).
2. *Similar compounds*: Here it is reported as the list of the six most similar compounds found in the training and test set of the model, along with their depiction and relevant information (mainly experimental value and predicted value).
3. *Applicability domain* Here it is reported as the list of all ADIs, starting with the global ADI. For each index, it is reported as its value and a brief explanation of the meaning of that value.
4. *Reasoning on fragments/structural alerts*: If some SAs are found, they are reported here (one for each page) with a brief explanation of their meaning and the list of the three most similar compounds that contain the same fragment. Note that if no SAs are found, this section is not shown.

TEST allows you to estimate the value for several toxicity end points using several different advanced QSAR methodologies.

A data set of 6512 chemicals was compiled from several different sources. The final data set consists of 5743 chemicals

(after removing salts, mixtures, ambiguous compounds, and compounds without CAS numbers).

Ames mutagenicity data set statistical external validation for demonstrating that the consensus method achieved the best prediction accuracy (concordance) and prediction coverage.

The prediction results for the Ames mutagenicity were as shown in Table 11.10.

The consensus method: The predicted toxicity is estimated by taking an average of the predicted toxicities from the hierarchical clustering, FDA, and nearest neighbor QSAR methods (provided the predictions are within the respective ADs):

- *Hierarchical method:* The toxicity for a given query compound is estimated using the weighted average of the predictions from several different cluster models.
- *FDA method:* The prediction for each test chemical is made using a new model that is fit to the chemicals that are most similar to the test compound
- *Nearest neighbor method:* The predicted toxicity is estimated by taking an average of the three chemicals in the training set that are most similar to the test chemical.

The prediction accuracy is then evaluated in terms of the fraction of compounds that are predicted accurately. The prediction accuracy is evaluated in terms of three different statistics: concordance, sensitivity, and specificity.

Concordance is the fraction of all compounds that are predicted correctly (i.e., experimentally active compounds that are predicted to be active and experimentally inactive compounds that are predicted to be inactive).

Sensitivity is the fraction of experimentally active compounds that are predicted to be active, while specificity is the fraction of experimentally inactive compounds that are predicted to be inactive.

11.5.6 Derek versus Leadscope

Please note that Derek and Leadscope Model Applier use very different algorithms. Derek predicts genotoxicity based

on substructure toxicity, that is, it will predict a positive if a particular substructure in the compound has reported genotoxic effects. The individual substructures in Derek predictions are chosen based on a review by a panel of experts, and the results are not numerical but instead are hierarchical: probable is more serious than plausible, plausible is more serious than doubted, etc. Leadscope instead performs a nonlinear regression against a group of agents, some classified as genotoxic, and some classified as nongenotoxic. The regression is based on structural similarity but does not use specific substructures. The known agents were selected for their predictive ability against a larger database of agents whose genotoxicity is known. Since regression is performed numerically, you get numerical results instead of classifications. Strength of association is based both on the probability that measures a degree of “closeness” to the agents in question and on the number of agents the structure is close to. This leads to a number of differences in results, specifically:

1. Derek will not predict a substance as nongenotoxic while Leadscope will.
2. Similarly, Derek either predicts something or not. Leadscope generates positives (structurally “close” to one or more known genotoxic agents), negatives (structurally close to one or more known nongenotoxic agents), or no prediction possible (not close enough to any agents in the database for prediction).
3. Derek predictions can always be traced back to a particular substructure and further information is available. Leadscope predictions are usually too complex for ready explanation.
4. Both will generate false positives.
5. Neither is good with idiosyncratic toxicities: Derek will not predict idiosyncratic toxicities unless the toxicity has been reported and included in their database. Leadscope usually reports no prediction possible but also has a false-positive rate for idiosyncratic toxicities.

Tables 11.3 and 11.11 contain comparisons between Derek, Leadscope, and other QSAR programs.

TABLE 11.10 Prediction Results for Ames Mutagenicity Characteristics

Method	Concordance	Sensitivity	Specificity	Coverage
Hierarchical	0.765	0.775	0.753	0.951
FDA	0.771	0.771	0.771	0.962
Nearest neighbor	0.798	0.833	0.772	0.802
Consensus	0.807	0.817	0.775	1.000

TABLE 11.11 Comparison of MCASE Versus Derek Versus Leadscope Versus TOPKAT—Current State of Predictive Toxicology FDA Purchased LEADSCOPE in 2001

	Derek	TOPKAT	MCASE	LEADSCOPE
Pros	<ul style="list-style-type: none"> • Predictions can be traced back to substructures making further information available (provides structural alerts) • Uses both bacterial mutagenicity data and all other available genotoxic data • Rule-based system • Has suggested permissible limit of distance from the OPS, precalculated and stored within database • Able to process more molecules than TOPKAT • Indicates presence of aromatic amines • Prediction extends to genotoxicity, toxicity, carcinogenicity, developmental and reproductive effects, and local time 	<ul style="list-style-type: none"> • Uses electrotopological descriptors rather than chemical structures, atomic size-adjusted E-states computed from rescaled count of valence electrons, molecular weight, topological shape indices, and symmetry indices (extension of QSAR) • Correlative structure–activity relationship (SAR) system 	<ul style="list-style-type: none"> • Breaks molecule into fragments (biophores) • Considers physicochemical properties and potentially deactivating fragments • Accounts for aqueous solubility and quantum chemical parameters such as highest occupied molecular orbital and lowest occupied molecular orbital energies • Able to identify the potential of existence of baseline activity due to a specific physical attribute • Can deal with noncongeneric data sets • Uses binary information to discriminate among structural features associated with active and inactive compounds • Focuses on genotoxicity and carcinogenicity 	<ul style="list-style-type: none"> • Able to predict nongenotoxic substances • Results numerical • Predicts genotoxicity at different levels, not clear-cut like Derek (either it is or it is not) • Allows for easy visualization of large sets of chemical compounds, their properties, and biological activities • Organizes into functional groups, aromatics, and heterocycles with common substituents (2D histograms(frequencies of each class in data set) and scatter plots) • Dynamically constructs series of detailed cross sections of the data set by expanding more specific structural classes, creating subprojects, and using interactive controls for properties • Free to explore any subset, not limited to the statistically significant feature
Cons	<ul style="list-style-type: none"> • Does not specifically call out nongenotoxic substances • Results are hierarchical, so it provides no numerical probability (categorical) • Predicts something or nothing 	<ul style="list-style-type: none"> • Uses only bacterial mutagenicity data, not other genotoxic data • Not useful in predicting the carcinogenicity of chemicals • Database too small and decisions rules not refined enough to accurately predict carcinogenicity 	<ul style="list-style-type: none"> • If substructure not related to observed activity, will be randomly placed • Among active/inactive compounds in the database • Cannot take advantage of provided training data 	<ul style="list-style-type: none"> • Predictions too complex to be traced back for explanations and/or causes • Generates false positives • Does not predict idiosyncratic toxicity well, occasionally reporting false positives. Although it usually reports no prediction possible

(Continued)

TABLE 11.11 (Continued)

Derek	TOPKAT	MCASE	LEADSCOPE
<ul style="list-style-type: none"> • Can generate false positives, but not false negatives • Does not predict idiosyncratic toxicity unless the toxicity has already been reported or included in database • If molecular weight is too high, it cannot generate genotoxicity predictions unless structure • When processing hundreds of compounds, compound-by-compound evaluation becomes impractical • Overpredicts the mutagenicity of aromatic amines, additional research required to refine the rules • Cannot take advantage of provided training data without programming input • Unknown SARs are not contained in database 	<ul style="list-style-type: none"> • Molecule must be within all dimensions to be acceptable; otherwise, it depends on the distance of the query from the OPS charge on a molecule • Cannot process if (i) a other than anionic oxygen or cationic nitrogen, (ii) compounds with manganese, and (iii) mixtures • Has defined chemical space increasing the changes of “unprocessability” • Cannot process molecules in batch mode making evaluations of large data sets unfeasible • Compound names and structures not searchable or organized alphabetically (finding one structure among hundreds becomes strenuous) • Struggles with predicting mutagenicity of aromatic amines 	<ul style="list-style-type: none"> • Yields lower prediction accuracy when the software cannot adapt to a specific chemical space 	

Neither TOPKAT nor Derek can reduce false-positive rates or false-negative rate simultaneously (reducing one allows for more specific use).

11.6 NEAR NEIGHBOR SURROGATES AND THEIR USE

As previously discussed in this chapter, QSAR methodologies are widely accepted as methods to evaluate the potential mutagenicity of tentatively identified compounds or compounds with no toxicity data available. Regulatory guidelines (ICH M7, ICH Q3A, ICH Q3B) have been developed to address and assess safe levels of impurities in drug products and drug substances, providing safe and allowable threshold levels. In some instances, a higher level may be qualified based on quantitative toxicity data. Chapter 34 provides a discussion on the generation of permissible daily exposure levels (PDEs) based on compound specific data. However, a common issue seen with impurities is that they often have no compound-specific toxicity data available to derive a PDE. One approach to derive a PDE when no compound-specific toxicity data is available is to use a near-neighbor surrogate approach.

Near-neighbor surrogates are compounds identified as similar in some way to the chemical being investigated or target chemical. Similarity is usually determined on the basis

of structural similarity or on the basis of the same mode or mechanism of action. For example, similarities may be based on the following:

- A common functional group (e.g., aldehyde, epoxide, ester, specific metal ion);
- Common constituents or chemical classes, similar carbon range numbers;
- An incremental and constant change across the compounds (chain-length);
- The likelihood of common precursors and/or breakdown products, via physical or biological process, which may result in structurally similar chemicals (e.g., the metabolic pathway approach)

Endpoint information (NOAELs, LOAELs, target organs of toxicity, etc.) can be collected from surrogates and used in a read-across approach to predict the same endpoint for the target chemical. Surrogate compounds should be evaluated using comprehensive risk assessment methodologies, as provided in ICH guidance, and further described in Chapter 34.

Additional safety factors may be needed to account for uncertainties between surrogate and target compounds. However, surrogate compounds, when appropriately justified, can be utilized to assess the safety and determine a safe limit for compounds and impurities that lack data.

TOXICOGENOMICS

12.1 INTRODUCTION

In the years since Frederick Sanger (Sanger et al., 1977) developed a rapid and efficient methodology to sequence DNA and RNA strands, the various “omnic” technologies have been advanced and can be integrated into nonclinical safety and efficacy studies. These technologies more sensitively and precisely evaluate therapeutic agent safety by providing information on the molecular and cellular events which underlie adverse drug effects (Campbell and Heyer, 2007; Boverhof and Gollapudi, 2011; Nicholson et al., 1999).

As we have come to be able to map the entire genome—an organization of an organism’s complete set of DNA, including all of its genes (the genome, consisting of ~30000 genes, for which we are only aware of the function of some (Fuchs et al., 2013)) for humans in 2001—(Venter et al., 2001). We have also gained the ability to identify the relationship between changes (including activation) of groups of genes and specific adverse effects of exposure to chemicals and physical agents. Although the perfect correlations between “hits” and adverse effects are not in hand, with there being both variation in the individual organisms’ susceptibility—and the need to understand dose–response relationships, the use of identifying which hits agents of concern may achieve a correlation of this to the potential for the agent of concern to strict toxicity in patient populations understanding these relationships is the subject of the field of toxicogenomics (TGX).

TGX may be defined as a toxicological subdiscipline of pharmacogenomics, which is defined as the study of interindividual variations in whole-genome or candidate gene single-nucleotide polymorphism maps, haplotype markers, and alterations in gene expression that might correlate with drug responses (Lesko et al., 2003; Lesko and Woodcock, 2004).

TGX was first mentioned in literature in 1999 by Nuwaysir. The hypothesis of one-gene-one-polypeptide, which said that each gene controls the production, function, and specificity of a particular protein, has been revised, and the whole picture of gene expression and regulation became more complex.

While some investigators particularly use toxicity/TGX profiles to identify potential problems with drug candidates that are potentially inherent, Table 12.1 summarizes the broader potential range of motivations for use.

The use by major pharmaceutical companies, as with the near cousin technologies of proteomics and metabolomics, has become more normalized over the last two decades. Included are the use of TGX in *in vivo* studies at various stages to answer the specific mechanics, the generalizations, and the potential relevance of findings in animal studies to potential human exposure to the drug (indeed, the most cited reason in surveys about TGX use (Vahle et al., 2018), to predict toxicities (rarely), as a screening tool, and to complement and clarify the meaning of findings by other technologies.

TABLE 12.1 Key Motivating Factors for Application of Toxicogenomics (TGX) to Provide Potential Mechanistic Insight

- | | |
|---|--|
| 1 | Limitation of traditional assays in satisfactorily characterizing toxicity |
| 2 | Limitation of traditional approaches for hypothesis generation relative to mechanisms of toxicity |
| 3 | Existence of gene expression response data in the literature or elsewhere that appears relevant to the observed toxicity |
| 4 | Specific request by a regulatory authority to generate the data |
| 5 | Ease and speed with which a transcriptomics assay can be performed compared to the pursuit of other mechanistic approaches |

An analysis of the function of genomic data is a big data problem. The data sets are, of course, the microarrays generated in response to exposure to a drug or classes of drugs. One can analyze these microarray results to discover the characteristic of members of functional classes of drugs, and then compare the functionality of members of a class, after that be able to predict a functionality of class members for which there are little or no *in vivo* (or even *in vitro*) data. Methodologies for these statistical analyses most commonly include principal component analysis (PCA) and hierarchical clustering (Gad, 1999). Table 12.2 presents a wider array of approaches.

Gene expression arrays allow the semiquantitative evaluation of responses to virtually all known drug toxicities across species with monitoring the function of genes (or gene sets) that alerted, allowing for identification of potential mechanisms. This understanding can be translated into the design of specific screens for improving selection of candidates for advancement in development (Lord et al., 2006). The extent of effects of a compound (or a physical agent) on the expression of one or more genes, and therefore on the production/functionality of a protein, mechanistically underlie the degree of effort (dose–response of the subject drug). There is a point at which a drug’s effect on gene expression exceeds the usual background variability, and this is the threshold effect if other functions are not “dampening” the functional expression of effect (Fuchs et al., 2013; Selmy, 2018).

As we have come to recognize that on a biochemical level, proteins and their interactions are the prime movers, the study of their interaction with proteomic technique has become increasingly attractive. Proteomic technologies are those that

are used to study the full collection of proteins in a biological sample, the proteome. However, study of the proteome has been more difficult compared to that of the genome or transcriptome because of the increasing complexity that is observed with proteins. For example, proteins can undergo numerous posttranslational modifications that affect their form, function, and stability. In addition, there is no approach for the amplification of proteins, as existing for nucleic acid sequences, so the limits of detection in the complex milieu of a protein extract can become problematic. Furthermore, protein instability can make analysis difficult as adducts and other forms of protein damage can complicate proteomic analysis approaches. However, as proteins are the main functional units of biology, understanding the protein complement of a cell or a tissue can provide insights into biological functions that cannot be gleaned from genomics or transcriptomics. The dominant technology applied to the study of proteomics has been mass spectrometry-based analysis of peptide fragments (Boverhof et al., 2006).

12.2 USES OF TOXICOGENOMICS

For much of the field of toxicology, the primary focus is on determining the probability and potential exposure-related aspects of risk. Table 12.3 presents potential uses of TGX in this process.

With the advent of TGX came the expectation of greater insights into chemical mechanisms of action and more facile and informative prediction of toxicity in shorter-term assays. This was predicated on the thought that toxicity is preceded

TABLE 12.3 Uses of Toxicogenomics in Risk Assessment

Mature or near-mature applications of toxicogenomics	Screening tools to predict toxicity and targets Identification of biomarkers of effect Hypothesis generation to aid in the determination of mode of action (MOA(s))
Future potential applications of toxicogenomics	Hypothesis testing (e.g., for evaluation of MOA and consideration of novel endpoints) Identifying critical targets or pathways that were not adequately investigated by <i>in vivo</i> studies, informing the choice of UF _D and of further toxicity testing Quantifying interspecies differences in toxicodynamics, based on the observed responses in <i>in vitro</i> studies Identifying potential sensitive populations, based on responses for key control genes or pathways in cell lines from different subpopulations Use directly in dose–response analyses, including BMD analyses, and in categorical regression, linked to clinically relevant endpoints Strengthening reliance on structure–activity relationship (SAR)/quantitative structure–activity relationship (QSAR) models as a relatively low-cost tool for helping validate predictions from <i>in silico</i> modeling A long-term goal is to use toxicogenomic information directly as point of departure (POD), to identify perturbations from homeostasis at the pathway level

by, and results in, alterations in gene expression, and that these responses are far more sensitive, characteristic, and measurable than the subsequent toxicity itself (Nuwaysir et al., 1999).

Insights into the specific gene expression responses that changed in response to chemical exposure were expected to identify cellular targets and pathways that would explain the downstream toxicity. Meanwhile, these same gene expression responses were expected to be shared by chemicals with similar toxic effects such that the establishment of transcriptional signatures would allow for prediction of toxicity prior to its manifestation. Other expectations included the ability to more effectively bridge *in vitro* and *in vivo* responses that would lead to less animal use and dramatically improve cross-species extrapolations, particularly rodent to human extrapolations.

There are, of course, a number of considerations involved in the use of TGX as a tool in risk assessment. With persistent application of TGX to toxicology and risk assessment, it seems inevitable that researchers will learn how to successfully apply this technology to advance the field. Emerging views, including the National Research Council (NRC)'s vision for toxicity testing in the twenty-first century, indicate that change is needed in the approaches to assessing toxicity and risk. All agree that new technologies such as TGX should greatly increase the numbers of chemicals comprehensively evaluated as well as broaden and improve the assessed toxicity end points for human relevance while also reducing the use of animals. The NRC report stresses that the twenty-first century vision for toxicity testing should remain consistent with the NRC risk assessment paradigm put forward in 1983. This paradigm consists of four key components: hazard identification, dose–response assessment, exposure assessment, and risk characterization (see Chapter 2 for additional details). Therefore, although there is a call to change the way in which we assess toxicity and exposure, and ultimately

risk, this will continue to be overlaid onto the current risk assessment paradigm. As a result, the focus should be on how new technologies can improve the risk assessment process as a whole, and we must do this with the knowledge and consideration of all components of the paradigm. Researchers need to have a good understanding of the risk assessment process and all its components so that studies can be designed in a manner that will allow the generated data to inform the process. As emerging technologies could impact the components of risk assessment differently, it is important to understand the strengths and weaknesses of the technologies applied to these components.

A particularly attractive application of TGX in risk assessment is understanding dose–response relationship (and perhaps even helping to identify threshold of effect levels) at low concentrations which are below the level at which our traditional tools (*in vivo* and *in vitro* methodologies) have sensitivity and specificity.

13

IMMUNOTOXICOLOGY IN DRUG DEVELOPMENT

13.1 INTRODUCTION

Unlike many of the other areas covered in this volume, immunotoxicity evaluation of drugs has undergone fundamental changes since the first edition. Before, there was no specific guidance. Now, with ICH S8A in place and in force, there are both a requirement and a road map, though biologics are excluded from coverage.

This is in particular a concern as biologics have attained their therapeutic promise with their hyperpharmacology providing the largest portion of safety concern for them (from the “cytokine storm” of TGN-1412 to the unintended immune issues associated with most mAbs). With immune modulation of some form being the primary intended therapeutic effects and with one-third of all new approved therapeutics being biologics, this is particularly a concern, while specifically not covered by ICH guidance approaches and requirements for immunotoxicity evaluations of these moieties are addressed, however, in this chapter.

All three ICH regions have made strong efforts to harmonize the immunotoxicity risk assessment for investigational new drugs. These efforts culminated in the release of the ICH S8 guideline, which was adopted by the CHMP in October 2005 and came into force in the United States in April 2006, as well as the MHLW in April 2006. According to this current guideline, initial immunotoxicity assessment should be based on the evaluation of data already available from standard toxicity studies and other characteristics of the drug substance like pharmacological properties, the intended patient population, known drug class effects, clinical data for the drug, and its disposition. The need for additional immunotoxicity testing should be decided on the basis of a weight of evidence assessment, taking into account all available information. Testing should thus be a tiered approach, trig-

gered and determined by concerns from the weight of evidence assessment.

Immunotoxicity is defined in the ICH S8 specifically guideline as unintended immunosuppression or enhancement. It must be noticed that drug-induced hypersensitivity and autoimmunity are not in the scope of ICH S8. Surprisingly, the ICH S8 guideline excludes biological and biotechnology-derived products, probably the larger area of concern for pharmaceuticals, which are now the bigger area of concern.

The immune system is a highly complex system of organ systems, cells, and soluble factors distributed throughout the body and involved in a multitude of functions including antigen presentation and recognition, amplification, and cell proliferation with subsequent differentiation and secretion of lymphokines and antibodies. These are, in health, in a state of balance, and there are extensive mechanisms to maintain this balance. The resulting integrated system is responsible for defense against foreign pathogens and spontaneously occurring neoplasms and is readily triggered to respond. To be effective, the immune system must be able to both recognize and destroy foreign antigens. To accomplish this, cellular and soluble components of diverse function and specificity circulate through blood and lymphatic vessels, thus allowing them to act at remote sites and tissues. For this system to function in balance and harmony requires regulation through cell-to-cell communications and precise recognition of self versus non-self. There are multiple opportunities for immunotoxicants to upset this balance by selectively disabling one or more of the cell types or alter membrane morphology and receptors. There are several undesired immune system responses that may occur upon repeated therapeutic administration of a pharmaceutical that may ultimately present barriers to its development, including:

- Down-modulation of the immune response (immunosuppression), which may result in an impaired ability to deal with neoplasia and infections. This is of particular concern if the therapeutic agent is intended to be used in patients with preexisting conditions such as cancer, severe infection, or immunodeficiency diseases.
- Up-modulation of the immune system (i.e., autoimmunity).
- Direct adverse immune responses to the agent itself in the form of hypersensitivity responses (anaphylaxis and delayed contact hypersensitivity).
- Direct immune responses to the agent that limit or nullify its efficacy (i.e., the development of neutralizing antibodies).

Immune-modulated responses to drugs (“drug allergies”) are a major problem and cause of discontinuance of use by patients who do need access to the therapeutic benefits (Patterson et al., 1986), and there remains no adequate pre-clinical methodology for identifying/predicting these responses to orally administered small molecule drugs (Hastings, 2001).

It is the intent of this chapter to provide an understanding of these adverse immunological effects, the types of pre-clinical tests that may be used to detect them, and approaches for testing and interpreting test results.

Immunotoxicology has evolved over the last 30 years as a specialty within toxicology that brings together knowledge from basic immunology, molecular biology, microbiology, pharmacology, and physiology. As a discipline, immunotoxicology involves the study of adverse effects that xenobiotics have on the immune system. As listed earlier, several different types of adverse immunological effects may occur, including immunosuppression, autoimmunity, and hypersensitivity. Although these effects are clearly distinct, they are not mutually exclusive. For example, immunosuppressive drugs that suppress suppressor cell activity can also induce autoimmunity (Hutchings et al., 1985), and drugs that are immunoenhancing at low doses may be immunotoxic at high doses. Chemical xenobiotics may be in the form of natural or man-made environmental chemicals—pharmaceuticals and biologicals that are pharmacologically, endocrinologically, or toxicologically active. Although, in general, xenobiotics are not endogenously produced, immunologically active biological response modifiers that naturally occur in the body should also be included, since many are not known to compromise immune function when administered in pharmacologically effective doses (Koller, 1987).

Although the types of immunological responses to various xenobiotics may be similar, the approach taken for screening potential immunological activity will vary depending on the application of the compound. Thus, this chapter will primarily focus on the immunotoxicology of pharmaceuticals. In con-

trast to potential environmental exposures, pharmaceuticals are developed with intentional but restricted human exposure and their biological effects are extensively studied in surveillance. Pharmaceuticals are developed to be biologically active and, in some cases, intentionally immunomodulating or immunosuppressive. Many will react with biological macromolecules or require receptor binding in order to be pharmacologically active. By their nature, these interactions may result in toxicity to the cells of the immune system, may adversely alter the appearance of “self” to produce an autoimmune response, or may form a hapten, which may then elicit a hypersensitivity response. Because of the fast-expanding development of new drugs that can potentially impact the immune responsiveness of humans, immunotoxicity testing of new pharmaceutical products has become a growing concern.

Until recently, immunotoxicology in pharmaceutical safety assessment has been poorly addressed both by regulatory requirements/guidelines and by existing practice. Notable exceptions are the testing requirements for delayed contact hypersensitivity for dermally administered agents and antigenicity/anaphylaxis testing for drugs to be registered in Japan. The most recently announced regulatory expectation for parenterally administered protein or peptide agents produced by biotechnology is that the development of antibodies (neutralizing and otherwise) should be evaluated in at least one (preferably two) of the animal models used to assess general systemic toxicity.

Unanticipated immunotoxicity is infrequently observed with drugs that have been approved for marketing. Except for drugs that are intended to be immunomodulatory or immunosuppressive as part of their therapeutic mode of action, there is little evidence that drugs cause unintended functional immunosuppression in man (Gleichmann et al., 1989). However, hypersensitivity (allergy) and autoimmunity are frequently observed and are serious consequences of some drug therapies (DeSwarte, 1986; Patterson et al., 1986; Choquet-Kastylevsky et al., 2001; Pieters, 2001). An adverse immune response in the form of hypersensitivity is one of the most frequent safety causes for withdrawal of drugs that have already made it to the market (see Table 13.1) and accounts for approximately 15% of adverse reactions to xenobiotics (deWeck, 1983; Bakke et al., 1984). In addition, adverse immune responses such as this (usually urticaria and frank rashes) are the chief “unexpected” finding in clinical studies. These findings are unexpected in that they are not predicted by preclinical studies because there is a lack of good preclinical models for predicting systemic hypersensitivity responses, especially to orally administered agents. Consequently, the unexpected occurrence of hypersensitivity in the clinic may delay, or even preclude further development and commercialization. Thus, a primary purpose for preclinical immunotoxicology testing is to help us detect these adverse effects earlier in development, before they are found in clinical trials (Burns-Naas and Pallardy, 2013).

TABLE 13.1 Drugs Withdrawn from the Market Due to Dose- and Time-Unrelated Toxicity Not Identified in Animal Experiments

Compound	Adverse Reaction	Year of Introduction	Years on Market
Aminopyrine	Agranulocytosis	ca. 1900	75
Phenacetin	Interstitial nephritis	ca. 1900	83
Dipyron	Agranulocytosis	ca. 1930	47
Clioquinol	Subacute myelo-optic neuropathy	ca. 1930	51
Oxyphenisatin	Chronic active hepatitis	ca. 1955	23
Nialamide	Liver damage	1959	19
Phenoxypropazine	Liver damage	1961	5
Mebanazine	Liver damage	1963	3
Ibuprofen	Hepatotoxicity	1966	2
Practolol	Oculomucocutaneous syndrome	1970	6
Alcolofenace	Hypersensitivity	1972	7
Azaribine	Thrombosis	1975	1
Ticrynafen	Nephropathy	1979	1
Benoxapofen	Photosensitivity, hepatotoxicity	1980	2
Zomepirac	Urticaria, anaphylactic shock	1980	3
Zimelidine	Hepatotoxicity	1982	2
Temafloxacin	Hepato- and renal toxicity	1990	2
Tronan	Hepato- and renal toxicity	1997	3
Renzalin	Hepatotoxicity	1996	4

13.2 OVERVIEW OF THE IMMUNE SYSTEM

A thorough review of the immune system is not the intent of this chapter, but a brief description of the important components of the system and their interactions is necessary for an understanding of how xenobiotics can affect immune function. A breakdown at any point in this intricate and dynamic system can lead to immunopathology.

The immune system is divided into two defense mechanisms: nonspecific, or innate, and specific, or adaptive, mechanisms that recognize and respond to foreign substances. Some of the important cellular components of nonspecific and specific immunity are described in Table 13.2. The nonspecific immune system is the first line of defense against infectious organisms. Its cellular components are the phagocytic cells such as the monocytes, macrophages, and polymorphic neutrophils (PMNs).

The innate immune system has been identified in immune defense in insects and alone in the phylogenetic sequence and serves the same purpose in all these organisms, including humans. The innate immune system encompasses all physical, chemical, and cellular barriers that protect the individual from microbial infections without the need to learn to discriminate self from nonself. The body protects itself from dangerous actions of the innate immune system by the lack of expression of molecular patterns of microorganisms and by the abundant expression of inhibitors. Most components of the innate immune system can work independently and in parallel to destroy microorganisms. Due to its redundancy, the innate immune system is rather robust regarding its actions.

The specific, or adaptive, immune system is present only in vertebrates and is characterized by memory, specificity, and the ability to distinguish “self” from “nonself.” The important cells of the adaptive immune system are the lymphocytes and antigen-presenting cells (APCs) that are part of nonspecific immunity. The lymphocytes, which originate from pluripotent stem cells located in the hematopoietic tissues of the liver (fetal) and bone marrow, are composed of two general cell types: T and B cells. The T cells differentiate in the thymus and are made up of three subsets: helper, suppressor, and cytotoxic. The B cells, which have the capacity to produce antibodies, differentiate in the bone marrow or fetal liver. The various functions of the T cells include presenting antigen to B cells, helping B cells to make antibody, killing virally infected cells, regulating the level of the immune response, and stimulating cytotoxic activity of other cells such as macrophages (Male et al., 2012).

Activation of the immune system is thought to occur when APCs such as macrophages and dendritic cells take up antigen via F_c or complement receptors, process the antigen, and present it to T cells (see Figure 13.1). Macrophages release soluble mediators such as interleukin-1 (IL-1), which stimulate T cells to proliferate. APCs must present antigen to T cells in conjunction with the class II major histocompatibility complex (MHC) proteins that are located on the surfaces of T cells. The receptor on the T cell is a complex of the T_i molecule that binds antigen, the MHC proteins, and the T_3 molecular complex, which is often referred to as the CD3 complex. Upon stimulation, T cells proliferate, differentiate, and express interleukin-2 (IL-2) receptors. T cells also produce and secrete

TABLE 13.2 Cellular Components of the Immune System and Their Functions

Cell Subpopulations	Markers ^a	Functions
<i>Nonspecific immunity</i>		
Granulocytes	—	Degranulate to release mediators
Neutrophils (blood)		
Basophils (blood)		
Eosinophils (blood)		
Mast cells (connective tissue)		
Natural killer (NK) cells	—	Nonsensitized lymphocytes; directly kill target cells
Reticuloendothelial	CD14; HLA-DR	Antigen processing, presentation, and phagocytosis (humoral and some cell-mediated responses)
Macrophage (peritoneal, pleural, alveolar spaces)		
Histiocytes (tissues)		
Monocytes (blood)		
<i>Specific immunity</i>		
<i>Humoral immunity</i>		
Activated B cells	CD19; CD23	Proliferate; form plasma cells
Plasma cells	—	Secrete antibody; terminally differentiated
Resting	—	Secrete IgM antibodies (primary response)
Memory	—	Secrete IgG antibodies (secondary response)
<i>Cell-mediated immunity</i>		
T-cell types		
Helper (T_h)	CD4; CD25	Assists in humoral immunity; required for antibody production
Cytotoxic (T_k)	CD8; CD25	Targets lysis
Suppressor (T_s)	CD8; CD25	Suppresses/regulates humoral and cell-mediated responses

^a Activation surface markers detected by specific monoclonal antibodies; can be assayed with flow cytometry.

IL-2, which, in turn, acts on antigen-specific B cells, causing them to proliferate and differentiate into antibody-forming (plasma) cells.

The adaptive arm of the immune system which depends on delicate tolerance mechanisms to shape the repertoire of the randomly produced antigen receptors makes this part of the immune system susceptible for the induction of autoimmunity. In contrast to innate immune responses, induction of an adaptive immune response depends on a well-regulated temporal and spatial sequence of activation events, which requires the cooperation of several cell types, and the migration of cells between different organs. As a result, activation of adaptive immune responses is a rather slow process, as compared with activation of innate defense mechanisms. All cellular interactions during the induction of an adaptive immune response are based on differentiated intercellular communications pathways involving a host of cytokines and surface receptors.

Antibodies circulate freely in the blood or lymph and are important in neutralizing foreign antigens. The various types of antibodies involved in humoral immunity and their functions are described in Table 13.3. There are multiple genes (polymorphisms) that encode diversity to the variable region of the antibody. B cells are capable of generating further diversity to antibody specificity by a sequence of molecular events involving somatic mutations, chromosomal rearrangements during mitosis, and recombination of gene segments (Roitt et al., 1985; Ladics, 2005).

The immune system is regulated in part by feedback inhibition involving complex interactions between the various growth and differentiation factors listed in Table 13.4. Since antigen initiates the signal for the immune response, elimination of antigen will decrease further stimulation (Male et al., 2012). T suppressor cells (T_s) also regulate the immune response and are thought to be important in the development of tolerance to self-antigens. In addition to the humoral immune system or the branch that is modulated by antibody, cell-mediated immunity and cytotoxic cell types play a major role in the defense against virally infected cells, tumor cells, and cells of foreign tissue transplants. Cytotoxic T_k cells (T killer cells) recognize antigen in association with class I molecules of the MHC, while natural killer (NK) cells are not MHC restricted. Cell killing results in a sequence of events following activation of the effector cell, lysosomal degranulation, and calcium influx into the targeted cell. The various types of cells involved in cell-mediated cytotoxicity and their mechanisms of action are outlined in Table 13.5.

13.3 IMMUNOTOXIC EFFECTS

The immune system is a highly integrated and regulated network of cell types that requires continual renewal to achieve balance and immunocompetence. The delicacy of this balance makes the immune system a natural target for cytotoxic drugs

FIGURE 13.1 Simplified schematic of immunoregulatory circuit that regulates activation of T cells and B cells involved in humoral (T-cell-dependent) and cell-mediated immunity. (1) Antigen (Ag) is processed by the APCs expressing class II MHC molecules. (2) Antigen plus class II MHC is then presented to antigen-specific T helper cells (CD4⁺), which stimulates secretion of IL-2. (3) IL-2 in turn stimulates proliferation (clonal expansion) of T cells and differentiation into T suppressor (T_s), T killer (T_k), and T helper (T_h) effector cells. The expanded clone has a higher likelihood of finding the appropriate B cell that has the same antigen and class II molecules on its surface. (4) Next, the antigen binds to an antibody (Ab) on the surface of a specific B cell. (5) The B cell in turn processes the antigen and presents it (plus class II MHC) to the specific T_h cell. The T_h cell is then stimulated to secrete additional ILs that stimulate clonal expansion and differentiation of the antigen-specific B cell.

or their metabolites. Since renewal is dependent on the ability of cells to proliferate and differentiate, exposure to agents that arrest cell division can subsequently lead to reduced immune function or immunosuppression. This concept has been exploited in the development of therapeutic drugs intended to treat leukemias, autoimmune diseases, and chronic inflammatory diseases and to prevent transplant rejection (Brunton et al., 2021). However, some drugs may adversely modulate the immune system secondarily to their therapeutic effects.

Two broad categories of immunotoxicity have been defined based on suppression or stimulation of normal immune function (Burlison et al., 1995; Luebke et al., 2007; Burns-Naas and Pallardy, 2013). Immunosuppression is a down-modulation of the immune system characterized by cell depletion, dysfunction, or dysregulation that may subse-

TABLE 13.3 Antibodies Involved in the Humoral Immune Response

Antibodies	Serum Concentration		Characteristics/Functions
	mg mL ⁻¹	%	
IgG	10–12	80	Monomeric structure (γ-globulin); secreted from B cells during secondary response; binds complement; can cross placenta
IgM	1–2	5–10	Pentameric structure; secreted from B cells during primary response; potent binder of complement; high levels indicative of systemic lupus erythematosus or rheumatoid arthritis; cannot cross placenta
IgA	3–4	10–15	Dimeric or monomeric structures; found in seromucous secretions (breast milk); secreted by B cells associated with epithelial cells in GI tract, lung, etc.
IgD	0.03	<1	Monomer; extremely labile; functions not well known
IgE	<0.0001		Reaginic antibody involved in immediate hypersensitivity; antihelminthic; does not bind complement

Source: Adapted from Clark (1983, pp. 1–453).

quently result in increased susceptibility to infection and tumors. By contrast, immunostimulation is an increased or exaggerated immune responsiveness that may be apparent in the form of a tissue-damaging allergic hypersensitivity response or pathological autoimmunity. However, as knowledge of the mechanisms involved in each of these conditions has expanded, the distinction between them has become less clear. Some agents can cause immunosuppression at one dose or duration of exposure and immunostimulation at others. For instance, the chemotherapeutic drug cyclophosphamide is in most cases immunosuppressive; however, it can also induce autoimmunity (Hutchings et al., 1985). Likewise, dimethylnitrosamine, a nitrosamine detected in some foods, has been shown to have both suppressing and enhancing effects on the immune system (Yoshida et al., 1989).

13.4 IMMUNOSUPPRESSION

The various cells of the immune system may differ in their sensitivity to a given xenobiotic. Thus, immunosuppression may be expressed as varying degrees of reduced activity of a single cell type of multiple populations of immunocytes.

TABLE 13.4 Growth and Differentiation Factors of the Immune System

Factors	Cell of Origin	Primary Immune Functions
<i>Interleukins^a</i>		
IL-1	Macrophage, B and T cells	Lymphocyte-activating factor; enhances activation of T & B cells, NK cells, and macrophages
IL-2	T cells (T_h)	T-cell growth factor; stimulates T-cell growth and effector differentiation; stimulates B-cell proliferation/differentiation
IL-3	T cells (T_h)	Mast cell growth factor; stimulates proliferation/differentiation of mast cells, neutrophils, and macrophages
IL-4	T cells (T_h), mast cells, B cells	B-cell growth factor; induces proliferation/differentiation of B cells and secretion of IgA, IgG ₁ , and IgE; promotes T-cell growth; activates macrophages
IL-5	T cells (T_h)	Stimulates antibody secretion (IgA), proliferation of B cells, and eosinophil differentiation
IL-6	T cells, fibroblasts, monocytes	Stimulates growth/differentiation of B cells and secretion of IgG; promotes IL-2-induced growth of T cells
IL-7	Bone marrow stromal cells	Stimulates pre-B- and pre-T-cell growth/differentiation; enhances thymocyte proliferation
IL-8	Monocytes, fibroblasts	Neutrophil chemotaxis
IL-9	T cells	Stimulates T cells and mast cells
IL-10	T cells	Stimulates mast cells and thymocytes; induction of class II MHC
<i>Interferons (INF)</i>		
A-INF	Leukocytes and mast cells	Antiviral: increases NK-cell function, B-cell differentiation, potentiates macrophage production of IL-1
B-INF	Fibroblasts, epithelial cells	Antiviral; potentiates macrophage production of IL-1; increases NK-cell function
Γ-INF	T cells (T_h), cytotoxic T cells	Antiviral; activates macrophages; induces MHC class II expression on macrophages, epithelial, and endothelial cells
<i>Tumor necrosis factors (TNF)</i>		
TNFα	Macrophage, B and T cells	Catectin; promotes tumor cytotoxicity; activates macrophages and neutrophils; enhances IL-2 receptor expression on T cells; inhibits antibody secretion
TNFβ	T cells (T_h) NK cells	Lymphotoxin; promotes T-cell-mediated cytotoxicity B-cell activation
<i>Colony stimulating factors (CSF)</i>		
	Stem cells	Promotes growth and differentiation of
Granulocyte CSF	Myeloid	Granulocytes and macrophages
Macrophage CSF	Myeloid	Macrophages and granulocytes
Granulocytemacrophage CSF	Myeloid	Granulocytes, macrophages, eosinophils, mast cells, and pluripotent progenitor cells

^aIncludes lymphokines, monokines, and cytokines produced by T cells, macrophages, and other cells, respectively. *Source:* Adapted from Golub and Green (1991).

Several lymphoid organs such as the bone marrow, spleen, thymus, and lymph nodes may be affected simultaneously or the immunodeficiency may be isolated to a single tissue, such as the Peyer's patches of the intestines. The resulting deficiency may in turn lead to an array of clinical outcomes of varying ranges of severity. These outcomes include increased susceptibility to infections, increased severity or persistence of infections, or infections with unusual organisms (e.g., systemic fungal infections). Immunosuppression can be induced in a dose-related manner by a variety of therapeutic agents at dose levels lower than those required to produce overt clinical signs of general toxicity. In addition, immunosuppression can occur without regard to genetic pre-

disposition, given that a sufficient dose level and duration of exposure have been achieved.

Humoral immunity is characterized by the production of antigen-specific antibodies that enhance phagocytosis and destruction of microorganisms through opsonization. Thus, deficiencies of humoral immunity (B lymphocytes) may lead to reduced antibody titers and are typically associated with acute gram-positive bacterial infections (i.e., *Streptococcus*). Although chronic infection is usually associated with dysfunction of some aspect of cellular immunity, chronic infections can also occur when facultative intracellular organisms such as *Listeria* or *Mycobacterium* evade antibodies and multiply within phagocytic cells.

Since cellular immunity results in the release of chemotactic lymphocytes that in turn enhance phagocytosis, a deficiency in cellular immunity may also result in chronic infections. Cellular immunity is mediated by T cells, macrophages, and NK cells involved in complex compensatory networks and secondary changes. Immunosuppressive agents may act directly by lethality to T cells or indirectly by blocking mitosis, lymphokine synthesis, lymphokine release, or membrane receptors to lymphokines. In addition, cellular immunity is involved in the production and release of interferon, a lymphokine that ultimately results in blockage of viral replication. Viruses are particularly susceptible to cytolysis by T cells since they often attach to the surface of infected cells. Thus, immunosuppression of any of the components of cellular immunity may result in an increase in protozoan, fungal, and viral infections as well as opportunistic bacterial infections.

Immune depression may result unintentionally as a side effect of cancer chemotherapy or intentionally from therapeutics administered to prevent graft rejection. In fact, both transplant patients administered immunosuppressive drugs and cancer patients treated with chemotherapeutic agents have been shown to be at high risk of developing secondary cancers, particularly of lymphoreticular etiology (Penn, 1977). Most of these drugs are alkylating or cross-linking agents that by their chemical nature are electrophilic and highly reactive with nucleophilic macromolecules (protein and nucleic acids). Nucleophilic sites are quite ubiquitous and include amino, hydroxyl, mercapto, and histidine functional groups. Thus, immunotoxic agents used in chemotherapy may induce secondary tumors through direct genotoxic mechanisms (i.e., DNA alkylation).

Reduced cellular immunity may result in increased malignancy and decreased viral resistance through indirect mechanisms as well, by modulating immune surveillance of aberrant cells. T lymphocytes, macrophage cells, and NK cells are all involved in immunosurveillance through cytolysis of virally infected cells or tumor cells, each by a different mechanism (Table 13.5) (Burnet, 1970). In addition to the common cell types described in Table 13.5, at least two other types of cytotoxic effector cells of T-cell origin have been identified, each of which has a unique lytic specificity phenotype and activity profile (Merluzzi, 1985). Of these, both LAK and TIL cells have been shown to lyse a variety of different tumor cells. However, TIL cells have 50–100 times more lytic activity than LAK cells. Most tumor cells express unique surface antigens that render them different from normal cells. Once detected as foreign, they are presented to the T helper cells in association with MHC molecules to form an antigen–MHC complex. This association elicits a genetic component to the immunospecificity reaction. T helper cells subsequently direct the antigen complex toward the cytotoxic T lymphocytes, which possess receptors for antigen–MHC complexes. These cells can then proliferate, respond to specific viral antigens or antigens on

TABLE 13.5 Cells and Mechanisms Involved in Cell-Mediated Cytotoxicity

Cell Type	Mechanism of Cytotoxicity
T_k cells	T_k cells that are specifically sensitized to antigens on target cells interact directly with target cells to lyse them
T_D	Cells involved in delayed hypersensitivity that act indirectly to kill target cells; T_D cells react with antigen and release cytokines that can kill target cells
NK cells	Nonspecific T cells that react directly with target cells (tumor cells) without prior sensitization
Null cells	Antibody-dependent cell-mediated cytotoxicity (ADCC) involving non-T/non-B cells (null cells) with F_c receptors specific for antibody-coated target cells
Macrophages	Nonspecific, direct killing of target by phagocytosis; also involved in presenting antigen to specific T_k cells that can then mediate cytotoxicity as described previously

the membranes of tumor cells, and destroy them (Yoshida et al., 1989).

In contrast, the macrophages and NK cells are involved in nonspecific immunosurveillance in that they do not require prior sensitization with a foreign antigen as a prerequisite for lysis and are not involved with MHC molecules. The enhancement of either NK-cell function or macrophage function has been shown to reduce metastasis of some types of tumors. Macrophage cells accumulate at the tumor site and have been shown to lyse a variety of transformed tumor cells (Volkman, 1984). NK cells are involved in the lysis of primary autochthonous tumor cells. Migration of NK cells to tumor sites has been well documented. Although not clearly defined, it appears that they can recognize certain proteinaceous structures on tumor cells and lyse them with cytolysin.

13.4.1 Immunosuppressive Drugs

Table 13.6 lists numerous types of drugs that are immunosuppressive and describes their immunotoxic effects Brunton et al., 2021. Several classes of drugs that characteristically depress the immune system are further discussed in the following.

13.4.1.1 Antimetabolites This class of drugs includes purine, pyrimidine, and folic acid analogs that have been successfully used to treat various carcinomas, autoimmune diseases, and dermatological disorders such as psoriasis. Because of their structural similarities to normal components of DNA and RNA synthesis, they are capable of competing with the normal macromolecules and alkylating biological nucleophiles.

TABLE 13.6 Immunosuppressive Drugs and Their Effects

Drugs	Biological Activity and Indications	Immunotoxic Effects
<i>Hormones and Antagonists</i>		
Corticosteroids (prednisone)	Anti-inflammatory; systemic lupus erythematosus; leukemias; rheumatoid arthritis; breast cancer	Depresses T- and B-cell function; reduces lymphokines; alters macrophage function; increases infections
Diethylstilbestrol	Synthetic estrogen; cancer chemotherapy	Depletes or functionally impairs T cells; enhances macrophage suppressor cell; increases infections and tumorigenesis
Estradiol	Synthetic estrogen; dysmenorrhea; osteoporosis	Decreases T_h cells and IL-2 synthesis; increases T_s cell function, infections, and tumorigenesis
<i>Antibiotics</i>		
Cephalosporins	β -Lactam antimicrobial	Granulocytopenia; cytopenia
Chloramphenicol	Wide-spectrum antimicrobial	Pancytopenia, leukopenia (idiosyncratic)
Penicillins	β -Lactam antimicrobial	Granulocytopenia; cytopenia
Rifampin	Macrocyclic antibiotic	Suppresses T-cell function
Tetracyclines	Antimicrobial	Decreased migration of granulocytes
<i>Chemotherapeutics and Immunomodulators</i>		
Arabinoside (AraA and AraC)	Antimetabolites; antivirals; leukemias; lymphomas	Leukopenia; thrombocytopenia
Azathioprine	Antimetabolite; leukemia; arthritis; transplant rejection	Inhibits protein synthesis; bone marrow suppression
Busulfan	Alkylating agent; chronic granulocytic leukemia	Leukopenia; myelosuppressive; granulocytopenia
Carmustine and lomustine (BCNU and CCNU)	Alkylating agents; Hodgkin's disease; lymphomas	Delayed hematopoietic depression; leukopenia; thrombocytopenia
Chlorambucil	Alkylating agent; leukemia; lymphomas; vasculitis	Bone marrow suppression; myelosuppressive
Cyclophosphamide (cytotoxin)	Alkylating agent; cancer chemotherapy; transplant rejection; rheumatoid arthritis	Decreased T_s cells, B cells, and NK cells
Cyclosporin A	Transplant rejections	Depresses T cells; inhibits IL-2 production
Interferon	Immunomodulator; antiviral, hairy cell leukemia	Bone marrow suppression; granulocytopenia; leukopenia
Melphalan (L-PAM)	Alkylating agent; breast and ovarian cancer	Leukopenia; bone marrow suppression; granulocytopenia; pancytopenia
6-Mercaptopurine	Antimetabolite; acute leukemias; arthritis	Decreased T-cell function; bone marrow suppression
Methotrexate	Folic acid analog; cancer chemotherapy, arthritis	Inhibits proliferation; T-cell suppression; granulocytopenia; lymphocytopenia
Pentostatin	Adenosine analog; T-cell leukemia	Inhibits adenosine deaminase; suppresses T and B cells
Zidovudine (AZT)	Antiviral (HIV)	Decreases T_h cells and granulocytes
<i>Miscellaneous</i>		
Colchicine	Antimitotic; gout; anti-inflammatory	Inhibits migration of granulocytes; leukopenia; agranulocytosis
Diphenylhydantoin (phenytoin)	Antiepileptic	Leukocytopenia; neutropenia
Indomethacin (Indocin)	Nonsteroidal anti-inflammatory; analgesic; antipyretic	Neutropenia
Procainamide	Antiarrhythmic	Agranulocytosis; leukopenia (rare)
Sulfasalazine	Antimicrobial anti-inflammatory; ulcerative colitis/inflammatory bowel diseases	Suppresses NK cells; impaired lymphocyte function

Thioguanine and mercaptopurine are purine analogs structurally similar to guanine and hypoxanthine that have been used to treat malignancies. Azathioprine, an imidazolyl derivative of mercaptopurine, has been used as an immunosuppressive therapeutic in organ transplants and to treat severe refractory rheumatoid arthritis (Hunter et al., 1975) and auto-

immune disorders including pemphigus vulgaris and bullous pemphigoid. These drugs act as antimetabolites to block *de novo* purine synthesis through the erroneous incorporation of thioinosinic acid into the pathway in place of inosine. The antimetabolite can bind to the inosine receptor, which in turn will inhibit the synthesis of DNA, RNA, protein synthesis, and

ultimately T-cell differentiation (Hadden et al., 1984). For example, both thioguanine and mercaptopurine can act as substrates for the HGPRT enzyme to produce thioinosine monophosphate (T-IMP) and thioguanine monophosphate (T-GMP), respectively. Thioinosine monophosphate is a poor substrate for guanylyl kinase, which would normally catalyze the conversion of GMP to GDP (Calabresi and Chabner, 1990). Thus, T-IMP can accumulate in the cell and inhibit several vital metabolic reactions. At high doses, these drugs can suppress the entire immune system. However, at clinical dosages, only the T-cell response is affected, without an apparent decrease in T-cell numbers (Spreafico and Anaclerio, 1977).

Pentostatin (2'-deoxycoformycin) is an adenosine analog that is a potent inhibitor of adenosine deaminase. Pentostatin is particularly useful for treating T-cell leukemia since malignant T cells have higher levels of adenosine deaminase than most cells. Similar to individuals that are genetically deficient in adenosine deaminase, treatment with pentostatin produces immunosuppression of both T and B lymphocytes, with minimal effect on other tissues. As a result, severe opportunistic infections are often associated with its clinical use.

5-Fluorouracil (5-FU), adenosine arabinoside (AraA), and cytosine arabinoside (AraC) are pyrimidine analogs to uracil, adenine, and cytosine, respectively. 5-FU is used primarily to treat cancer of the breasts and gastrointestinal tract as well as severe recalcitrant psoriasis (Alper et al., 1985). AraC is predominantly indicated for the treatment of acute leukemia and non-Hodgkin's lymphomas. Although high-dose therapy with AraC has a good likelihood of producing complete remission, it is often accompanied by severe leukopenia, thrombocytopenia, and anemia (Barnett et al., 1985). Likewise, myelosuppression is the major toxicity associated with bolus-dose regimens of 5-FU.

13.4.1.2 Glucocorticosteroids Corticosteroids are commonly used to reduce inflammation, treat autoimmune diseases such as systemic lupus erythematosus (SLE), and as a prophylactic measure to prevent transplant rejection. The adrenocorticosteroid prednisone is often coadministered with other immunosuppressives such as cyclosporine and azathioprine (Elion and Hitchings, 1975). Glucocorticosteroids act pharmacologically by modulating the rate of protein synthesis. The molecule reacts with specific receptors to form a complex that crosses into the nucleus of the cell and regulates transcription of specific mRNA. The corticosteroid complex releases inhibition of transcription, thus enhancing protein synthesis (Hollenberg et al., 1987). This may lead to the initiation of *de novo* synthesis of the phospholipase A2-inhibiting protein, lipocortin, which blocks the synthesis of arachidonic acid and its prostaglandin and leukotriene metabolites (Wallner et al., 1986). Glucocorticosteroids induce immunosuppression and anti-inflammation as a result of the inhibition of specific leukocyte functions such as lymphokine activity. Glucocorticoids can also inhibit

recruitment of leukocytes and macrophages into the site of inflammation. In addition, amplification of cell-mediated immunity can be suppressed by inhibiting the interaction of IL-2 with its T-cell receptors. However, the immunosuppression is reversible and immune function recovers once therapy has ceased.

13.4.1.3 Cyclosporine Cyclosporin A (cyclosporine) is an 11-amino-acid cyclic peptide residue of fungal origin isolated from the fermentation products of *Trichoderma polysporum* and *Cylindrocarpon lucidum*. In addition to having a very narrow range of antibiotic activity, it was also found to inhibit proliferation of lymphocytes, which made it unsuitable as an antibiotic. Cyclosporine inhibits the early cellular response of helper T cells to antigens (Kay and Benzie, 1984) primarily by inhibiting production of IL-2 (Elliot et al., 1984), and at higher doses it may inhibit expression of IL-2 receptors (Herold et al., 1986). Cyclosporine does not prevent the stimulation of helper T-cell clonal expansion by IL-2, only its activation. Since it is not myelosuppressive at therapeutic dosages, the incidence of secondary infection is lower than that induced by other classes of immunosuppressives. Thus, cyclosporine is ideal as an immunosuppressive agent to prevent transplant rejection and graft-versus-host disease (Kahan and Bach, 1988). Cyclosporine has also been used as an antihelminthic and as an anti-inflammatory agent to treat rheumatoid arthritis and other autoimmune type diseases.

13.4.1.4 Mustards Nitrogen mustards characteristically consist of a bis(2-chloroethyl) group bonded to nitrogen. These molecules are highly reactive bifunctional alkylating agents that have been successfully used in cancer chemotherapy. Included in this group are mechlorethamine, L-phenylalanine mustard (melphalan), chlorambucil, ifosfamide, and cyclophosphamide. The cytotoxic effects of each on the bone marrow and lymphoid organs are similar; however, their pharmacokinetic and toxic profiles can vary on the basis of the substituted side group. For example, the side group may consist of a simple methyl group, as is the case of mechlorethamine, or substituted phenyl groups, in the cases of melphalan and chlorambucil.

Cyclophosphamide, which contains a cyclic phosphamide group bonded to the nitrogen mustard, is representative of this class. The parent compound itself is not active *in vitro* unless treated in conjunction with an exogenous P450 microsomal enzyme system (Colvin, 1982) such as rat liver S9 homogenate, which metabolizes it to a highly reactive alkylating agent (4-hydroxy-cyclophosphamide). Thus, *in vivo*, cyclophosphamide is not toxic until it is metabolically activated in the liver. Cyclophosphamide has been the most widely used nitrogen mustard where it has been effective as a cancer chemotherapeutic and to treat autoimmune-type diseases including SLE, multiple sclerosis, and rheumatoid arthritis (Calabresi and Parks, 1985). Treatment with cyclophosphamide suppresses

all classes of lymphoid cells, which may result in reduced lymphocyte function as well as lymphopenia and neutropenia (Webb and Winkelstein, 1982). Thus, it has also been administered as a large single dose prior to bone marrow transplants to suppress cellular immunity and subsequently inhibit rejection (Shand, 1979).

13.4.1.5 Estrogens β -Estradiol (Luster et al., 1984; Pung et al., 1984) and therapeutics with estrogenic activity, such as diethylstilbestrol (DES), have also been shown to be immunosuppressive (Luster et al., 1985). Estrogens have been shown to increase T suppressor cell activity in splenocytes, decrease numbers of T helper cells, inhibit IL-2 synthesis, and modulate production of immunoregulatory factors (Luster et al., 1987). These effects have been particularly characterized in studies with DES, a nonsteroidal synthetic estrogen used widely in the treatment of prostate and breast cancers, as well as administered to pregnant women as a "morning-after" contraceptive. Decreased mitogenicity of human peripheral blood lymphocytes has been observed in men treated with DES for prostate cancer and women exposed *in utero* (Haukaas et al., 1982; Ways et al., 1987). In mice, thymic involution, and atrophy with depletion of the cortical lymphocytes have been observed histologically. Function is also modulated, as evident by depressed mixed lymphocyte responses, mitogenicity, and T-cell release of IL-2 (Pung et al., 1985). Dean et al. (1980) speculated that DES treatment selectively depletes or functionally impairs T cells and/or the induction of suppressor macrophages, resulting in immunosuppression. Macrophage suppressor cell activity is enhanced (Luster et al., 1980) and PMN cells accumulate following bacterial challenge. Although macrophage functions of phagocytosis and tumor growth inhibition are potentiated, defects in macrophage migration and decreased bactericidal activity contribute to decreased host resistance with resulting increased susceptibility to bacterial infections.

13.4.1.6 Heavy Metals Some heavy metals such as gold and platinum are used pharmacologically as immunomodulators to treat rheumatoid arthritis and as antineoplastic drugs, respectively. Most heavy metals inhibit mitogenicity, antibody responses, and host resistance to bacterial or viral challenge and tumor growth. Platinum has been shown to suppress humoral immunity, lymphocyte proliferation, and macrophage function (Lawrence, 1985). Clinically, mild to moderate myelosuppression may also be evident with transient leukopenia and thrombocytopenia. Mercury salts can induce autoimmune reactions (Bellon et al., 1982).

Likewise, injectable gold salts such as gold sodium thiomalate affect a variety of immune responses in man (Bloom et al., 1987). Severe thrombocytopenia occurs in 1% of patients as a result of an immunological disturbance that accelerates the degradation of platelets. Leukopenia, agranu-

locytosis, and fatal aplastic anemia may also occur. Although better tolerated than parenteral preparations, the organic gold compound, auranofin, administered orally is also immunosuppressive. In a dog study, auranofin was shown to produce thrombocytopenia similar to that described in humans administered parenteral preparations (Bloom et al., 1985a). Long-term toxicity studies with these compounds in dogs show evidence of immune-modulating activity, possible drug-induced immunotoxicity, and treatment-related changes in immune function (e.g., lymphocyte activation).

13.4.1.7 Antibiotics β -Lactam-containing antibiotics such as the cephalosporins may also induce significant immunosuppressive effects (Caspritz and Hadden, 1987) in a small percentage of human patients. Adverse effects including anemia, neutropenia, thrombocytopenia, and bone marrow depression were observed in dogs administered high doses of cefonicid for 6 months (Bloom et al., 1985b). A similar syndrome has been characterized in cefazidone treated dogs expressing an agglutinating red cell antibody. Further studies with this drug indicated that both cytopenia (Bloom et al., 1985b) and suppression of bone marrow stem cell activity appear to be antibody mediated (Deldar et al., 1985).

13.5 IMMUNOSTIMULATION

A variety of drugs as well as environmental chemicals have been shown to have immunostimulatory or sensitizing effects on the immune system, and these effects are well documented in humans exposed to drugs (DeSwarte, 1986). The drug or metabolite can act as a hapten and covalently bind to a protein or other cellular constituent of the host to appear foreign and become antigenic. Haptens are low molecular weight substances that are not in themselves immunogenic but will induce an immune response if conjugated with nucleophilic groups on proteins or other macromolecular carriers. In both allergy and autoimmunity, the immune system is stimulated or sensitized by the drug conjugate to produce specific pathological responses. An allergic hypersensitivity reaction may vary from one which results in an immediate anaphylactic response to one which produces a delayed hypersensitivity reaction or immune complex reaction. Allergic hypersensitivity reactions result in a heightened sensitivity to nonself antigens, whereas autoimmunity results in an altered response to self-antigens. Unlike immunosuppression, which nonspecifically affects all individuals in a dose-related manner, both allergy and autoimmunity have a genetic component that creates susceptibility in those individuals with a genetic predisposition. Susceptible individuals, once sensitized, can respond to even minute quantities of the antigen. Several examples of drugs that can stimulate the immune system are presented in Table 13.7.

TABLE 13.7 Drugs That Produce Immunostimulation

Drug	Type of Response
<i>Hypersensitivity</i>	
Antibiotics	
Cephalosporins	Anaphylaxis, urticaria, rash, granulocytopenia
Chloramphenicol	Rash, dermatitis, urticarial
Neomycin	Dermal exposure—rash, dermatitis
Sulfathiazole	Rash, dermatitis, urticarial
Spiramycin	Rash, dermatitis, urticarial
Quinolones	Photosensitivity
Tetracyclines	Photosensitivity, anaphylaxis, asthma, dermatitis
Others	
Allopurinol	Rash, urticaria, fever, eosinophilia
Avridine	Delayed-type hypersensitivity; increases NK cells, T cells, IL-1, and IL-2
Isoprinosine	Delayed-type hypersensitivity; increases T-lymphocytes
Indomethacin	Rash, urticaria, asthma, granulocytopenia
Quinidine	Fever, anaphylaxis, asthma
Salicylates	Rash, urticarial
<i>Autoimmunity</i>	
Amiodarone	Thyroiditis
Captopril	Autoimmune hemolytic anemia, pemphigus, granulocytopenia
Chlorpromazine	Granulocytopenia
Halothane	Autoimmune chronic active hepatitis
Hydralazine	Autoimmune hemolytic anemia, drug induced SLE, myasthenia gravis, pemphigus, glomerulonephritis, Goodpasture's disease
Methyldopa	Autoimmune hemolytic anemia, leukopenia, drug-induced SLE, pemphigus
Nitrofurantoin	Peripheral neuritis
d-penicillamine	Autoimmunity; drug induced SLE, myasthenia gravis, pemphigus, glomerulonephritis, Goodpasture's disease
Propranolol	Autoimmunity
Procainamide	Autoimmunity, drug-induced SLE, rash, vasculitis, myalgias
Pyriethoxine	Pemphigus
<i>Hypersensitivity and Autoimmunity</i>	
Antibiotics	
Isoniazid	Rash, dermatitis, vasculitis, arthritis, drug-induced SLE
Penicillins	Anaphylaxis, dermatitis; vasculitis, serum sickness, hemolytic anemia
Sulfonamides	Dermatitis, photosensitivity; pemphigus, hemolytic anemia, serum sickness, drug-induced SLE
Others	
Acetazolamide	Rash, fever, autoimmunity
Lithium	Dermatitis; autoimmune thyroiditis, vasculitis
Thiazides	Hypersensitivity, photosensitivity; autoimmunity (diabetes)
Phenytoin	Rash; drug-induced SLE, hepatitis

13.5.1 Hypersensitivity (or Allergenicity)

The four types of hypersensitivity reactions as classified by Coombs and Gell (1975) are outlined in Table 13.8. The first three types are immediate antibody-mediated reactions, whereas the fourth type is a cellular-mediated delayed-type response that may require 1–2 days to occur after a secondary exposure. Type I reactions are characterized by an anaphylaxis response to a variety of compounds, including proteinaceous materials and pharmaceuticals such as penicillin. Various target organs may be involved depending on the route of exposure. For example, the gastrointestinal tract is usually involved with food allergies, the respiratory system with inhaled allergens, the skin with dermal exposure, and smooth muscle vasculature with systemic exposure. The type of response elicited often depends on the site of exposure and includes dermatitis and urticaria (dermal), rhinitis and asthma (inhalation), increased gastrointestinal emptying (ingestion), and systemic anaphylactic shock (parenteral).

13.5.1.1 Type I Hypersensitivity During an initial exposure, IgE antibodies are produced and bind to the cell surface of mast cells and basophils. Upon subsequent exposures to the antigen, reaginic IgE antibodies bound to the surface of target cells at the F_c region (mast cells and basophils) become cross-linked (at the F_{ab} regions) by the antigen. Cross-linking causes distortion of the cell surface and IgE molecule, which, in turn, activates a series of enzymatic reactions, ultimately leading to degranulation of the mast cells and basophils. These granules contain a variety of pharmacological substances (Table 13.9), such as histamines, serotonin, prostaglandins, bradykinins, and leukotrienes (SRS-A and ECR-A). Upon subsequent challenge exposures, these factors are responsible for eliciting an allergic reaction through vasodilation and increased vascular permeability. The nasal passages contain both mast cells and plasma cells that secrete IgE antibodies. Allergic responses localized in the nasal mucosa result in dilation of the local blood vessels, tissue swelling, mucus secretion, and sneezing. Reactions localized in the respiratory tract, also rich in mast cells and IgE, result in an allergic asthma response. This condition is triggered by the release of histamine and SRS-A, which induce constriction of the bronchi and alveoli, pulmonary edema, and mucous secretions that block the bronchi and alveoli, together resulting in severe difficulty in breathing. In the case of a challenge dose of a drug administered systemically, the reactive patient may have difficulty breathing within minutes of exposure and may experience convulsions, vomiting, and low blood pressure. The effects of anaphylactic shock and respiratory distress, if severe, may ultimately result in death. The best models for this use guinea pigs (Mazzone and Canning, 2002).

TABLE 13.8 Types of Hypersensitivity Responses

Type and Designation	Agents: Clinical Manifestations	Components	Effects	Mechanism
I, Immediate (reaginic)	Food additives (GI allergies; anaphylactic)	Mast cells; IgE	Anaphylaxis, asthma, urticaria, rhinitis, dermatitis	IgE binds to mast cells to stimulate release of humoral factors
II, Cytotoxic	Penicillin: urticaria and dermatitis Cephalosporin: hemolytic anemia	IgG, IgM	Hemolytic anemia, Goodpasture's disease	IgG and IgM bind to cells (e.g., RBCs), fix complement (opsonization), then lyse cells
III, Immune complex (Arthus)	Quinidine: thrombocytopenia Methicillin: chronic glomerulonephritis	Antigen-antibody complexes (Ag-Ab)	SLE, rheumatoid arthritis, glomerular nephritis, serum sickness, vasculitis	Ag-Ab complexes deposit in tissues, and may fix complement
IV, Delayed hypersensitivity	Penicillin: contact dermatitis	T _D cells; macrophages	Contact dermatitis, tuberculosis	Sensitized T cells induce a delayed-hypersensitivity response upon challenge

TABLE 13.9 Proteins and Soluble Mediators Involved in Hypersensitivity

Factor	Origin	Characteristics/Functions
Histamine	Mast cells, basophils	Contraction of smooth muscle; increases vascular permeability
Serotonin	Mast cells, basophils	Contraction of smooth muscle; leukotriene
SRS-A	Lung tissue	(Slow-reacting substance of anaphylaxis); contraction of smooth muscle; acidic polypeptide
ECF-A	Mast cells	(Eosinophilic chemotactic factor of anaphylaxis); attracts eosinophils; small peptide
Prostaglandins	Various tissues	Modifies release of histamine and serotonin from mast cells and basophils

Source: Adapted from Clark (1983, pp. 1-453).

Antibiotics containing β-lactam structures, such as penicillin and cephalosporins, are the most commonly occurring inducers of anaphylactic shock and drug hypersensitivity in general. Other hypersensitivity reactions may include urticarial rash, fever, bronchospasm, serum sickness, and vasculitis with reported incidences of all types varying from 0.7 to 10% (Idsøe et al., 1968) and the incidence of anaphylactoid reactions varying from 0.04 to 0.2%. When the β-lactam ring is opened during metabolism, the penicilloyl moiety can form covalent conjugates with nucleophilic sites on proteins. The penicilloyl conjugates can then act as haptens to form the determinants for antibody induction. Although most patients that have received penicillin produce antibodies against the metabolite benzylpenicilloyl, only a fraction experience

allergic reaction (Garratty and Petz, 1975), which suggests a genetic component to susceptibility.

13.5.1.2 Type II Hypersensitivity Type II cytolytic reactions are mediated by IgG and IgM antibodies that can fix complement, opsonize particles, or induce antibody-dependent cellular cytotoxicity reactions. Erythrocytes, lymphocytes, and platelets of the circulatory system are the major target cells that interact with the cytolytic antibodies causing depletion of these cells. Hemolytic anemia (penicillin, methyl dopa), leukopenia, thrombocytopenia (quinidine), and/or granulocytopenia (sulfonamide) may result. Type II reactions involving the lungs and kidneys occur through the development of antibodies (autoantibodies) to the basement membranes in the alveoli or glomeruli, respectively. Prolonged damage may result in Goodpasture's disease, an autoimmune disease characterized by pulmonary hemorrhage and glomerulonephritis. Several other autoimmune-type diseases have been associated with extended treatments with D- penicillamine and other pharmaceuticals. Various types of autoimmune responses and examples of drug-induced autoimmunity are discussed in further detail later in this section.

13.5.1.3 Type III Hypersensitivity Type III reactions (Arthus) are characterized as an immediate hypersensitivity reaction initiated by antigen-antibody complexes that form freely in the plasma instead of at the cell surface. Regardless of whether the antigens are self or foreign, complexes mediated by IgG can form and settle into the tissue compartments of the host. These complexes can then fix complement and release C3a and C5a fragments that are chemotactic for phagocytic cells. Polymorphonuclear leukocytes are then attracted to the site, where they phagocytize the complexes and release hydrolytic enzymes into the tissues. Additional

damage can be caused by binding to and activating platelets and basophils, which, in the end, results in localized necrosis, hemorrhage, and increased permeability of local blood vessels. These reactions commonly target the kidney, resulting in glomerulonephritis through the deposition of the complexes in the glomeruli.

Some antibiotics (β -lactam) have been reported to produce glomerular nephritis in humans that has been attributed to circulating immune complexes. These complexes have also been observed in preclinical toxicology studies with baboons treated with a β -lactam antibiotic, prior to the appearance of any biochemical or clinical changes (Descotes and Mazue, 1987). In addition, immunoglobulin complexes have been observed in rats treated with gold and autologous immune complex nephritis has been observed in guinea pigs (Ueda et al., 1980). Similar evidence of immunomediated nephrotoxicity has been reported in rheumatoid arthritis patients administered long-term treatments with gold compounds; proteinuria has been observed in approximately 10% of these patients.

Other target organs such as the skin with lupus, the joints with rheumatoid arthritis, and the lungs with pneumonitis may be affected. The deposition of antigen–antibody complexes through the circulatory system results in a syndrome referred to as serum sickness, which was quite prevalent prior to 1940 (Clark, 1983), when serum therapy for diphtheria was commonly used. Serum sickness occurs when the serum itself becomes antigenic as a side effect from passive immunization with heterologous antiserum produced from various sources of farm animals. The antitoxin for diphtheria was produced in a horse and administered to humans as multiple injections of passive antibody. As a consequence, these people often became sensitized to the horse serum and developed a severe form of arthritis and glomerulonephritis caused by deposition of antigen–antibody complexes. Clinical symptoms of serum sickness present as urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. Drugs such as sulfonamides, penicillin, and iodides can induce a similar type of reaction. Although uncommon today, transplant patients receiving immunosuppressive therapy with heterologous anti-lymphocyte serum or globulins may also exhibit serum sickness.

13.5.1.4 Type IV Delayed-Type Hypersensitivity (DTH)

Delayed-type hypersensitivity (DTH) reactions are T-cell mediated with no involvement of antibodies. However, these reactions are controlled through accessory cells, suppressor T cells, and monokine-secreting macrophages, which regulate the proliferation and differentiation of T cells. The most frequent form of DTH manifests itself as contact dermatitis. The drug or metabolite binds to a protein in the skin or the Langerhans cell membrane (class II MHC molecules) where it is recognized as an antigen and triggers cell proliferation. After a sufficient period of time for migration of the antigen and clonal expansion (latency period), a subsequent exposure

will elicit a dermatitis reaction. A 24–48 h delay often occurs between the time of exposure and onset of symptoms to allow time for infiltration of lymphocytes to the site of exposure. The T cells ($CD4^+$) that react with the antigen are activated and release lymphokines that are chemotactic for monocytes and macrophages. Although these cells infiltrate to the site via the circulatory vessels, an intact lymphatic drainage system from the site is necessary since the reaction is initiated in drainage lymph nodes proximal to the site (Clark, 1983). The release (degranulation) of enzymes and histamines from the macrophages may then result in tissue damage. Clinical symptoms of local dermal reactions may include a rash (not limited to sites of exposure), itching, and/or burning sensations. Erythema is generally observed in the area around the site, which may become thickened and hard to the touch. In severe cases, necrosis may appear in the center of the site followed by desquamation during the healing process. The immune-enhancing drugs isoprinosine and avidine have been shown to induce a DTH reaction in rats (Exon et al., 1986).

A second form of DTH response is similar to that of contact dermatitis in that macrophages are the primary effector cells responsible for stimulating $CD4^+$ T cells; however, this response is not necessarily localized to the epidermis. A classic example of this type of response is demonstrated by the tuberculin diagnostic tests. To determine if an individual has been exposed to tuberculosis, a small amount of fluid from tubercle bacilli cultures is injected subcutaneously. The development of induration after 48 h at the site of injection is diagnostic of prior exposure.

Shock, similar to that of anaphylaxis, may occur as a third form of a delayed systemic hypersensitivity response. However, unlike anaphylaxis, IgE antibodies are not involved. This type of response may occur 5–8 h after systemic exposure and can result in fatality within 24 h following intravenous or intraperitoneal injection.

A fourth form of delayed hypersensitivity results in the formation of granulomas. If the antigen is allowed to persist unchecked, macrophages and fibroblasts are recruited to the site to proliferate, produce collagen, and effectively “wall off” the antigen. A granuloma requires a minimum of 1–2 weeks to form.

13.5.2 Photosensitization

Regardless of the route of exposure, some haptens (photoantigens) that are absorbed locally into the skin, or reach the skin through systemic absorption, can be photoactivated by ultraviolet (UV) light between 320 and 400 nm. Once activated, the hapten can bind to the dermal receptors to initiate sensitization (photoallergy). Subsequent exposures to the hapten in the presence of UV light can result in a hypersensitivity response. Clinical symptoms of photoallergy may occur within minutes (immediate hypersensitivity) of

exposure to sunlight, or 24 h or more after exposure (DTH). Symptoms may range from acute urticarial reactions to eczematous or papular lesions. Although both phototoxic and photoallergic reactions require the compound to be exposed to sunlight in order to elicit a response, their mechanisms of action are quite different. Since photosensitization is an immune-mediated condition, repeated exposures with a latency period between the initial exposure and subsequent exposures is required, the response is not dose related (small amounts can produce a response once sensitized), and not all individuals exposed to the compound will necessarily respond (genetic component to susceptibility). Although both conditions can present similar symptoms (erythema), phototoxicity is limited mainly to erythema, whereas photoallergy can result in erythema, edema, and dermatitis as described previously.

Several drug classes, including tetracycline, sulfonamide, and quinolone antibiotics, as well as chlorothiazide, chlorpromazine, and amiodarone hydrochloride, have been shown to be photoantigens. Photosensitivity may persist even after withdrawal of the drug, as has been observed with the antiarrhythmic drug amiodarone hydrochloride, since it is lipophilic and can be stored for extended periods in the body fat (Unkovic et al., 1984). In addition, it is quite common for cross-reactions to occur between structurally related drugs of the same class.

13.5.3 Autoimmunity

In autoimmunity, as with hypersensitivity, the immune system is stimulated by specific responses that are pathogenic, and both tend to have a genetic component that predisposes some individuals more than others. However, as is the case with hypersensitivity, the adverse immune response of drug-induced autoimmunity is not restricted to the drug itself but also involves a response to self-antigens.

Autoimmune responses directed against normal components of the body may consist of antibody-driven humoral responses and/or cell-mediated, DTH responses. T cells can react directly against specific target organs, or B cells can secrete autoantibodies that target “self.” Autoimmunity may occur spontaneously as the result of a loss of regulatory controls that initiate or suppress normal immunity causing the immune system to produce lymphocytes reactive against its own cells and macromolecules such as DNA, RNA, or erythrocytes.

Although autoantibodies are often associated with autoimmune reactions, they are not necessarily indicative of autoimmunity (Russel, 1981). Antinuclear antibodies can occur normally with aging in some healthy women without autoimmune disease, and all individuals have B cells with the potential of reacting with self-antigens through Ig receptors (Dighiero et al., 1983). The presence of an antibody titer to a particular immunogen indicates that haptization of serum albumin has occurred as part of a normal immune response.

However, if cells are stimulated to proliferate and secrete autoantibodies directed against a specific cell or cellular component, a pathological response may result. The tissue damage associated with autoimmune disease is usually a consequence of type II or III hypersensitivity reactions that result in the deposition of antibody–antigen complexes.

Several diseases have been associated with the production of autoantibodies against various tissues. For example, an autoimmune form of hemolytic anemia can occur if the antibodies are directed against erythrocytes. Similarly, antibodies that react with acetylcholine receptors may cause myasthenia gravis, those directed against glomerular basement membranes may cause Goodpasture’s syndrome, and those that target the liver may cause hepatitis. Other forms of organ-specific autoimmunity include autoimmune thyroiditis (as seen with amiodarone) and juvenile diabetes mellitus, which can result from autoantibodies directed against the tissue-specific antigens thyroglobulin and cytoplasmic components of pancreatic islet cells, respectively.

In contrast, systemic autoimmune diseases may occur if the autoantibodies are directed against an antigen that is ubiquitous throughout the body, such as DNA or RNA. For example, SLE occurs as the result of autoimmunity to nuclear antigens that form immune complexes in the walls of blood vessels and basement membranes of tissues throughout the body.

The etiology of drug-induced autoimmunity is not well established and is confounded by factors such as age, sex, and nutritional state, as well as genetic influences on pharmacological and immune susceptibility. Unlike idiopathic autoimmunity, which is progressive or characterized by an alternating series of relapses and remissions, drug-induced autoimmunity is thought to subside after the drug is discontinued. However, this is not certain since a major determining factor for diagnosis of a drug-related disorder is dependent on the observation of remission upon withdrawal of the drug (Bigazzi, 1988).

One possible mechanism for xenobiotic-induced autoimmunity involves xenobiotic binding to autologous molecules, which then appear foreign to the immunosurveillance system. If a self-antigen is chemically altered, a specific T helper (T_h) cell may see it as foreign and react to the altered antigenic determinant portion, allowing an autoreactive B cell to react to the unaltered hapten. This interaction results in a carrier–hapten bridge between the specific T_h and autoreactive B cell, bringing them together for subsequent production of autoantibodies specific to the self-antigen that was chemically altered (Weigle, 1980). Conversely, a xenobiotic may alter B cells directly, including those that are autoreactive. Thus, the altered B cells may react to self-antigens independent from T_h -cell recognition and in a nontissue-specific manner.

Another possible mechanism is that the xenobiotic may stimulate nonspecific mitogenicity of B cells. This could result in a polyclonal activation of B cells with subsequent production of autoantibodies. Alternatively, the xenobiotic may stimulate mitogenicity of T cells that recognize self,

which in turn activate B-cell production of antibodies in response to “self” molecules. There is also evidence to suggest that anti-DNA autoantibodies may originate from somatic mutations in lymphocyte precursors with antibacterial or antiviral specificity. For example, a single amino acid substitution resulting from a mutation in a monoclonal antibody to phosphorylcholine was shown to result in a loss of the original specificity and an acquisition of DNA reactivity similar to that observed for anti-DNA antibodies in SLE (Talal, 1987).

The mechanisms of autoimmunity may also entail interaction with MHC structures determined by the HLA alleles. Individuals carrying certain HLA alleles have been shown to be predisposed to certain autoimmune diseases, which may account in part for the genetic variability of autoimmunity. In addition, metabolites of a particular drug may vary between individuals to confound the development of drug-induced autoimmunity. Dendritic cells, such as the Langerhans cells of the skin and B lymphocytes that function to present antigens to T_h cells, express class II MHC structures. Although the exact involvement of these MHC structures is unknown, Gleichmann et al. (1989) have theorized that self-antigens rendered foreign by drugs such as D-penicillamine may be presented to T_h cells by MHC class II structures. An alternate hypothesis is that the drug or a metabolite may alter MHC class II structures on B cells, making them appear foreign to T_h cells.

A number of different drugs have been shown to induce autoimmunity in susceptible individuals. A syndrome similar to that of SLE was described in a patient administered sulfadiazine in 1945 by Hoffman (see Bigazzi, 1988). Sulfonamides were one of the first classes of drugs identified to induce an autoimmune response, while to date, over 40 other drugs have been associated with a similar syndrome.

Autoantibodies to red blood cells and autoimmune hemolytic anemia have been observed in patients treated with numerous drugs, including procainamide, chlorpropamide, captopril, cefalexin, penicillin, and methyldopa (Logue et al., 1970; Kleinman et al., 1984). Hydralazine and procainamide-induced autoantibodies may also result in SLE. Approximately 20% of patients administered methyldopa for several weeks for the treatment of essential hypertension developed a dose-related titer and incidence of autoantibodies to erythrocytes, 1% of which presented with hemolytic anemia. Methyldopa does not appear to act as a hapten but appears to act by modifying erythrocyte surface antigens. IgG autoantibodies then develop against the modified erythrocytes.

D-penicillamine is used to treat patients with rheumatoid arthritis, to reduce excess cystine excretion in patients with cystinurias, and as a chelating agent for copper in patients with Wilson's disease. D-penicillamine can cause multiple forms of autoimmunity including SLE, myasthenia gravis, pemphigus, and autoimmune thyroiditis. This drug is thought to act as immunomodulator in patients by initiating or even potentiating anti-DNA antibody synthesis (Mach et al., 1986).

The highly reactive thiol group may react with various receptors and biological macromolecules to induce autoantibodies. Long-term (many months) treatment has been shown to induce autoimmunity resulting in myasthenia gravis in 0.5% of patients (Bigazzi, 1988) and SLE in approximately 2% of patients as exhibited by varying degrees of joint pain, synovitis, myalgia, malaise, rash, nephritis, pleurisy, and neurological effects. In patients exhibiting myasthenia gravis, D-penicillamine may act to alter the acetylcholine receptors. Autoantibodies to acetylcholine receptors have been detected in these patients and have been shown to decrease gradually after drug withdrawal concomitant with reversibility of the clinical syndrome.

However, myasthenia gravis may persist for long periods of time after D-penicillamine therapy has ceased.

Although rare, cases of renal lupus syndrome and pemphigus blisters have also been reported as a consequence of D-penicillamine-induced immune complexes (Ntoso et al., 1986; Bigazzi, 1988), as well as with other drugs. With renal lupus syndrome, secondary glomerulonephritis may result if granular IgG antibodies are produced and deposited on the basement membranes. In patients with pemphigus blisters, autoantibodies to the intercellular substance of the skin have been recovered from the sera, and dermal biopsies have demonstrated intracellular deposits or immunoglobulin deposits on the basement membranes. Pemphigus has also been observed in patients treated with sulfhydryl compounds such as captopril and pyrithioxine (Bigazzi, 1988).

Some metals that are used therapeutically have also been shown to induce autoimmune responses. Gold salts used to treat arthritis may induce formation of antiglomerular basement membrane antibodies, which may lead to glomerulonephritis similar to that seen in Goodpasture's disease (see type II hypersensitivity). Since gold is not observed at the site of the lesions (Druet et al., 1982), it has been hypothesized that the metal elicits an antiself response. Lithium, used to treat manic depression, is thought to induce autoantibodies against thyroglobulin, which in some patients results in hypothyroidism. In studies with rats, levels of antibodies to thyroglobulin were shown to increase significantly in lithium-treated rats compared to controls immediately after immunization with thyroglobulin; however, rats that were not immunized with thyroglobulin did not produce circulation antithyroglobulin antibodies upon receiving lithium, and there was no effect of lithium on lymphocytic infiltration of the thyroid in either group (Hassman et al., 1985).

Some drugs such as penicillin have been shown to induce autoimmunity as well as anaphylaxis (Gleichmann et al., 1989). The carbonyl of the β -lactam ring of penicillin can form a covalent penicilloyl conjugate with nucleophilic sites on proteins, particularly the amino groups of lysine residues. This conjugate, which acts as the major immunogenic determinant, may become biotransformed to other isomeric forms of clinical relevance (Batchelor et al., 1965).

A genetic predisposition to drug-induced development of SLE has been shown to occur in some individuals treated with the drugs hydralazine, isoniazid, procainamide, and sulfamethazine. A polymorphism, which is known to exist for the genes responsible for expression of hepatic *N*-acetyltransferase enzymes, determines the rate of acetylation of these drugs to regulate the rate of drug inactivation. Individuals that are relatively slow acetylators of these drugs are more likely to develop antinuclear antibodies and are at a higher risk for developing SLE (Perry et al., 1970). Other predisposing factors, such as HLA phenotype (HLA-DR4 and/or C4 allele), may also play a genetic role in determining susceptibility to hydralazine-induced SLE (Spears and Batchelor, 1987).

In addition, silicone-containing medical devices, particularly breast prostheses, have been reported to cause serum sickness-like reactions, scleroderma-like lesions, and an SLE-like disease termed human adjuvant disease (Guillaume et al., 1984; Kumagai et al., 1984). Some patients may also present with granulomas and autoantibodies. Human adjuvant disease is a connective tissue or autoimmune disease similar to that of adjuvant arthritis in rats and rheumatoid arthritis in humans. Autoimmune disease-like symptoms usually develop 2–5 years after implantation in a small percentage of people that receive implants, which may indicate that there is a genetic predisposition similar to that for SLE. An early hypothesis is that the prosthesis or injected silicone plays an adjuvant role by enhancing the immune response through increased macrophage and T-cell helper function. There is currently controversy as to whether silicone, as a foreign body, induces a nonspecific inflammation reaction, a specific cell-mediated immunological reaction, or no reaction at all. However, there is strong support to indicate that silicone microparticles can act as haptens to produce a delayed hypersensitivity reaction in a genetically susceptible population of people. It should be noted that there are currently no known drug-induced type I autoimmunities.

13.6 REGULATORY POSITIONS

The pharmaceutical and medical device industries are increasingly concerned with whether preclinical testing of their products should include routine immunotoxicologic screening or be done on an “as-needed basis,” triggered by the toxicological profile of the xenobiotic established in routine preclinical safety testing (Bloom et al., 1987). The FDA has released a guideline for immunotoxicity testing of pharmaceuticals (CDER, 2006). Recent drug development efforts in the areas of biotechnology, prostaglandins, interleukins, and recombinant biological modifiers have elicited the expectation that the development of antibodies (neutralizing and otherwise) should be evaluated in at least one of the animal models used to assess general systemic toxicity. And

more to the point, draft guidelines have been released for devices (Center for Devices and Radiological Health (CDRH), 1999). The other available guidances have been the draft guidelines in the revision of the “Redbook” (FDA, 1993) and the EMEA (2012). The ICH S8 guidance (2006) supersedes all of them (for pharmaceuticals) (Pattels and Taylor, 2008). Table 13.10 presents a summary comparison of different regulatory requirements for drugs.

The FDA had drafted a similar two-leveled approach (Hinton, 1992) for assessing immunotoxicity of food colors, additives, and drugs, and these are reflected in the S8 guidance. In all of these testing schemes, the initial tier generally includes a fundamental standard toxicity assessment with emphasis on histopathology of the major components of the immune system (Snyder, 2012). Additional tiers are then added to more precisely evaluate the functionality of the components that appeared to be adversely affected in the first tier of tests. These test strategies are primarily geared toward the detection of small molecule pharmaceutical-induced immunosuppression; thus, the effectiveness of these test schemes for detecting immunostimulation has still not been determined (Spreafico, 1988). Table 13.11 presents items that should be considered in such an initial evaluation and Table 13.12 presents guidance as to evaluating findings in clinical pathology parameters.

The FDA, ICH, and EMEA guidelines are not currently entirely aligned. The ultimate immune test would be to examine the effects of xenobiotics on the intact animal’s response to challenge by viral, bacterial, or parasitic pathogens or neoplastic cells. The ability of the immune system to compensate or, conversely, its inability to compensate for loss or inhibition of its components is fully examined through host-resistance mechanisms. This tiered test approach has been validated with 50 selected compounds, and results from these studies have shown that the use of only two or three immune tests is sufficient to predict known immunotoxic compounds in rodents with a greater than 90% concordance (Luster et al., 1992a, b). Specifically, the use of either a humoral response assay for plaque-forming colonies (PFC response) or determination of surface marker expression in combination with almost any other parameter significantly increased the ability to predict immunotoxicity when compared to the predictivity of any assay alone.

The FDA guidelines for immunotoxicity testing of food additives start with a type I battery of tests. Type I tests can be derived from the routine measurements and examinations performed in short-term and subchronic rodent toxicity studies, since they do not require any perturbation of the test animals (immunization or challenge with infectious agents). These measurements include hematology and serum chemistry profiles, routine histopathologic examinations of immune-associated organs and tissues, and organ and body weight measurements including thymus and spleen. If a compound

TABLE 13.10 Comparison of Current ICH and Former European Union (EU) and US Immunotoxicity

	ICH S8 (in Operation in All ICH Regions Since 2006)	U.S. FDA CDER (Still in Operation Since 2002)	EU CPMP (Still in Operation Since 2000)
Specific immunotoxicity guideline	Yes	Yes	No, included in guidance on repeat-dose toxicity
Drug-induced hypersensitivity, immunogenicity, and autoimmunity excluded	Yes	No, these categories are included in the guideline	Yes. (Note: Skin sensitizing potential addressed in CPMP Note for Guidance on Non-Clinical Local Tolerance Testing, 2001)
Screening study(ies) required	Yes, the initial screen for potential immunotoxicity involves standard toxicity studies (STSs) from short-term to chronic repeat-dose studies in rodents and nonrodents	Yes, including all standard repeat dose toxicology studies that have been performed	Yes, screening required for all new active substances in at least one repeat-dose toxicity study (duration ideally should be 28 days). Rats or mice are species of choice
Screening study(ies) immunotoxicity parameters	Changes in hematology, lymphoid organ weights, histopathology of immune system, and serum globulins and increased incidences of infections and tumors should be evaluated for signs of immunotoxic potential in the STSs	Changes in hematology lymphoid organ weights, gross pathology and histopathology of immune system, and serum globulins and increased incident of infections and tumors should be evaluated for signs of immunotoxic potential	Hematology, lymphoid organ weights, histopathology of lymphoid tissues, bone marrow, cellularity, distribution of lymphocyte subsets, and NK-cell activity (if latter two unavailable, primary antibody response to T-cell-dependent antigen)
Other factors to consider in evaluation of potential immunotoxicity and the need for additional immunotoxicity studies	Pharmacological properties of drug; patient population; structural similarities to known immunomodulators; drug disposition; clinical data	Patient population; known drug class effects (including SARs); drug pharmacokinetics; clinical data. If drug intended for HIV, immune function studies required	None specifically included in the guideline
“Follow-on”/“Additional” immunotoxicity studies	“Additional” studies may be required depending on the “weight of evidence review” of STSs and “other factors.” “Additional” studies addressed in 3.2, 3.3, and Appendix of guideline	Not specified	Not specified

produces any primary indicators of immunotoxicity from these measurements, more definitive immunotoxicity tests, such as those indicated in the preceding paragraph, may be recommended on a case-by-case basis.

The following is a brief explanation of some of the indicators that may be used to trigger additional definitive testing and a description of some of the most commonly used assays to assess humoral, cell-mediated, or nonspecific immune dysfunction, which are common to most immunotoxicology test strategies.

13.6.1 CDER Guidance for Investigational New Drugs

CDER’s 2001 promulgated draft guidance for pre-INDA immunotoxicity clearly established the framework for FDA’s approach, which was finalized under ICH S8 (2006). It begins by characterizing five adverse event categories:

1. Immunosuppression
2. Antigenicity
3. Hypersensitivity
4. Autoimmunity
5. Adverse immunostimulation

Specific tests are proposed for each of these categories. It notes that immune system effects in nonclinical toxicology studies are often attributed and written off as due to stress (Aden and Cohen, 1993). Such effects are frequently reversible with repeat dosing and tend not to be dose related. It is also proposed that when possible dose extrapolations to those in clinical use be based on relative body area. Specific recommendations are made for when to conduct specific testing (as opposed to the broader general evaluations integrated into existing repeat-dose testing) (Figure 13.2) and for follow-up studies for exploring mechanisms (Figure 13.3).

TABLE 13.11 Typical Indicators of Immunotoxicity, Which May Be Observed during Regulatory Repeat-Dose Toxicity Studies

Findings	Possible Indicator of
<i>During the in-life phase</i>	
Increased frequencies of infectious disease	Immunosuppression
Increased frequencies of tumors in long-term studies in the absence of genotoxicity or nongenotoxic indicators of tumorigenicity (e.g., endocrine)	Immunosuppression
Unexpected pathological symptoms or deaths shortly after administration	Hypersensitivity
Strong inflammatory reactions at the site of administration	Hypersensitivity
<i>Gross necropsy</i>	
Significant increase or decrease of size and weight of lymphatic organs	Unintended immunostimulation or immunosuppression
<i>Hematology</i>	
Changes in total or differential blood counts	Unintended immunostimulation or immunosuppression
Anemia	Type II hypersensitivity
Altered frequencies of lymphocyte subsets (flow cytometry) ^a	Unintended immunostimulation or immunosuppression
<i>Clinical chemistry</i>	
Altered total globulin levels or albumin/globulin ratio	Unintended immunostimulation or immunosuppression
Changes of immunoglobulin isotype levels ^a	Unintended immunostimulation or immunosuppression
Reduction of hemolytic complement activity ^a	Unintended immunostimulation type III hypersensitivity
Antinuclear or anticytoplasmic antibodies ^a	Unintended immunostimulation or autoimmunity
<i>Histopathology</i>	
Changes of cellularity and/or microanatomy of lymphatic organs	Unintended immunostimulation or immunosuppression
Vasculitis, glomerulonephritis	Type III hypersensitivity

^a This parameter is normally not measured during standard toxicity studies but may be integrated when a focus is drawn on immunotoxicity assessment.

TABLE 13.12 Evaluation of Clinical Pathology

Observation	Possible Considerations Clinical chemistry
Hyperglobulinemia	Inflammation Infection Certain lymphoid tumors
Hypoalbuminemia	Immune-mediated glomerulonephritis (when present with hypercholesterolemia)
Hypercholesterolemia	Immune-mediated glomerulonephritis (when present with hypoalbuminemia)
Pancytopenia	Hematology Direct toxicity to bone marrow architecture or stem cells Antimitotic effect Effects on differentiation and/or maturation
Monocytes	Immune-mediated (antibody- or cell-mediated) destruction of stem cells
Morphology	Activated appearance (vacuolated, “fluffy”) Infection/sepsis (intracellular microorganisms)
Monocytosis	Stress (dogs and primates) Necrosis (immune-mediated or nonimmune) Inflammation (immune-related or nonimmune) Immune-mediated hemolytic anemia or thrombocytopenia Altered production or turnover
<i>Lymphocytes</i>	
Lymphopenia	Stress Direct toxicity (peripheral or bone marrow) Antiproliferative effect or signal Immunosuppression Infection/acute inflammation
Lymphocytosis	Excitability/fear (fight or flight syndrome) Immunostimulation Lymphoid neoplasia Chronic inflammation

(Continued)

TABLE 13.12 (Continued)

Observation	Possible Considerations Clinical chemistry
<i>Neutrophils</i>	
Morphology	Bone marrow (asynchronous maturation) Infection/sepsis (intracellular microorganisms) Trafficking/prolonged presence in circulation (hypersegmentation) Inflammation (toxic change—vacuolation, basophilic stippling, Dohle bodies)
Neutropenia	Direct bone marrow suppression (including cytokine alterations) Tissue demand exceeds production capacity (inflammation, infection) Increased margination/trafficking to tissues Immune-mediated destruction Inhibition of release from bone marrow
Neutrophilia	Adrenaline-induced (excitation; fear) Corticosteroid-induced (stress) Inflammation (immune-relation or nonimmune) Immune-mediated hemolytic anemia or thrombocytopenia Effects on trafficking (defect in adhesion molecules/tissue migration)
<i>Eosinophils</i>	
Eosinophilia	Hypersensitivity Fungal infection, parasitemia Tumors (e.g., mast cell, basophilic or eosinophilic)
Eosinopenia	Stress General bone marrow suppression Suppression/alteration of differentiation Excitation/fear Acute infection/inflammation
<i>Basophils</i>	
Basophilia	Persistent lipemia Parasitemia Allergy
<i>Erythrocytes</i>

13.7 EVALUATION OF THE IMMUNE SYSTEM

The ICH/FDA CDER guidelines for immunotoxicity testing of small molecule pharmaceuticals (ICH S8) start with evaluation of parameters evaluated in repeat-dose (typically 28 days) systemic toxicity studies. These tests can generally be derived from the routine measurements and examinations performed in short-term and subchronic rodent and nonrodent toxicity studies, since they do not

require any perturbation of the test animals (immunization or challenge with infectious agents). These measurements include hematology and serum chemistry profiles, routine histopathologic examinations of immune-associated organs and tissues, and organ and body weight measurements including thymus and spleen. If a compound produces any primary indicators of immunotoxicity from these measurements, more definitive immunotoxicity tests, such as those indicated in the preceding paragraph, may be recommended

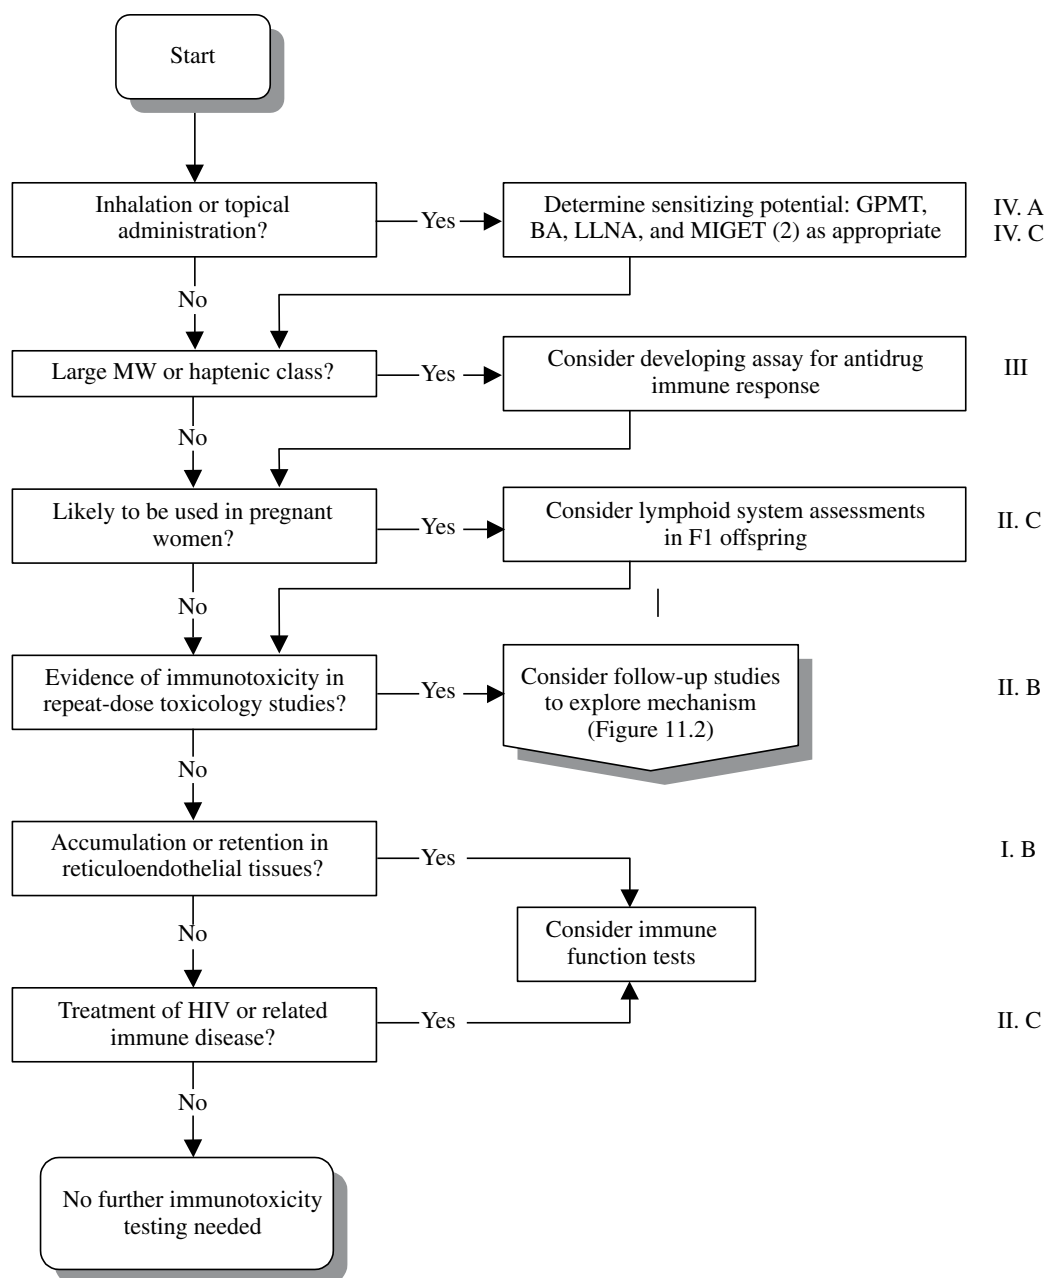

FIGURE 13.2 CDER flowchart for determining when to conduct specific immunotoxicity testing. Annotations in right margin indicate location of text describing specific advice. GPMT, guinea pig maximization test; BA, Buehler assay (Buehler patch test); LLNA, local lymph node assay; MIGET; mouse IgE test. (There is only a relatively small database available for assessing the usefulness of the MIGET for drug regulatory purposes.)

on a case-by-case basis. While detection of up-modulated immune responses is believed to be effective in current nonclinical testing approaches, detection of immunosuppressive responses (leading to greater susceptibility to infection) is not felt to be as well served (Germolec, 2004). This has certainly proved to be the case of induction of progressive multifocal leukoencephalopathy (PM2, a usu-

ally fatal viral infection of the white matter of the brain) in some cases associated with the use of several immunosuppressive monoclonal antibodies.

The following is a brief explanation of some of the indicators that may be used to trigger additional definitive testing and a description of some of the most commonly used assays to assess humoral, cell-mediated, or nonspecific immune

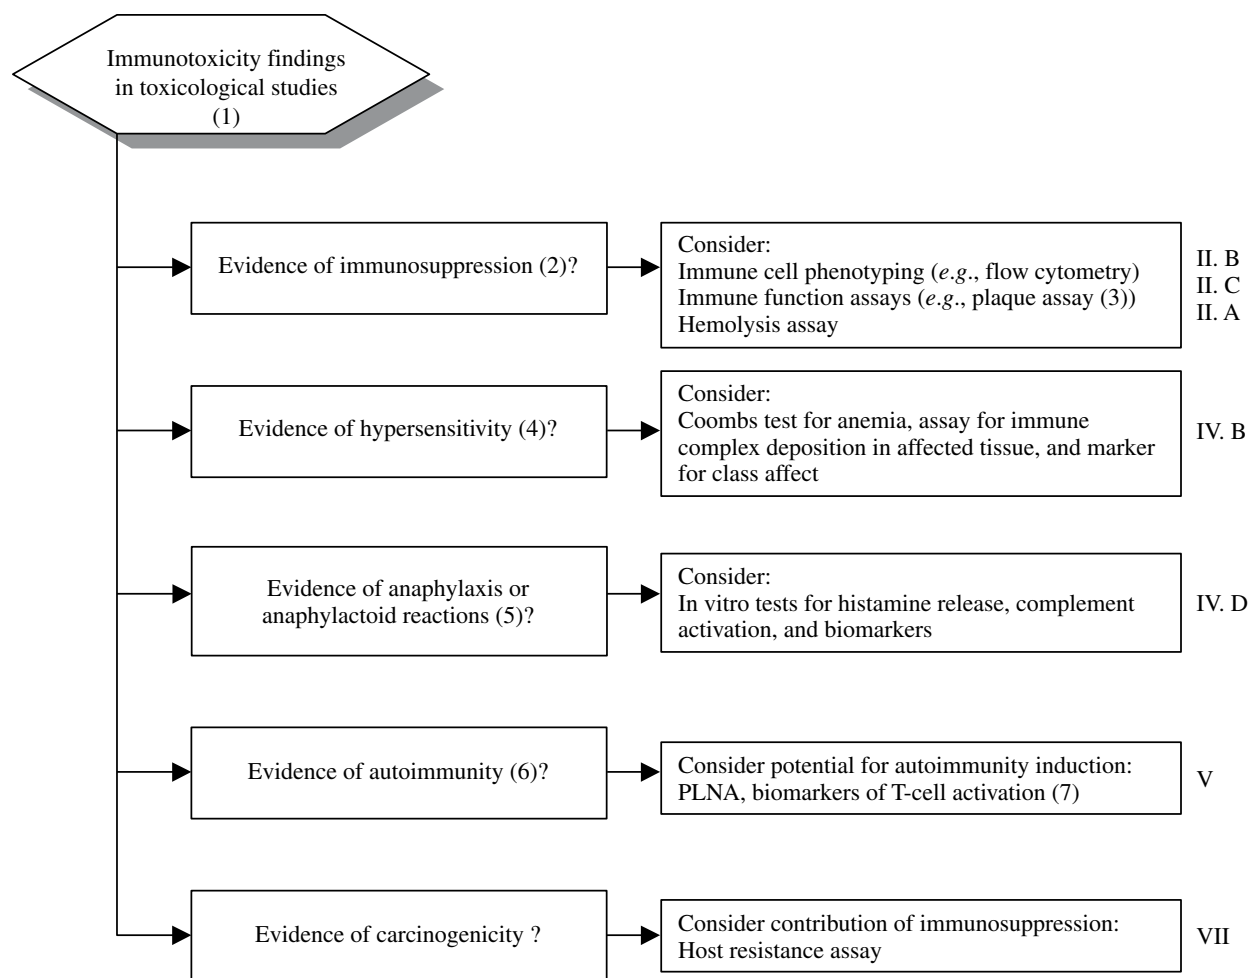

FIGURE 13.3 Follow-up studies to consider for exploring mechanisms of immunotoxicity. Annotations in right margin indicate location of text describing specific advice. (1) Examples include myelosuppression, histopathology in immune-associated tissues, increased infection, tumors, decreased serum Ig, and phenotypic changes in immune cells. (2) Other acceptable assays include drug effect on NK-cell function *in vitro* blastogenesis, cytotoxic T-cell function cytokine production, DTH, and host resistance to infections or implanted tumors. (3) Examples include anemia, leukopenia, thrombocytopenia, pneumonitis, vasculitis, lupus-like reactions, and glomerulonephritis. (4) Examples include cardiopulmonary distress, rashes, flushed skin, and swelling of face or limbs. (5) Examples include vasculitis, lupus-like reactions, glomerulonephritis, and hemolytic anemia. (6) There are no established assays that reliably assess potential for autoimmunity and acute systemic hypersensitivity. (7) The popliteal lymph node assay (PLNA) has only a relatively small database available for assessing its usefulness for drug regulatory purposes.

dysfunction, which are common to most immunotoxicology test strategies.

13.7.1 Immunopathologic Assessments

Various general toxicological and histopathologic evaluations of the immune system can be made as part of routine preclinical safety testing to obtain a preliminary assessment of potential drug-related effects on the immune system. At necropsy, various immunological organs of the immune system such as thymus, spleen, and lymph nodes are typically observed for gross abnormalities and weighed in order to detect decreased or increased cellularity. Bone marrow

and peripheral blood samples are also taken to evaluate abnormal types and/or frequencies of the various cellular components. Tables 13.13 and 13.14 summarize the observations and interpretations.

13.7.1.1 Organ and Body Weights Changes in absolute weight, organ-to-body weight ratios, and organ-to-brain weight ratios of tissues such as thymus and spleen are useful general indicators of potential immunotoxicity. However, these measures are nonspecific for immunotoxicity since they may also reflect general toxicity and effects on endocrine function that can indirectly affect the immune system.

TABLE 13.13 Examples of Antemortem and Postmortem Findings That May Include Potential Immunotoxicity if Treatment Related

Parameter	Possible Observation (Cause)	Possible State of Immune Competence
<i>Antemortem</i>		
Mortality	Increased (infection)	Depressed
Body weight	Decreased (infection)	Depressed
Clinical signs	Rales, nasal discharge (respiratory infection)	Depressed
	Swollen cervical area (sialodacryoadenitis virus)	Depressed
Physical examinations	Enlarged tonsils (infection)	Depressed
Hematology	Leukopenia/lymphopenia	Depressed
	Leukocytosis (infection/cancer)	Enhanced/depressed
	Thrombocytopenia	Hypersensitivity
	Neutropenia	Hypersensitivity
Protein electrophoresis	Hypogammaglobulinemia	Depressed
	Hypergammaglobulinemia (ongoing immune response or infection)	Enhanced/activated
<i>Postmortem</i>		
Organ weights		
Thymus	Decreased	Depressed
Histopathology		
Adrenal glands	Cortical hypertrophy (stress)	Depressed (secondary)
Bone marrow	Hypoplasia	Depressed
Kidney	Amyloidosis	Autoimmunity
	Glomerulonephritis (immune complex)	
Lung	Pneumonitis (infection)	Depressed
Lymph node	Atrophy	Depressed
Spleen	Hypertrophy/hyperplasia	Enhanced/activated
	Depletion of follicles	Depressed B cells
	Hypocellularity of periarteriolar sheath	Depressed T cells
	Active germinal centers	Enhanced/activated
Thymus	Atrophy	Depressed
Thyroid	Inflammation	Autoimmunity

13.7.2 Humoral (Innate) Immune Response and Possible Entry Points for Immunotoxic Actions

13.7.2.1 Hematology Hemacytometers or electronic cell counters can be used to assess the numbers of lymphocytes, neutrophils, monocytes, basophils, and eosinophils in the peripheral blood, while changes in relative ratios of the various cell types can be assessed by microscopic differential evaluation. Similar evaluations can be performed with bone marrow aspirates, where changes may reflect immunotoxicity to the pluripotent stem cells and newly developing lymphoid precursor cells. Potential hematological indicators of immunotoxicity include altered white blood cell counts or differential ratios, lymphocytosis, lymphopenia, or eosinophilia. Changes in any of these parameters can be followed up with more sophisticated flow cytometric analyses or immunostaining techniques that are useful for phenotyping the various types of lymphocytes (B cell, T cell) and the T-cell subsets (CD4⁺ and CD8⁺) on the basis of unique surface markers. Decreases or increases in the percentages of any of the cell populations relative to controls or in the ratios

of B cells/T cells or CD4⁺/CD8⁺ cells may be indicators of immunotoxicity.

13.7.2.2 Clinical Chemistry Nonspecific clinical chemistry indicators of potential immune dysfunction include changes in serum protein levels in conjunction with changes in the albumin-to-globulin (A/G) ratio. Immunoelectrophoretic analysis of serum proteins can then be performed to quantify the relative percentages of albumin and the α-, β-, and γ-globulin fractions. To perform these assays, a drop of serum (antigen) is placed into a well cut in a gel, and then the gel is subjected to electrophoresis so that each molecule in the serum moves in the electric field according to its charge. This separation is then exposed to specific anti-serum, which is placed in a trough cut parallel to the direction in which the components have moved. By passive diffusion, the antibody reaches the electrophoretically separated antigen and reacts to form Ag–Ab complexes. The γ-globulin fractions can be separated and further quantified for the relative proportions of IgG, IgM, IgA, and IgE using similar techniques.

TABLE 13.14 Immune System Components in Organ Sites

Organ	Antigen-Presenting Cell	B Cell	CD4* ⁺ T Cell	Possible Immunotoxic Entry Point	Outcome
Bone marrow	Differentiation from pluripotent stem cells	Differentiation from pluripotent stem cells: rearrangement of antigen receptors, central repertoire selection, homing, antibody production	Differentiation from pluripotent stem cells: rearrangement of antigen receptors	Inhibition of cell proliferation, interference with signal transduction, genotoxicity, interference with gene recombination, interference with DNA repair, interference with signal transduction, interference with apoptosis, interference with signal transduction, inhibition of protein synthesis	Leukopenia, malignancies, lymphopenia, selective lymphopenia, autoimmunity, impaired adaptive immune response
Thymus	—	—	Proliferation and positive/negative repertoire selection	Interference with signal transduction, interference with apoptosis	Selective lymphopenia, autoimmunity
Peripheral tissue	Antigen uptake and processing, maturation	—	—	Inhibition of cell motility, interference with phagolysosomal degradation, interference with intracellular transport, inhibition of cell motility, interference with signal transduction	Lack of antigen presentation, impaired adaptive immune response, lack of antigen presentation, impaired adaptive immune response
Lymphatic organ	Antigen presentation	Antigen uptake and presentation, cross-communication with T-cell, activation, proliferation, differentiation	Antigen recognition (APC) and activation; proliferation; differentiation, cross-communication with B-cell	Inhibition of cell motility, interference with phagolysosomal degradation or intracellular transport, interference with signal transduction, inhibition of cytokine release, interference with signal transduction, inhibition of cell proliferation, interference with signal transduction	Impaired adaptive immune response, impaired adaptive immune response, autoimmunity; allergy, impaired adaptive immune response

Serum concentrations of immunoglobulin classes and subclasses can also be measured using various techniques such as radioimmunoassays (RIAs) or enzyme-linked immunosorbent assays (ELISAs). In the ELISA, antigens specific for each class of immunoglobulin can be adsorbed onto the surfaces for microtiter plates. To determine the quantity of each antibody in a test sample, an aliquot of antiserum is allowed to react with the adsorbed antigens. Unreacted molecules are rinsed off and an enzyme-linked anti-Ig is then added to each well. Next, substrate is added and the amount of color that develops is quantified using a spectrophotometric device. The amount of antibody can then be extrapolated from standard curves since the amount of color is proportional to the amount of enzyme-linked antibody that reacts. Variations in levels of a given antibody may indicate the decreased ability of B cells of decreased numbers of B cells producing that antibody. In

addition, serum autoantibodies to DNA, mitochondria, and parietal cells can be used to assess autoimmunity. Serum cytokines (IL-1, IL-2, and γ -interferon) can also be evaluated using immunochemical assays to evaluate macrophage, lymphocyte, and lymphokine activity; prostaglandin E₂ can also be measured to evaluate macrophage function.

CH50 determinations can be used to analyze the total serum complement and are useful for monitoring immune complex diseases (Sullivan, 1989); activation of complement (Table 13.14) in the presence of autoantibodies is indicative of immune complex diseases and autoimmunity. The various components of the complement system (C3, C4) can also be measured to assess the integrity of the system. For instance, low serum concentrations of C3 and C4, with a concomitant decrease in CH50, may indicate activation of complement, while a low C4 alone is a sensitive indicator of reduced

activation of the complement system. Since C3 is used as an alternate complement pathway, it usually measures high. Therefore, a low C3 with a normal C4 may indicate an alternate pathway of activation.

13.7.2.3 Histopathology Histopathologic abnormalities can be found in lymphoid tissues during gross and routine microscopic evaluations of the spleen, lymph nodes, thymus, bone marrow, and gut-associated lymphoid tissues such as Peyer's patches and mesenteric lymph nodes. Microscopic evaluations should include descriptive qualitative changes such as types of cells, densities of cell populations, proliferation in known T- and B-cell areas (e.g., germinal centers), relative numbers of follicles and germinal centers (immune activation), and the appearance of atrophy or necrosis. In addition, unusual findings such as granulomas and scattered, focal mononuclear cell infiltrates in nonlymphoid tissues may be observed as indicators of chronic hypersensitivity or autoimmunity. A complete histopathologic evaluation should also include a quantitative assessment of cellularity through direct counts of each cell type in the various lymphoid tissues. In addition, changes in cellularity of the spleen can be more precisely quantitated from routine hematoxylin and eosin (H&E) sections using morphometric analysis of the germinal centers (B cells) and periarteriolar lymphocyte sheath (T cells). Similar morphometric measurements can be made of the relative areas of the cortex and medulla of the thymus. If changes in cellularity are apparent from routinely stained histopathology sections, special immunostaining (immunoperoxidase or immunofluorescence) of B cells in the spleen and lymph nodes using polyclonal antibodies to IgG, or immunostaining of the T cells and their subsets in the spleen using mono- or polyclonal antibodies to their specific surface markers, can be used to further characterize changes in cellularity.

Numerous physiological and environmental factors such as age, stress, nutritional deficiency, and infections may affect the immune system (Sullivan, 1989). Thus, adverse findings in animal studies may reflect these indirect immunotoxic effects rather than the direct immunotoxic potential of a chemical or drug. Indirect immunotoxic effects may be assessed through histopathologic evaluations of endocrine organs such as the adrenals and pituitary.

It is also well known that the functional reserves of the immune system can allow biologically significant, immunotoxic insults to occur without the appearance of morphological changes. In addition, there is some built-in redundancy in the system in that several mechanisms may produce the same outcome. For instance, cytotoxic T cells may alone be sufficient to protect the organism against a bacterial infection; however, the body will also produce antibodies for future protection. Thus, if one mechanism is insufficient to fight off infection, the second mechanism can serve as a backup. Because of this functional reserve, adverse effects

may remain subclinical until the organism is subjected to undue stress or subsequent challenge (Bloom et al., 1987). Therefore, routine immunopathologic assessments as part of standard preclinical toxicity tests may not be sufficient to detect all immunotoxins. Although changes detected in routine toxicological and pathological evaluations are nonspecific and of undetermined biological significance to the test animal, they can be invaluable as flags for triggering additional testing.

As described previously, the humoral immune response results in the proliferation, activation, and subsequent production of antibodies by B cells following antigenic exposure and stimulation. The functionality and interplay between the three primary types of immune cells (macrophage, B cells, and T cells) required to elicit a humoral response can be assessed through various *in vitro* assays using cells from the peripheral blood or lymphoid tissues.

13.7.2.4 Antibody Plaque-Forming Cell (PFC) Assay

The number of B cells producing antibody (PFC) to a T-dependent antigen such as sheep red blood cells (SRBCs) can be assessed *in vitro* following *in vivo* exposure to the test article and antigen (*ex vivo* tests). The PFC response to a T-dependent antigen is included as a tier I test by the NTP since it appears to be the most commonly affected functional parameter of exposure to immunosuppressants. However, this test is designated as a type II test in the FDA Redbook since it requires an *in vivo* immunization of the animals with antigen and, thus, cannot be evaluated as part of an initial toxicity screen.

Although this assay requires that B cells be fully competent in secreting antibodies, T cells and macrophage cells are also essential for the proper functioning of humoral immunity. However, this assay is nonspecific in that it cannot determine which cell type(s) is responsible for dysfunction. Macrophage cells are needed to process antigen and produce IL-1. T cells are needed for several functions including antigen recognition of surface membrane proteins and B-cell maturation through the production of various lymphokines that stimulate growth and differentiation. SRBCs are most commonly used as the T-dependent antigen, although T-cell independent antigens may also be useful to rule out T helper dysfunction as a cause of immunodysfunction.

The PFC assay has evolved from methodology originally developed as a hemolytic plaque assay (or Jerne plaque assay) by Nils Jerne to quantitate the number of antibody-forming cells in a cell suspension plated with RBCs onto agar plates (Jerne and Nordin, 1963). In its present form, animals are treated *in vivo* with the test compound, immunized with approximately 5×10^8 SRBCs administered intravenously within 2–3 days posttreatment, and then sacrificed 4 days (IgM) or 6 days (IgG) later. Antibody-producing spleen cell suspensions are then mixed *in vitro* with SRBCs, placed onto covered slides, and incubated for a few hours in the presence

of complement. During incubation, antibody diffuses from the anti-SRBC-producing cells and forms Ag–Ab complexes on the surfaces of nearby SRBCs. In the presence of complement, the Ag–Ab complexes cause lysis of the SRBCs, resulting in the formation of small, clear plaques on the slide. Plaques are then counted and expressed as PFCs/10⁶ spleen cells. A dose-related reduction in PFCs is indicative of immunosuppression.

13.7.2.5 B-Cell Lymphoproliferation Response The NTP has classified this assay as a tier I test since mitogenesis can be performed easily in tandem with other tests to provide an assessment of the proliferative capacity of the cells (Luster et al., 1988). Since this assay is performed *ex vivo* with peripheral blood (or spleen) and is well characterized for use in various animal species, it has also been included as an expanded type I test in the revised Redbook.

The proliferation of peripheral blood or splenic B cells following stimulation with lipopolysaccharide (LPS) or other mitogens (pokeweed mitogen extract) is another measurement of humoral immunity. LPS (a bacterial lipopolysaccharide) is a B-cell-specific mitogen that stimulates polyclonal proliferation (mitosis) as part of the natural sequence of antigen recognition, activation, and clonal expansion. The mitogen does not interact with just one particular antigen-specific clone but with all cells bearing the carbohydrate surface marker for which it is specific. Since mitogens are both polyclonal and polyfunctional, they can stimulate a wider spectrum of antigenic determinants than antigens, which can only stimulate a low number (10⁻⁶) of specific cells.

In this assay, lymphocytes from animals are treated *in vivo* and cultured *in vitro* in microtiter plates in the presence of tritiated [³H]thymidine (or uridine) using a range of at least three concentrations of mitogen to optimize the response. Lymphocytes can be obtained aseptically from peripheral blood or from single cell suspensions of spleen cells that are prepared by pushing the tissue through sterile gauze or 60-mesh wire screens. A decrease in DNA synthesis (incorporation of ³H) as compared to the unexposed cells of control animals may indicate that the B cells were unable to respond to antigenic stimulation. Alternative methodology employs a 18–20h incubation with ¹²⁵I-labeled iododeoxyuridine ([¹²⁵I] IudR) and fluorodeoxyuridine (FudR) (White et al., 1985). After incubation, the cells are collected onto filter disks and then counted with a gamma counter.

Assays such as this that use polyclonal mitogens for activation may not be as sensitive as specific antigen-driven systems (Luster et al., 1988). In addition, suppression of the mitogen response does not always correlate with the PFC response. Since mitogenesis represents only a small aspect of B-cell function and maturation, this end point is not sensitive to early events that may affect activation or later events that may affect differentiation of B cells into antibody-secreting cells (Klaus and Hawrylowicz, 1984).

13.7.3 Cell-Mediated Immunity

13.7.3.1 T-Cell Lymphoproliferation Response This assay is analogous to the B-cell lymphoproliferative response assay described previously. Thus, this assay is also classified as a tier I test by the NTP and as an expanded type I test in the revised draft of the Redbook.

T cells from the peripheral blood or spleen undergo blastogenesis and proliferation in response to specific antigens that evoke a cell-mediated immune response. T-cell proliferation is assessed using T-cell-specific mitogens such as the plant lectins, concanavalin A (Con A), and phytohemagglutinin (PHA) or T-cell-specific antigens (i.e., tuberin, *Listeria*). Uptake of ³H as an indicator of DNA synthesis is used as described previously for evaluating B-cell proliferation. T-cell mitogens do not just stimulate synthesis of DNA but, in fact, they also stimulate the expression of cell-specific function. For instance, Con A can trigger the expression of T helper, suppressor, and cytotoxic effector cells, and either mitogen may induce the expression (or reexpression of memory cells) of differentiated function (Clark, 1983). Since cell populations responsive to Con A are thought to be relatively immature compared to those that are stimulated with PHA, the parallel usage of both mitogens may be useful for distinguishing the affected subset (Tabo and Paul, 1973). A secondary response to T-cell antigens such as purified protein derivative (PPD) of tuberculin or tetanus toxoid can also be assessed.

13.7.3.2 Mixed Lymphocyte Response (MLR) Assay

This assay has been shown to be sensitive for the detection of chemical-induced immunosuppression and is a recommended tier I assay by the NTP (Luster et al., 1988). In addition, it has been shown to be predictive of host response to transplantation and of general immunocompetence (Harmon et al., 1982).

The mixed lymphocyte response (MLR) assay assesses the ability of T cells to recognize foreign antigens on allogenic lymphocytes and, thus, is an indirect measure of the cell-mediated ability to recognize graft or tumor cells as foreign. Responder lymphocytes from animals treated *in vivo* with the test compound are mixed with allogenic stimulator lymphocytes that have been treated *in vitro* with mitomycin C or irradiated to render them unable to respond (Bach and Voynow, 1966). Both cell types are cultured *in vitro* for 3–5 days and then incubated with ³H for an additional 6h. Once the radiolabel is incorporated into the DNA of the responding cells, the DNA is extracted, and the amount of radioactive label is measured to quantitate proliferation of the responder cells of drug-treated animals compared to those of the controls.

13.7.3.3 Cytotoxic T Lymphocyte (CTL)-Mediated Assay

This assay is similar to the MLR assay and can be

performed in parallel or as a tier II follow-up to the MLR assay.

The cytotoxic T Lymphocyte (CTL) assay ascertains the ability of cytotoxic T cells to lyse an allogenic target cell or the specific target cell type with which they were immunized. In general, the cytolytic response of activated effector cells is assessed by measuring the amount of radioactivity (^{51}Cr) that is released from the target cell. When performed in conjunction with the MLR assay, lymphoid cells of the two strains are cultured together *in vitro* as described previously; however, ^{51}Cr is added to the culture after 4–5 days (instead of ^3H). Both responder and target cells are labeled with the ^{51}Cr , which is taken up rapidly by the cells through passive diffusion but is released slowly as long as the cell membrane is intact. Furthermore, since chromium is reduced from Cr^{6+} to Cr^{3+} and since Cr^{3+} enters the cells at a much slower rate than Cr^{6+} , the ^{51}Cr released from the damaged target cells is not significantly reincorporated into undamaged cells (Clark, 1983), which would reduce the sensitivity of the assay. Thus, the amount of chromium released into the medium and recovered in the supernatant of the mixture of the cells is directly proportionate to the extent of lysis of the target cells by the sensitized responder cells.

In a capillary tube assay developed in 1962 by George and Vaughan, the inhibition of migration of macrophage cells can be used to assess normal T-cell function (see Clark, 1983). T cells are obtained from the peripheral blood of animals treated *in vivo* with a test article and injected with antigen (e.g., tuberculin). These T cells are functioning normally, and they should release migration inhibition factor (MIF). As a consequence, the macrophages, which generally show a propensity for migration upon stimulation with the antigen, should show a MIF-induced reduction in migratory behavior.

13.7.3.4 Delayed-Type Hypersensitivity (DTH) Response

The DTH response assay is considered to be a comprehensive tier II assay for cell-mediated immunity by the NTP.

To express a DTH inflammatory response, the immune system must be capable of recognizing and processing antigen, blastogenesis and proliferation of T cells, migration of memory T cells to the challenge site of exposure to antigen, and subsequent production of inflammatory mediators and lymphokines that elicit the inflammatory response. Thus, by measuring a DTH response to an antigen, these assays assess the functional status of both the afferent (antigen recognition and processing) and efferent (lymphokine production) arms of cellular immunity. Various antigens have been used for assessing DTH, including keyhole limpet hemocyanin (KLH), oxazolone, dinitrochlorobenzene, and SRBCs (Vos, 1977; Godfrey and Gell, 1978; Luster et al., 1988).

In one such assay described by White et al. (1985), mice previously treated with the test article are sensitized to SRBCs by inoculation of SRBCs into the hind footpad and 4 days later challenged in the same footpad. Seventeen hours following

challenge, they are injected intravenously with ^{125}I -labeled human serum albumin (HSA) and then sacrificed 2 h later. Both hind feet are then radioassayed in a gamma counter (the second foot serves as a control for background infiltration of the label). With a normal functioning cell-mediated response, ^{125}I -labeled HSA will extravasate into the edematous area produced by the DTH response (Paranjpe and Boone, 1972). In general, a decrease in the extravasation of ^{125}I -labeled HSA is indicative of immunosuppression of the efferent arm of the cell-mediated immune system.

To assay specifically the afferent arm of the DTH response, the proliferation of the popliteal lymph node cells to SRBCs can also be measured (White et al., 1985). As described previously, mice treated with the test article are sensitized to SRBCs by inoculation of SRBCs into the hind footpad. However, 1.5 h later they are challenged intraperitoneally with FUdR and 2 h later they are administered [^{125}I] IUdR intravenously (instead of ^{125}I -labeled HSA). Mice are sacrificed 24 h after challenge and both popliteal lymph nodes are removed and counted in a gamma counter.

Similar assays for DTH have been traditionally performed with the antigen *Mycobacterium tuberculosis*, which preferentially elicits a cell-mediated response. In this assay a small amount of antigen contained in the supernatant fluid from the medium in which the pathogen was grown is injected into the footpad. Upon challenge, a visible and palpable lump should appear by 48 h. The amount of swelling is then measured and compared with the footpad that did not receive the challenge. Alternatively, methods used by the NTP employ a modified ^{125}I -labeled uridine (UdR) technique to measure the monocyte influx at the challenge site (ear) injected with KLH antigen. This assay has been shown to correlate well with decreased resistance to infectious disease (Luster et al., 1988). However, one should note that regardless of which technique is used, antiinflammatory drugs may produce false-positive results in this type of assay.

Anaphylaxis is an acute allergic response currently seen in treatment with some biotherapeutics as well as to latex proteins (from gloves and other medical devices), bee stings, peanuts, and some surfactants. It requires exposure to a large molecule (3000 or greater MW), which can be either innately large molecules or small molecules bound to macromolecule carriers. Unlike a type IV delayed constant hypersensitivity response, this type I response can affect the entire body, rapidly becoming more severe and even life threatening. There is rapid elevation of serum histamine and/or tryptase levels or agent specific IgE antibodies. While this is much more dangerous than a type IV topical response, there are currently no regulatorily mandated or accepted methods for predicting the potential effect from a drug or agent, though the Japanese previously had three such test protocols (Maki, 1997; Verdier et al., 1994). Passive cutaneous anaphylaxis (PCA) (Brocklehurst et al., 1960), active cutaneous anaphylaxis (ACA), and active systemic anaphylaxis (ASA) (Chazal

et al., 1994; Choquet-Kastylevsky et al., 2001). But while effective in predicting protein (large molecule) induced responses, they have been deemed not reliable for predicting such responses to small molecules (CDER, 2002).

13.8 NONSPECIFIC IMMUNITY FUNCTION ASSAY

13.8.1 Natural Killer Cell Assays

This assay is a tier I test for nonspecific immunity in the NTP testing scheme (Luster et al., 1988) and is proposed as an additional type I test in the draft Redbook.

NK cells, like cytotoxic T cells, have the ability to attack and destroy tumor cells or virus-infected cells. However, unlike T cells, they are not antigen specific, do not have unique, clonally distributed receptors, and do not undergo clonal selection. In *in vitro* or *ex vivo* tests, target cells (e.g., YAC-1 tumor cells) are radiolabeled *in vitro* or *in vivo* with ^{51}Cr and incubated *in vitro* with effector NK cells from the spleens of animals that had been treated with a xenobiotic. This assay can be run in microtiter plates over a range of various ratios of effector/target cells. Cytotoxic activity is then measured by the amount of radioactivity released from the damaged tumor cells as was previously described for cytotoxic T cells. This assay can also be performed *in vivo*, where YAC-1 cells labeled with [^{125}I]IUdR are injected directly into mice and NK-cell activity is correlated with its level of radioactivity (Riccardi et al., 1979). Immunotoxicity observed as reduced NK-cell activity is correlated with increased tumorigenesis and infectivity.

13.8.2 Macrophage Function

Several assays are available to measure various aspects of macrophage function, including quantitation of resident peritoneal cells, antigen presentation, cytokine production, phagocytosis, intracellular production of oxygen free radicals (used to kill foreign bodies), and direct tumor-killing potential. Techniques for quantitation of peritoneal cells and functional assays for phagocytic ability are classified as comprehensive tier II tests by the NTP and as additional type I tests in the draft Redbook.

Macrophage cells and other polymorphonuclear cells (PMNs) contribute to the first-line defense of nonspecific immunity through their ability to phagocytize foreign materials, including pathogens, tumor cells, and fibers (e.g., silica, asbestos). Xenobiotics can affect macrophage function by direct toxicity to macrophages or by modulating their ability to become activated. Differential counts of resident peritoneal cells can be made as a rapid, preliminary assessment of macrophage function for xenobiotics that are not administered parenterally.

Numerous *in vitro* assays can be employed to assess common functions of macrophages and PMNs including adherence to glass, migration inhibition, phagocytosis, respiratory activity (chemiluminescent assays or nitroblue tetrazolium), and target cell killing. In one such assay, the chemotactic response to soluble attractants is evaluated using a Boyden chamber with two compartments that are separated by a filter. Macrophage cells or PMNs from treated animals are placed in one side and a chemotactic agent in the other. Chemotaxis is then quantified by counting the number of cells that pass through the filter. In another assay, the ability of the macrophages to phagocytize foreign materials can be evaluated by adding fluorescent latex beads to cultures containing macrophage cells and then determining the proportion of cells that have phagocytized the beads using a fluorescent microscope or by flow cytometry (Duke et al., 1985). Similar functions can be evaluated by incubating the cells with known amounts of bacteria. The cells are then removed by filtration or centrifugation, the remaining fluid is plated onto bacterial nutrient agar, and, after a few days of incubation, the bacterial colonies are counted. Furthermore, the efficiency of the cells to kill the bacteria once phagocytized can be assayed by lysing the cells and plating the lysate onto bacterial agar.

Various *in vivo* assessments of macrophage function have also been used. For example, peritoneal exudate cell (PEC) recruitment can be assessed using eliciting agents such as *Corynebacterium parvum*, MVE-2, or thioglycolate (Dean et al., 1984). In one such assay (White et al., 1985), mice are injected intraperitoneally with thioglycolate, sacrificed 4 days later, and the peritoneal cavity is flushed with culture medium. The cell suspension is then counted, the cell concentration is adjusted to a known density ($2 \times 10^5 \text{ mL}^{-1}$), and the cells are cultured for 1 h in 24-well culture dishes. Adherent cells are then washed with medium and aliquots of ^{51}Cr -labeled SRBCs that were opsonized with mouse IgG are added to each well and incubated for various times. This same system can be used to assess adherence and chemotaxis of the PECs (Laskin et al., 1981). Phagocytosis can also be evaluated *in vivo* by measuring the clearance of injected particles from the circulation and the accumulation of the particles in lymphatic tissues such as the spleen.

13.8.3 Mast Cell/Basophil Function

The function of mast cells and basophils to degranulate can be evaluated using a PCA test (Cromwell et al., 1986). Serum containing specific anaphylactic (IgE) antibodies from donor animals previously exposed to a known antigen is first administered by intradermal (or subcutaneous) injection into unexposed host animals. After a sufficient latency period to allow binding of the donor IgE to the host tissue mast cells, the animals are administered a second intravenous injection of the antigen. The anaphylactic antibodies present in the serum will stimulate normally functioning

mast cells to degranulate (release histamines) and produce a marked inflammatory response. Using similar *in vitro* assays with mast cells and basophils, the quantities of histamines that are released from the cells can be measured directly in the culture medium.

13.8.3.1 Host-Resistance Assays Host-resistance assays can be used to assess the overall immunocompetence of the humoral or cell-mediated immune systems of the test animal (host) to fend off infection with pathogenic microbes or to resist tumorigenesis and metastasis. These assays are performed entirely *in vivo* and are dependent on all of the various components of the immune system to be functioning properly. Thus, these assays may be considered to be more biologically relevant than *in vitro* tests that only assess the function of cells from one source and of one type. Since these assays require that the animal be inoculated with a pathogen or exogenous tumor cell, they cannot be performed as part of a general preclinical toxicity assessment and are thus classified as type II tests in the revised Redbook. These assays are also included as tier II tests by the NTP.

Several host-resistance assays have been developed using various infectious agents, including bacteria (*Listeria monocytogenes*, *Streptococcus*, and *Escherichia coli*), viruses (influenza, cytomegalovirus, and herpes), yeast (*Candida albicans*), and parasites (*Trichinella spiralis* and *Plasmodium berghei*). These assays have been described in the NTP guidelines (Luster et al., 1988). In general, animals previously treated with a xenobiotic are injected with the pathogen at a target dose that is estimated to kill 10–30% of control animals (LD^{10-30}). After a period of time, the animals receive a challenge dose at a much higher concentration (LD^{60-80}) and by a different route to determine if animals are resistant to reinfection. Although these assays are similar in their mechanisms of resistance to different pathogens, they have been shown to differ with regard to varying degrees of susceptibility by the same drug (Morahan et al., 1979). Thus, for screening purposes, it is recommended that at least two tests be used (Descotes and Mazue, 1987). Although these tests are relatively easy to perform, those involving the use of pathogens require special handling, containment, and decontamination procedures to prevent infection to man and spread throughout the animal colony.

Similar host-resistance assays are used to evaluate the immunosurveillance of spontaneous tumors, which is assessed as the capacity of the organism to reject grafted syngeneic tumors. Various animal-bearing tumor models (Pastan et al., 1986) and host-resistance models have been used to assess immunotoxicity. Several of the host-resistance assays utilize cultured tumor cell lines such as PYB6 sarcoma and B16F10 melanoma cells that are used with C57/BL/6 mice or the MADB106 lung tumor cell lines that are used with Fischer 344 rats. For example, the PYB6 sarcoma model uses death as

an end point. In this assay, syngeneic mice are injected with the PYB6 sarcoma cells and death due to tumor is recorded daily. In another routinely used assay, animals that have been treated with a xenobiotic are injected with either B16F10 melanoma cells or Lewis lung carcinoma cells, and then approximately 20 days later, they are sacrificed, and pulmonary tumors are measured and counted.

13.9 T-CELL-DEPENDENT ANTIBODY RESPONSE (TDAR)

The TDAR should be performed using a recognized T-cell-dependent antigen like SRBCs, bovine serum albumin (BSA), or KLH that results in a robust antibody response. For the SRBC assay, IgM measurement is considered the most appropriate end point, whereas IgG measurement is considered to be most appropriate for BSA or KLH. Antibody can be measured by using an ELISA or other immunoassay method. One advantage of ELISA over the traditional plaque-forming cell (PFC) assay (Ladics, 2005) is that samples can be collected serially during the study, if necessary. Since immunization is likely to have effects on hematology, clinical chemistry, and histology of lymphatic organs, TDAR studies should always be performed as separate studies or at least in satellite groups of repeat-dose toxicity studies. Brief details of the assay are as follows.

13.9.1 Treatment

1. Use a suitable SPF mouse strain like BALB/c or C57BL/6×C3H F1 (B6C3F1).
2. Allocate 120 animals in six groups of 10 males and 10 females each. The group sizes may be reduced to five males and five female animals per group when a substantial immunosuppressive effect can be expected. The larger group size should be chosen when immunosuppressives are excluded, since otherwise the statistical power of the assay might be insufficient to prove a lack of immunosuppression.
3. Allow acclimatization for 7 days before sampling of pretest serum (day 7) from the test groups, and allow an additional 7 days of rest before first dosing. Pretest serum of recovery groups may be taken on day 35, which is 1-week postdosing.
4. Administer the test substance and vehicle daily over a period of 28 days (days 1–28) to all animals using an appropriate route of administration.
5. Use a low, intermediate, and high dose level, whereby the high dose level should be above the NOAEL and below a dose level that causes stress, if possible. The intermediate dose (or low dose) level should ideally represent the intended clinical dose level.

6. Immunize all mice of the test groups on day 14 and mice of the recovery groups on day 42 by intraperitoneal injection of 100 µg KLH per mouse without the use of adjuvant.
7. Sample immune serum from all animals of the test groups on day 29 and from all of the recovery groups on day 57.
8. Store serum at -20°C until ELISA testing.

13.9.2 Hypersensitivity

13.9.2.1 Type I Hypersensitivity Although there are acceptable systems for evaluating type I (immediate) reactions following systemic exposure, there are no reliable animal models for predicting type I reactions following dermal applications or oral administrations of drug. Repeated exposure of a xenobiotic is required to produce a type I response. A drug in the form of a hapten must covalently bind to macromolecules (proteins, nucleic acids) before it can initiate a primary antibody response. Once sensitized, even the smallest exposure to the xenobiotic can elicit a rapid, intensive IgE antibody-mediated inflammatory response. With the exception of antivirals and chemotherapeutic drugs, most drugs should not be reactive with biological nucleophiles since these drugs are usually screened out as mutagens or carcinogens in preclinical safety studies. However, type I hypersensitivity is a particular problem with biotechnology products themselves (e.g., insulin, growth hormones, interleukins), trace impurities from the producing organisms (e.g., *E. coli* proteins, mycelium), or the vehicles used to form emulsions (Matori et al., 1985).

The production of neutralizing antibodies to recombinant DNA protein products or their contaminants may be assayed using ELISAs or RIAs. A suitable animal model used to evaluate the potential for a type I response to protein hydrolysates is detailed in the US Pharmacopoeia. This test is very sensitive for testing proteins administered by the parenteral route but is of little value for low molecular weight drugs and those that are administered orally (Descotes and Mazue, 1987). ASA assay can be assessed in guinea pigs following systemic exposure to the test compound. For dermal exposures, however, rabbits or guinea pigs must be exposed to the test article by intradermal injections and then evaluated for their ability to mount a systemic anaphylactic response. The PCA test (as described previously for mast cells) can also be used to assess a potential anaphylactic response to a test compound. The serum containing potential anaphylactic (IgE) antibodies from donor animals previously exposed to the test compound is first administered by intradermal (or subcutaneous) injection into unexposed host animals. After a latency period, the animals are administered an intravenous injection of the test compound together with a dye. If anaphylactic antibodies are present in the serum, the subsequent exposure to the test compound will

cause a release of vasoactive amines (degranulation of mast cells), ultimately resulting in the migration of the dye to the sites of the intradermal serum injections.

13.9.2.2 Types II and III Hypersensitivity No simple animal models are currently available to assess type II (antibody-mediated cytotoxicity) hypersensitivity reactions. IgE antibodies and immune complexes in the sera of exposed animals can be assayed using ELISA or RIA (Radio immune assay) techniques that require the use of specific antibodies to the drug.

Type III (immune complex-related disease) reactions have been demonstrated by the presence of proteinuria and immune complex deposits in the kidneys of the Brown-Norway, Lewis, and PVG/C rat strains. However, susceptibility to the deposition and the subsequent lesions (glomerulonephritis) are often variable and dependent on the strain (Bigazzi, 1988). For example, despite the appearance of clinical signs and proteinuria, after 2-month administration of mercuric chloride, detectable levels of circulating antinuclear autoantibodies can no longer be observed in the Brown-Norway strain (Bellon et al., 1982). By contrast, in PVG/C rats administered mercuric chloride, immune complex deposition and antinuclear autoantibodies are present for longer periods of time; however, proteinuria is not observed (Weening et al., 1978).

13.9.2.3 Type IV Hypersensitivity There are several well-established preclinical models for assessing type IV (delayed type) hypersensitivity reactions following dermal exposure but not for predicting this response after systemic exposure.

Type IV hypersensitivity responses are elicited by T lymphocytes and are controlled by accessory cells and suppressor T cells. Macrophages are also involved in that they secrete several monokines, which results in proliferation and differentiation of T cells. Thus, there are numerous points along this intricate pathway in which drugs may modulate the final response. To achieve a type IV response, an initial high-dose exposure or repeated lower-dose exposures are applied to the skin; the antigen is carried from the skin by Langerhans cells and presented to cells in the thymus to initiate T-cell proliferation and sensitization. Once sensitized, a second "challenge" dose will elicit an inflammatory response. Thus, before sensitivity can be assessed, each of the models used to evaluate dermal hypersensitivity requires as a minimum:

- An initial induction exposure
- A latency period for expression
- A challenge exposure

A preliminary test for acute irritancy is also required to ensure that the initial dose is sufficient to stimulate sensitization and that the challenge dose is sufficient to ensure expression

of the response without producing irritation, which would confound the response. To confirm suspected sensitization or determine a threshold dose, each assay may also include a second challenge dose 1–2 weeks after the first challenge, at the same or lower concentrations. To increase penetration of the test article, various methods of abrasion (e.g., tape stripping) and occlusive coverings may also be used.

Several systems are used routinely to test compounds for dermal hypersensitivity (Magnusson and Kligman, 1969). The two most commonly used, the modified Buehler test and the guinea pig maximization test (GPMT), are briefly reviewed. More detailed methodology and a description of alternative test systems can be found in Gad and Chengelis (1998). Although either rabbits or guinea pigs are sensitive test species, guinea pigs have traditionally been the animal of choice. Guinea pig models of skin sensitization have been (and remain) widely used and have been valuable in assessing human risk (Andersen and Maibach, 1985).

13.9.2.4 Modified Buehler Buehler (1964) developed the first test system to use an occlusive patch to maximize dermal exposure and to increase the test sensitivity (Buehler, 1964). Although this assay is still insensitive for some xenobiotics that may not sufficiently traverse the epidermis, it is particularly useful for compounds that are either

highly irritating by intradermal injection or cannot be dissolved or suspended in a form that is conducive to injection. Other advantages are that the test produces few false positives, rarely overpredicts the potency of sensitizers, and is less likely to produce limiting system toxicity or ulceration at the induction sites. Figure 13.4 shows the test design in its current (OECD) form. The assay is no longer accepted in Europe due to a belief that it has an unacceptable rate of false-negative outcomes and is appropriate only for true topical (dermal) exposures.

During the induction phase, the test compound is applied to a cotton patch (1 in. × 1 in.) or placed in a Hilltop-style occlusive chamber. The patch is then placed onto a shaven area of epidermis on the left flank of a guinea pig and secured firmly in place for 24 h, after which time the patch is removed and the area is observed and scored for irritation (i.e., edema, erythema). A fresh patch is then reapplied for 6 h every other day during the induction period for a total of 10 treatments while continuing to score the application site at 24 and 48 h from the start of each treatment. Two weeks after the last induction exposure, the animals receive a challenge exposure for 24 h in the form of a patch applied to a shaven area of epidermis on the other flank (opposite the one used for induction). The challenge dose should be the highest concentration that does not produce dermal irritation after a single, 24 h exposure.

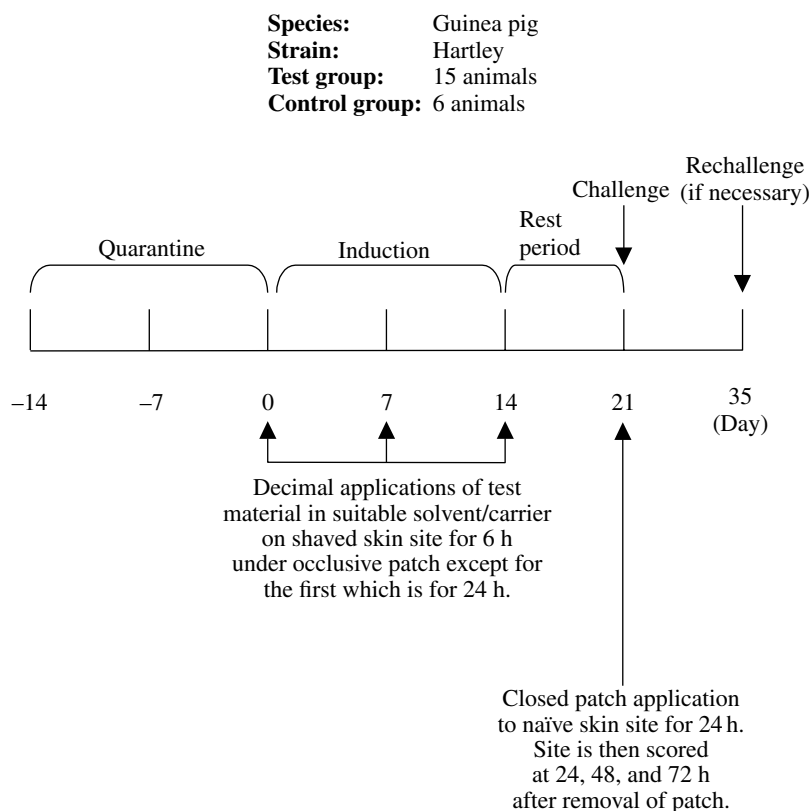

FIGURE 13.4 Line chart for modified Buehler test for delayed contact dermal sensitization in guinea pig.

The challenge site is observed for evidence of inflammation 24, 48, and 72 h after the patch is removed. Both the intensity and duration of a response to the test article compared to that of the vehicle are used to determine the potential and severity of sensitization.

13.9.2.5 Guinea Pig Maximization Test This assay, as developed by Magnusson and Kligman (1969), differs from the Buehler test in that the compound is administered by intradermal injection during the first stage of induction and coadministered with an adjuvant (Freund’s complete adjuvant (FCA)) during the induction phase to further stimulate the immune system. This test system is more sensitive (fewer false negatives) than the Buehler test; however, it may over-predict the potency for many sensitizers. Figures 13.5 and 13.6 illustrate the study design.

Prior to induction, a 4×6 cm area of fur is clipped from the shoulder region of each guinea pig. On day 0, three pairs of intradermal injections are made along opposite sides of the dorsal midline of the animal. The first pair (closest to the head) are administered as test substance in vehicle, the second pair are administered proximal to the first pair and consist only of FCA, and the third pair (spaced most posteriorly) are administered as the test substance in FCA. Seven days later (day 7), a mild to moderately irritating dose of the test article is spread onto a 1×2 in. filter paper patch, secured, and occluded for 48 h on the epidermal site that received the initial injections. On day 21, an area of fur on each flank is shaved and a 1×1 in. patch containing a nonirritating concentration of the test article is applied to one flank and a patch containing vehicle alone is applied to the other flank. The patches are secured and occluded for 24 h, and the challenge sites are scored for inflammation 24 and 48 h after removal of the patches. The incidence of animals that respond and the intensity and duration of a response to the test article

are used to determine the potential and severity of sensitization.

13.9.3 Local Lymph Node Assay (LLNA)

This method has developed out of the work of Ian Kimber and associates (Kimber et al., 1986, 1991; Kimber et al., 1989; Basketter and Scholes, 1991). It has the advantage over the other methods discussed in this chapter in that it provides an objective and quantifiable end point. The method is based on the fact that dermal sensitization requires the elicitation of an immune response. This immune response requires proliferation of a lymphocyte subpopulation. The local lymph node assay (LLNA) relies on the detection of increased DNA synthesis via tritiated thymidine incorporation. Sensitization is measured as a function of lymph node cell proliferative responses induced in a draining lymph node following repeated topical exposure of the test animal to the test article. Unlike the other tests discussed in this chapter, this assay looks only at the induction phase, as there is neither a challenge (elicitation) phase or sufficient period of evaluation for development of the underlying clonal expansion in response. Additionally, acute clinical formulations cannot be evaluated in this test system—meaning the all-important question of whether there is actually the potential for the drug to react with the immune system in clinical use remains unaddressed. Rather, in the case of a positive outcome, such interaction is presumed to occur.

The typical test (illustrated in Figure 13.7) is performed using mice—normally female CBA mice 6–10 weeks of age. Female BALB/c and ICR mice have also been used. After animal receipt, they are typically acclimated to standard laboratory husbandry conditions for 7–10 days. The usual protocol will consist of at least two groups (vehicle control and test article treated) of five mice each. They are treated on the

FIGURE 13.7 Mouse LLNA.

dorsal surface of both ears with 25 µL (on each ear) of test article solution for three consecutive days. Twenty-four to forty-eight hours after the last test article exposure, the animals are given a bolus (0.25 mL) dose of [³H]thymidine (20 µCi with a specific activity of 5.0–7.0 Ci mmol⁻¹) in phosphate-buffered saline via a tail vein. Five hours after the injection, the animals are euthanized by CO₂ asphyxiation and the auricular lymph nodes removed.

After removal, the lymph nodes can either be pooled by group or processed individually. Single cell suspensions are prepared by gentle mechanical disaggregation through a nylon (100 µm) mesh. Cells are washed twice by centrifugation in an excess of PBS. After the final supernatant wash is removed, the cells are precipitated with cold 5% trichloroacetic acid (TCA) and kept at 4°C for 12–18 h. The precipitate

is then pelleted by centrifugation and resuspended in 1 mL 5% TCA, and the amount of radioactivity is determined by liquid scintillation counting, using established techniques for tritium.

The data are reduced to the stimulation index (SI):

$$SI = \frac{H(\text{dpm}) \text{ treated group}}{H(\text{dpm}) \text{ control group}}$$

An SI of 3 or greater is considered a positive response, that is, the data support the hypothesis that the test material is a sensitizer.

The test article concentration is normally the highest non-irritating concentration. Several concentrations could be tested at the same time should one wish to establish a dose–response

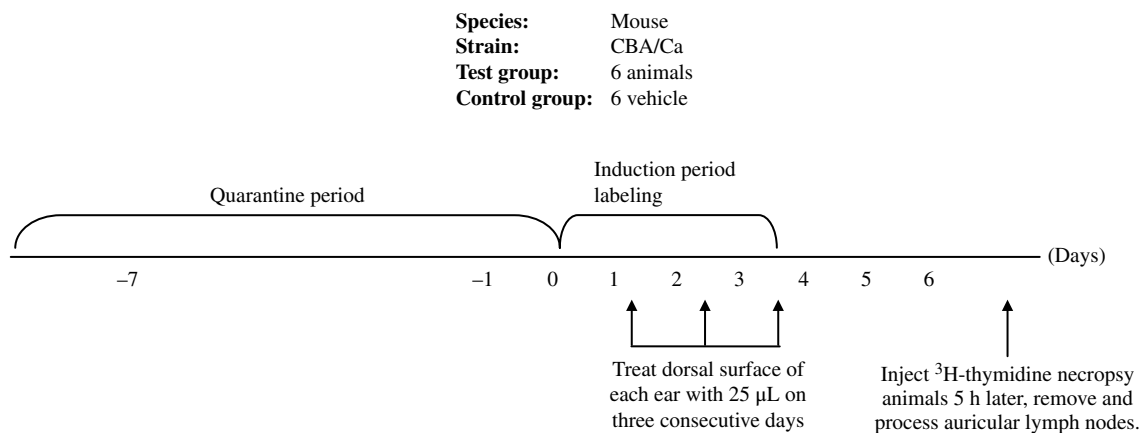

FIGURE 13.8 Mouse local lymph node assay (LLNA) (ICVAM protocol). Modification using flow cytometry instead of radiolabeling is preferable.

curve for induction. The test is easiest to perform if the vehicle is a standard nonirritating organic, such as acetone, ethanol, or dimethylformamide, or a solvent–olive oil blend. Until a laboratory develops its own historical control base, it is also preferable to include a positive control group. Either 0.25% dinitrochlorobenzene or 0.05% oxazolone is recommended for positive controls. If the vehicle for the positive control is different than the vehicle for the test material, then two vehicle control groups may be necessary.

This method has been extensively validated in two international laboratory exercises (Basketter et al., 1991; Loveless et al., 1996). In the earlier work (Basketter et al., 1991), there was good correlation between the results obtained with guinea pig tests and those obtained with the LLNA. In the 1996 report, for example, five laboratories correctly identified dinitrochlorobenzene and oxazolone as sensitizers and the fact that *p*-aminobenzoic acid was not (Loveless et al., 1996). Arts et al. (1996) demonstrated that rats could be used as well as mice. Interestingly, they validated their assay (for both rats and mice) using BrdU uptake and immunohistochemical staining (rather than [³H]thymidine) to quantitated lymph node cell proliferation.

This method is relatively quick and inexpensive because it uses relatively few mice (which are much less expensive than guinea pigs) and takes considerably less time than traditional guinea pig assays. It has an advantage over other methods in that it does not depend on an arguably subjective scoring system and produces a quantifiable end point. It does require a radiochemistry laboratory and license. Unless one already has an appropriately equipped laboratory used for other purposes (most likely metabolism studies), setting one up for the sole purpose of running the LLNA does not make economic sense. The standard version of the test has been adopted by OECD (OECD429), ICVAM, EMEA, and FDA (see Figure 13.8) but also has been shown to have a modest falsepositive rate (misidentifying strong irritants as sensitizers).

Indeed, it has become clear that certain classes of structures (e.g., surfactants, fatty acids, fatty alcohols, siloxanes, and polyols) yield high incidences of false-positive outcomes. Though initially thought to be associated with (and due to) strong irritant responses, this is now clearly not the case (Kreiling et al., 2008; Mehling et al., 2008). In 2022, both the BMA and FDA announced that they would no longer accept the LLNA for new drugs, the EMA also committed to accepting a set of three *in vitro* assay as sufficient to address the sensitization endpoint.

The other possibility, of course, is clinical evaluation using the human repeat insult path test (HRIPT). This 5-week hazard test is rarely taken due to cost, though actual clinical formulations are effectively evaluated clinically in the normal course of clinical development of a drug.

13.9.4 Photosensitization

Some compounds can act as photoantigens that require exposure to UV light to become photoactive haptens. The physicochemical characteristics of compounds can sometimes reveal them as potentially photoactive, particularly if they are photounstable to light in the UV range. There are several *in vivo* tests that are used for determining photosensitization. The two assays described here are similar to those previously described for DTH with the primary exception that the dermal test sites are exposed to a light source during the induction and challenge phases. Like the DTH assays, these assays may also include a second challenge dose or the use of various methods of abrasion and occlusion to increase dermal penetration of the test article. The methods outlined in the following are more thoroughly described in Gad and Chengelis (1998).

13.9.4.1 Harber and Shalita Method This method (Harber and Shalita, 1975) is similar to the Buehler test in that the compound is applied topically to guinea pigs without

the use of adjuvants; however, the test site is not occluded during exposure. During the induction phase, the compound is applied on alternate days during a 12-day period for a total of six applications. Thirty minutes after each application, the test sites are exposed to a sunlamp for 30 min and then to a black light for 30 min. The challenge dose is applied 21 days after the last induction exposure. Thirty minutes after application, the challenge sites are shielded with a 3 mm thick piece of glass, while the site is exposed to the black light for an additional 30 min. The glass filters out erythrogenic (causing redness) radiation of less than 320 nm that may confound scoring the reaction. The challenge sites are observed and scored for inflammatory reactions 24 h later.

13.9.4.2 Armstrong Method This test (Ichikawa et al., 1981) resembles the GPMT in that the FCA is injected intradermally at the test sites; however, covered Hilltop chambers are used to apply and occlude the test article at the test site as was described for the Buehler test. During induction, four intradermal injections of FCA are administered at the test site; the test article is applied to the Hilltop chamber, which is then applied over the test site and occluded. After 4 h, the patches are removed, and the test site is exposed to UV-A light (320–400 nm) for 30 min. Five additional applications of the test article (without FCA) with subsequent exposure to light are made on alternate days throughout the 11-day induction period. Nine to thirteen days after the last induction exposure, the animals are challenged for 2 h with a nonirritating concentration of the test article on an occluded Hilltop chamber. The patches are then removed, and the sites are exposed to the UV-A light. Each site is graded for inflammation 24 and 48 h after challenge.

Despite its extreme clinical importance, the evaluation of small molecule pharmaceutical for allergenic potential is extremely unreliable in nonclinical toxicology studies. First, a drug that has been proved to be immunogenic in a laboratory animal species may not necessarily be immunogenic in humans, and vice versa. Second, the subtle factors that determine whether an individual responds to an antigen with an IgG or an IgE response can hardly be extrapolated from one species to another. Thus, an immune response that manifests as an allergic response in a laboratory animal may not necessarily manifest as an allergic response in humans, and vice versa.

13.10 APPROACHES TO COMPOUND EVALUATION

As outlined previously, there are numerous assays available to assess the various end points that are relevant to immunotoxicity. Early in the development process, a new compound should be evaluated with regard to various factors that may flag it as a potential immunotoxin, including chemical struc-

tural or physiochemical properties (e.g., photoallergen) and therapeutic class (i.e., immunomodulators, anti-inflammatory drugs, and antimetabolites) (Herzyk and Bussiere, 2008). Compounds from therapeutic or structural classes that are known to be potential immunotoxins or immunomodulators should be evaluated for the effects in question on a case-by-case basis. With the exception of immunomodulators, protein products, and products of biotechnology, the majority of pharmaceuticals can be assessed for most forms of immunotoxicity during routine preclinical toxicity tests. In general, a well-conducted preclinical toxicity study can detect most serious immunotoxins in the form of altered clinical, hematologic, or histological end points (Haley et al., 2005). For example, possible effects on humoral immunity may be indicated from clinical observation of gastrointestinal or respiratory pathology, changes in serum total protein and globulin, and by histological changes in lymphoid cellularity. Likewise, effects on the cell-mediated response may be observed as increases in infections and tumor incidences and by changes in the T-cell compartments of lymphoid tissues. In the case of immunosuppressive drugs such as cyclophosphamide and cyclosporin A, the immune effects seen in rodents are similar to those observed in the clinic (Dean et al., 1987).

If perturbations are observed in any hematologic or histopathologic indicators of immunotoxicity, it is then prudent to follow up these findings with one or more of the following:

- Use of special immunochemical and cytological assays that can be performed retrospectively on samples taken from the animals in question
- Use of more specific *in vitro* assays to further assess effects on the pertinent target system and potential mechanism of activity
- Use of more specific *in vitro* and *ex vivo* assays to determine toxicological significance
- Inclusion of additional nonroutine parameters for immunotoxicity assessment in subsequent (longer-term) toxicity assays (can also include additional satellite groups for functional tests that may require coadministration of adjuvants, pathogens, or tumor cells)

13.10.1 Use of *in vivo* Tests

In vivo tests are more relevant indicators than are *in vitro* tests of immunotoxicity since the dynamic interactions between the various immunocomponents, as well as the pertinent pharmacokinetic (absorption, distribution, plasma concentrations) and metabolic factors, are taken into consideration. However, it is important to select the appropriate animal model and to design the protocol such that it will accurately reflect drug (or relevant metabolite) exposure to humans. For example, one should consider species variability when selecting the animal model, since biological

diversity may further obscure the ability to accurately predict human toxicity.

13.10.1.1 Species Selection When possible, the species selected should demonstrate similar pharmacology and toxicity profiles to those anticipated in the clinic. Thus, the test animals should metabolize the drug and express the same target organ responses and toxic effects as humans. Although the rat and dog are the most common species used in preclinical safety tests, they are not as well characterized and validated as the mouse for assessing effects on immune function. For most immunosuppressive drugs, rodent data on target organ toxicities and comparability of immunosuppressive doses have been reflective of what was later observed in the clinic. Immunosuppressive effects and the doses that produced them have been shown to be similar in the various species that are typically used in preclinical safety tests (Dean and Thurmond, 1987). An exception has been seen with glucocorticosteroids, which are lympholytic in rodents but not in primates (Claman, 1972; Haynes and Murad, 1985). Although some compounds may show different pharmacokinetics and pharmacological effects in rodents than in humans, rodents still appear to be the most appropriate animals for assessing immunotoxicity of non-species-specific compounds (Dean and Thurmond, 1987).

The appropriate animal model is also important when performing follow-up testing or additional mechanistic tests to further investigate findings observed as part of the routine preclinical safety tests. When possible, these studies should employ the same animals or animal model in which the change was initially observed for several reasons, as outlined by Bloom et al. (1987), including:

- The incidence of adverse effect may be low and not easy to reproduce.
- Another species may not be genetically susceptible to the toxic effect.
- The biological significance of the change is well defined in that model.
- If the change follows long-term exposure to the drug, reproducing the effect in another model may be costly and impractical.

13.10.1.2 Route and Treatment Regimen When possible, it is important to administer the compound by the route and treatment regimen most appropriate for demonstrating the specific response and/or reflecting the intended clinical route of administration. It is also necessary for the compound to be in the same dosage form (i.e., salt form, excipients, solubilizers) that will be used clinically. With the exception of tests for contact hypersensitivity, most of the *in vivo* tests can be carried out with a minimum of three dose levels, which are needed to assess a dose–response relationship.

Dose levels should range from the proposed clinical dose, or one that approximates the no effect level, to a maximum-tolerated (or limit) dose that is lower than the LD₁₀ but that produces some evidence of general toxicity (e.g., reduced body weight). A wide dose interval may be necessary to detect immune changes that show a nonlinear dose response. Proper dose selection is crucial for a meaningful interpretation of test results since severe stress and malnutrition may produce indirect immunotoxic effects that would confound a clear interpretation of the data.

For compounds such as antibiotics, with a relatively short duration of therapeutic exposure, a short treatment period of 1–2 weeks in the animal model is generally appropriate. Longer treatments may not be suitable for these drugs since animals can adapt to toxic doses or develop a tolerance by inducing enzymes that increase metabolism of the drug. However, for compounds with intended chronic or prolonged usage, animals should be treated at least daily for at least a month, to assess the cumulative effects of the drug.

13.10.2 Use of *in vitro* Tests

In vitro tests are useful as sensitive follow-up tests to determine potential effects or mechanisms of effects on specific cell types at the cellular and molecular levels (Urbisch et al., 2015). In addition, most are relatively simple to perform and *ex vivo* tests can be performed in conjunction with preclinical *in vivo* tests. There are several advantages to using *in vitro* tests, which are listed as follows:

- Specific cell types of humoral components of the immune system can be isolated and studied.
- Cells can be stimulated with various mitogens to assess their proliferative functions *in vitro*.
- For mechanistic studies, cells and their secretory products can be systematically studied in isolation and in various combinations to assess their interactions and cell-to-cell communications.

However, for general preclinical assessments and screening purposes, *in vitro* tests should be well validated and used cautiously for several reasons:

- They may over- or underestimate an effect or give contradictory results compared to *in vivo* tests.
- Most immunotoxic responses express a clear dose–response relationship that can be used for human risk assessment. However, it is more difficult to extrapolate *in vitro* concentrations than *in vivo* animal doses (plasma concentrations) to the clinical dose.
- It is difficult to simulate *in vitro* the interaction of all the various cell types and modulators of immune function that make up the *in vivo* system.

- Cells can be harvested from a variety of sources and each source may have a different sensitivity since they may be at various stages of maturation or activation.

13.10.3 Assessment of Immunotoxicity and Immunogenicity/Allergenicity of Biotechnology-Derived Drugs

This is an area outside of current ICH S8 guidance and yet of clinical importance to the safety of current new therapeutics. The decision on a suitable species for preclinical immunotoxicity assessment of biotechnology-derived drugs must be made on a case-by-case basis. In any case, the limits of predictivity should be clearly stated in the rationales for choosing a certain assay protocol. The biological activity together with species and/or tissue specificity of many biotechnology-derived pharmaceuticals (e.g., recombinant cytokines, therapeutic antibodies) often precludes standard toxicity testing designs in commonly used species (e.g., rats and dogs). The same holds for immunotoxicity testing (Shankar et al., 2007). The design of immunotoxicity testing programs for biotechnology-derived drugs should include the use of relevant species. A relevant species is one in which the test material is pharmacologically active due to expression of the receptor or an epitope (in the case of monoclonal antibodies). A variety of techniques (e.g., immunochemical or functional *in vitro* tests) can be used to identify a relevant species. In some cases, nonhuman primates may be the only suitable species available. When no relevant species exists, the use of transgenic mice expressing the human receptor or epitope may be accepted by regulatory agencies. The information gained from use of a transgenic mouse model expressing the human receptor is optimized when the interaction of the product and the humanized receptor has similar physiological consequences to those expected in humans. The entrance of “Follow-on Biologicals” into the marketplace has raised levels of concern that these may well lead to undesirable immunogenicity as a complication (Wadhwa, 2007).

In other cases, the use of the homologous animal protein instead of the human counterpart may be considered. While useful information may be also gained from the use of homologous proteins, it should be noted that the production process, range of impurities/contaminants, pharmacokinetics, and exact pharmacological mechanism(s) may differ between the homologous form and the product intended for clinical use. Thus, from a formalistic point of view, the test item used in such protocols is not identical to the drug substance to be assessed. Results from such studies can therefore only be weighed as “supportive data.” In such situations, it is highly recommended to discuss the testing strategy with the responsible regulatory agency for scientific advice. Where it is not possible to use transgenic animal models of homologous pro-

teins, it may be advisable to assess certain aspects of potential immunotoxicity *in vitro* using human material like PBMCs, monocyte-derived macrophages, or long-term cultivated cell lines of hematopoietic origin.

Most biotechnology-derived pharmaceuticals intended for human use are *per se* immunogenic in animals. The induction of antibody formation in animals is therefore not predictive of a potential for antibody formation in humans. In this regard, the results of, for example, a guinea pig anaphylaxis test, which is usually positive for xenogeneic protein products, are not predictive for reactions in humans. Such studies are therefore considered of little value for the routine evaluation of these types of products. It must be kept in mind that even humanized proteins may be immunogenic in humans. In most cases, reliable information on immunogenicity of biotechnology-derived drugs can therefore only be obtained during clinical studies. However, immunogenicity studies in animals using biotechnology-derived drugs may yield valuable information when comparing the immunogenic potential of a test compound with a biosimilar reference compound or between different production batches.

Even if immunogenicity assessment of biotechnology derived pharmaceuticals has limited predictivity for the human situation, measurement of antibodies associated with the administration of biotechnology-derived drugs should always be included in the design of a repeat-dose toxicity study (Wierda et al., 2001). Antibody responses should be characterized with regard to titer, number of responding animals, and neutralizing or nonneutralizing antibodies. Furthermore, the detection and quantization of antibodies should be correlated with any pharmacological and/or toxicological changes. Specifically, the effects of antibody formation on pharmacokinetic/pharmacodynamic parameters, incidence and/or severity of adverse effects, complement activation, or the emergence of new toxic effects should be considered when interpreting the data. Attention should also be paid to the evaluation of possible pathological changes related to immune complex formation and deposition.

13.10.4 Suggested Approaches to Evaluation of Results

Several rodent toxicity studies have shown impaired host resistance to infectious agents or tumor cells at exposure levels of drugs that did not cause overt signs of toxicity (Vos, 1977; Dean et al., 1982). One serious limitation to the incorporation of specific immunotoxicological evaluations into general use in safety assessment for pharmaceuticals is a lack of clarity in how to evaluate and use such findings. This problem is true for all new diagnostic techniques in medicine and for all the new and more sensitive tools designed to evaluate specific target organ toxicities. Ultimately, as we have more experience and a reliable database that allows us to correlate laboratory findings with

clinical experience, the required course of action will become clearer. However, some general suggestions and guidance can be offered:

- First, it is generally agreed that adverse effects observed above a certain level of severity should be given the same importance as any other life-threatening events when assessing biological significance. These are effects that are so severe that they are detected as part of the routine evaluations made in safety assessment studies. Such findings may include death, severe weight loss, early appearance of tumors, and the like. Findings such as significantly increased mortalities in a host resistance assay would also fit into this category.
- Second, there are specific end-point assays for which an adverse outcome clearly dictates the action to be taken. These end points include either immediate or delayed hypersensitivity reactions, because once the individual is sensitized, a dose–response relationship may not apply.
- Third, as with most toxicological effects, toxic effects to the immune system are dependent upon dose to the target site. The dose–response curve can be used to determine no-effect and low-effect levels for immunotoxicity. These levels can then be compared to the therapeutic levels to assess whether there is an adequate margin of safety for humans.

If we consider both the specific immunotoxicity assays surveyed earlier in the chapter and the arrays of end points evaluated in traditional toxicology studies, which may be indicative of an immune system effect, these guidelines leave many potential questions unanswered. As additional data on individual end points indicative of immune system responses are collected, the pharmaceutical toxicologist is challenged with various issues regarding assay interpretation and relevance to proposed (or future) clinical trials. For example, what do significant, but non-life-threatening, decreases in antibody response, lymphocyte numbers, macrophage functions, or host resistance in an animal mean about the clinical use of a drug in a patient? The intended patient population is clearly relevant here—if the disease is one in which the immune system is already challenged or incorrectly modulated, any immune system effect other than an intended one should be avoided. There are several additional considerations and questions that should be answered when evaluating the biological and clinical significance of a statistically significant immune response:

1. *Is there a dose response?* The dose response should be evaluated as a dose-related trend in both incidence and severity of the response. If there is a dose-related response, is the lowest dose (preferably plasma level)

at which the effect is seen near or below the target clinical dose (plasma level), and is there an adequate therapeutic margin of safety?

2. *Does the finding stand alone?* Is a change observed in only one parameter, or are there correlated findings that suggest a generalized, biologically significant effect? For example, are there changes in lymph node and spleen weights and morphological changes in these tissues to accompany changes in lymphocyte numbers?
3. *Is the effect a measure of function or a single endpoint measurement?* Functional measures such as host resistance of phagocytosis involve multiple cells and immunocomponents and, therefore, are considered to be more biologically relevant than a significant change in a single end-point measurement (e.g., T-cell number).
4. *Is the effect reversible?* Reversibility of a response is dependent on the drug itself, exposure levels/duration, and factors related to the test animal (metabolic capability, genetic susceptibility, etc.). Most effects produced by immunosuppressive drugs have been shown to be reversible after cessation of therapy, such as those produced during cancer chemotherapy. However, if a tumor develops before the immune system is restored, the effect is not reversible, as is the case of secondary tumors related to chemotherapy.
5. *Is there sufficient systematic toxicity data available at levels that demonstrate adequate exposure?* If a study was designed such that there was insufficient exposure or duration of exposure to potential lymphoid target tissues, the test protocol may not be adequate to demonstrate an adverse effect.

In general, a well-conducted long-term study in two species, with no indication of immunotoxicity, based on the considerations outlined previously, should be adequate to evaluate the potential for drug-induced immunotoxicity. If the results from these studies do not produce evidence of immune specific toxicity after examination of standard and/or additional hematologic, serum chemical, and histopathologic parameters, then additional testing should not be indicated. However, if there are structure–activity considerations that may indicate a potential for concern, or if significant abnormalities are observed that cannot be clearly attributed to other toxicities, then it is important to perform additional tests to fully assess the biological significance of the findings.

13.11 PROBLEMS AND FUTURE DIRECTIONS

There are some very pressing problems for immunotoxicology, particularly in the context of pharmaceuticals and

biologic therapeutics and the assessment of their safety. Unlike industrial chemicals, environmental agents, or agricultural chemicals, pharmaceutical products are intended for human exposure, are usually systemically absorbed, and have intentional biological effects on man—some of which are intentionally immunomodulating (interleukins, growth factors) or immunotoxic (cyclosporin, cyclophosphamide).

13.11.1 Data Interpretation

The first major issue was presented and explored in the preceding section. This is how to evaluate and utilize the entire range of data that current immunotoxicological methodologies provide to determine the potential for immunotoxicity and how to interpret the biological significance of minor findings.

13.11.2 Appropriate Animal Models

As previously addressed, most routine preclinical toxicology tests are performed with rats and dogs; therefore, toxicity, pharmacokinetic, and pharmacology data are most abundant for these species. However, most immunological parameters are best characterized and validated with mice. In addition, the NTP test battery was developed for the mouse, and some of these assays cannot be readily transferred to the rat. Over the last few years, several laboratories have begun adapting tests to both the rat and the dog (Bloom et al., 1987; Thiem et al., 1988); however, efforts need to continue along these lines to further our understanding of the immune responses in these species and how they correlate with other animal models and man.

13.11.3 Indirect Immunotoxic Effects

A problem related to data interpretation is how to distinguish secondary effects that may indirectly result in immunotoxicity from the primary effects of immunotoxicity in preclinical toxicity studies. Various factors may produce pathology similar to that of an immunotoxin, including:

- Stress in a chronically ill animal as related to general toxicity, such as lung or liver damage, can result in immune suppression.
- Malnutrition in animals with drug-induced anorexia or malabsorption can trigger immune suppression.
- Infections and/or parasites may also modulate immune parameters.

These indirect factors must be systematically ruled out, and additional mechanistic studies may be necessary to address this problem. The potential for some indirect effects may be assessed through histopathologic evaluation of endocrine organs such as the adrenals and pituitary.

13.11.4 Hypersensitivity Tests

Probably the largest immunotoxicity concern in clinical studies is unexpected hypersensitivity reactions. While the available guinea pig- and mouse-based tests for delayed contact hypersensitivity resulting from dermal exposure are generally good predictors, there are currently no well-validated models for either immediate or (dermal) delayed hypersensitivity responses resulting from either oral ingestion or parenteral administration. Yet these two situations are the largest single cause for discontinuing clinical trials.

One assay that may hold some promise for delayed hypersensitivity is an adoptive transfer-popliteal lymph node assay (Klinkhammer et al., 1988). This assay, based on the techniques previously described for the popliteal lymph node assay, allows assessment of hypersensitivity following systemic exposure of the drug. Donor mice are first injected with drug for five consecutive days. After a 4-week latency period, potentially sensitized T cells obtained from the spleen are injected into the footpad of a syngeneic mouse together with a subcutaneous challenge dose of the drug. Two to five days after the cell transfer, the popliteal lymph nodes are measured and observed for evidence of a response (enlargement). Once this assay is validated, it should allow for a more relevant assessment of hypersensitivity for drugs that are administered systemically (Gleichmann et al., 1989).

13.11.5 Anaphylaxis Tests

With regard to antibody-mediated hypersensitivity, anaphylaxis, immediate hypersensitivity responses require exposure to large molecules (3000 or greater MW), which can be either innately large molecules or small molecules bound to macromolecule carriers.

While there are currently no regulatorily approved tests for potential anaphylaxis, the Japanese did have three methods (Maki, 1997). These three methods have been used extensively to assess the induction of drug-specific (type I) anaphylactic reactions:

- The PCA assay
- The ACA assay
- The ASA assay

All three assays are normally conducted in guinea pigs, which is the only rodent species that develops symptoms of severe anaphylactic reactions and even fatal allergic shock. However, the usefulness of these assays for the safety assessment of drugs is considered limited. Since IgE as well as IgG antibodies can cause anaphylactic reactions in guinea pigs, a positive result in any of the three assays can only be weighted as proof of immunogenicity but not allergenicity of a drug. The PCA, ACA, and ASA assays are therefore not

requested or recommended for the routine evaluation of allergenicity of investigational new drugs by any regulatory agency.

The situation is as unsatisfactory for the prediction of a type II and type III allergenic potential of drugs. Although there are examples of drugs that are associated with type II and type III hypersensitivity reactions, there are no standard nonclinical methods for predicting these effects. Manifestations of both kinds of immunopathies are often indistinguishable from direct, nonimmune-mediated drug toxicity. Thus, in some instances of hemolytic anemia, vasculitis, or glomerulonephritis, which may be observed during standard toxicity studies, follow-up studies should be considered to determine if antibody-mediated immune mechanisms are involved.

Since all available nonclinical assays to assess the antibody-based allergenic potential of drugs have a limited predictivity for the human situation, detection of drug immunogenicity should already be considered to be a potential safety alert. Whether proven immunogenicity in a nonclinical test does in fact lead to allergic implications in patients can only be convincingly demonstrated (or excluded) in clinical trials or even later still during postmarketing surveillance of the approved drug.

The most robust and predictive procedures available for assessment of allergenicity are those measuring the skin sensitizing potential of topically administered drug substances. In these cases, a drug has to permeate the keratinized skin, bind to MHC molecules of dermal APCs, and stimulate CD4⁺ T cells for proliferation and T_H1 differentiation. Any drug that is able to induce the aforementioned sequence of events will inevitably induce an inflammatory reaction, a so-called DTH reaction, after subsequent challenge exposure to the skin. Thus, in this special situation of dermal sensitization, a proof of immunogenicity is also a proof of allergenicity.

When a drug is intended for topical administration (dermal, ocular, vaginal, rectal), the skin sensitizing potential of the drug should be determined using an appropriate assay based on sensitization and challenge as part of nonclinical safety evaluation. The most common methods for evaluating the dermal sensitizing potential of drugs have been the Buehler assay (BA) and the GPMT. Both *in vivo* guinea pig-based methods are reliable and have demonstrated a high correlation with known human skin sensitizers. Techniques using mice, like the mouse ear swelling test, which uses an induction and challenge pattern similar to the traditional guinea pig tests, or the murine LLNA, correlate well with traditional guinea pig tests. Especially the LLNA, which is designed to detect lymphoproliferation in draining lymph nodes of the exposition area instead of inflammation following challenge, gives quantitative results. Furthermore, the assay is now accepted by most regulatory agencies with regard to reduction, refinement, and replacement of animal experimentation.

Pseudoallergic (anaphylactoid) reactions, which are independent of antigen-specific immune responses, result

from direct drug-mediated histamine release or complement activation. Anaphylactoid reactions can be differentiated from true IgE-mediated anaphylaxis by *in vitro* testing of drug-induced histamine release from mast cell lines or by the detection of activated complement products in serum of animals showing signs of anaphylaxis.

13.11.6 Autoimmunity

Traditional methods for assessing immunotoxicity as part of routine preclinical toxicity tests are primarily geared toward the detection of immunosuppressive effects. Although it is possible to incorporate clinical methods for detecting immune complexes and autoantibodies into the preclinical test protocols, the significance of adverse findings is ambiguous. Since these effects have a genetic component to their expression, the relevance of findings in animals is of questionable significance, particularly since these findings in the clinic do not always correlate with pathological effects.

13.11.7 Functional Reserve Capacity

As previously discussed, the immune system has a tremendous reserve capacity that offers several levels of protection and backups to the primary response. As a consequence, this functional reserve can allow biologically significant, immunotoxic insults to occur without the appearance of morphological changes. Furthermore, adverse effects may remain subclinical until the organism is subjected to undue stress or subsequent challenge. Thus, there is some concern that routine immunopathologic assessments by themselves may not be sufficiently sensitive to detect all immunotoxins, particularly when testing is conducted in a relatively pathogen-free, stress-free laboratory environment.

13.11.8 Significance of Minor Perturbations

Although the immune system has a well-developed reserve capacity, some of these systems may act synergistically rather than independently. For instance, a macrophage can recognize and kill bacteria coated with antibodies more effectively than can either the macrophage or antibodies alone. Thus, even minor deficiencies and impairments may have some impact on the organism's ability to fend off infection or tumors, particularly if the organism is very young, old, ill, stressed, genetically predisposed to certain cancers, or otherwise immunocompromised. These considerations lead to some additional questions that must be addressed:

- What level of immunosuppression will predispose healthy or immunocompromised individuals to increased risk of infections or tumors?

- Will slight disturbances or immunosuppression lead to a prolonged recovery from viral or bacterial infections?
- Will slight up-modulation for extended periods result in autoimmune diseases or increased susceptibility to allergy?
- Are individuals that are slightly immunosuppressed at higher risk of developing AIDS after exposure to HIV?

13.11.9 Biotechnology Products

Immunotherapeutics such as interferons and interleukins hold tremendous promise for those diseases where malfunctioning of the immune system is not the root of pathogenesis. Likewise, many of the new approaches to therapy of yet untreatable diseases are aimed at modulating the body's own immune system. Many of the new therapeutics coming from biotechnology are proteins of human origin. As such, they can evoke antibody responses in nonhuman species that are not indicative of what will be seen in patients. Meaningful evaluations must allow the toxicologist to discriminate between those responses that are relevant to clinical development/utilization and those that are not. With "follow on" biologic therapeutics now entering the marketplace, there is a greater risk of potential unwanted immunogenicity (Wadhwa, 2007).

The quantification of antigenicity differences between mutated antigens relies heavily on experiments such as antibody- or antiserum-binding assays or the counting of amino acid mutations at essential antigenic sites. Among these experimental approaches, the HI test has traditionally been performed to determine the antigenic variations between current circulating influenza virus strains and candidate vaccines. Moreover, comprehensive serological tests have been performed on both experimental animals and vaccinated or infected patients to identify the serological relationship between the subtypes of Dengue virus (DENV). Typically, immunological experiments require extensive antibody or antiserum preparation, dilution, and standardization. Thus, computational algorithms for estimating the antigenic distance between multiple protein antigens in a high-throughput manner are highly desired. Regarding *in silico* approaches, there have been multiple efforts aimed at antigenic distance prediction between influenza vaccines and circulating strains by generating theoretical models based on the sequence or the structure of antigen proteins. For instance, the mutations between two antigen proteins were counted at antigenic sites, and the numbers of mutations were correlated with the experimental distance. Additionally, structural features could be derived from antigen proteins to establish an antigenicity prediction model based on the spatial context of the antigenic sites. The collection of sequences and the experimental dataset could be important for the detection of mutations and the design of sequence-based and structure-based antigenicity

prediction models. However, the construction of *in silico* methods is still a great challenge due to the lack of standard benchmark datasets. (Qiu et al., 2020)

13.12 SUMMARY

Besides unexpected up or down modulation of immune function, the major safety and regulatory concern foreseen in therapeutic proteins is immunogenicity. Regulatory guidelines have been promulgated by both FDA and EMA concerning both what testing is required but also how test methods should be developed and valuable.

In summary, it is the role of preclinical immunotoxicology testing to allow us to identify potential immune hazards early in development, before they are found in the clinic, and to provide us with a mechanistic understanding for the basis of these effects so that we may direct the development of alternative agents and/or treatment regimens to avoid them. The challenge for the toxicologist is to determine the appropriate course of action for evaluating each unique drug and to differentiate the desired therapeutic effects from the undesired and potentially adverse effects.

NONRODENT ANIMAL STUDIES

14.1 INTRODUCTION

Most safety assessment studies are conducted in rodents (rats, mice, guinea pigs, and hamsters) or their close “cousins” rabbits (though rabbits are also considered nonrodents for some purposes). Outside of the pharmaceutical, medical device, and veterinary product industries, it has become rare for the practicing toxicologist to have close familiarity with the nonrodent animal species addressed in this chapter. Indeed, it is unlikely that a toxicologist has received any significant academic experience or training with these species. For purposes of safety assessment findings in nonrodent species are generally considered more relevant to predict human risk than those performed in rodents. Additionally, use of these species in the European Union (EU) even for therapeutics has become very difficult at best. However, the proper use of nonrodent species is essential in the evaluation of potential new therapeutic entities on both scientific and regulatory grounds. Indeed, there are numerous studies showing significantly better concordance as to pharmacokinetics, target organs, and tolerance between man and nonrodents with man than with rodents for detection of adverse responses to pharmaceuticals (Olson et al., 2000; Emerson and Cole, 1983; Peckham, 1980). This is tacitly recognized in regulatory practice for those new product development plans where a single species is deemed appropriate and sufficient (medical devices, protein therapeutics, and 505(b)(2) approval candidates) and the single species is overwhelmingly a nonrodent. This critical aspect of nonrodents is reflected by recent books focused on such use in single species (the nonhuman primate [NHP] in Bluemel et al., 2015 and the minipig in McAnulty et al., 2010).

In addition to rodent studies, regulatory guidelines for pharmaceuticals require that repeated-dose safety studies of

up to 9 months (in the United States, where 12 months is also infrequently a regulatory requirement—6 months elsewhere) in duration be conducted in a nonrodent species. These nonrodent species also tend to be closer to man than do rodents in many aspects including gastrointestinal absorption and transit times (DeSesso and Williams, 2008). The most commonly used nonrodent species is the dog, followed by the NHP, and then the pig (though the minipig is gaining in frequency and scope of use). Another nonrodent model used to a limited extent in systemic safety evaluation is the ferret. The major objectives of this chapter are (i) to discuss differences in rodent and nonrodent experimental design; (ii) to examine the feasibility of using the dog, NHP, pig, and ferret in safety assessment testing; and (iii) to identify the advantages and limitations associated with each species.

14.2 COMPARISON BETWEEN RODENT AND NONRODENT EXPERIMENTAL DESIGN

14.2.1 Number of Animals

One of the main differences in experimental design between rodent and nonrodent safety studies is the number of animals used (Table 14.1). In general, approximately nine times as many rodents are used in toxicity studies, as compared to nonrodents. This difference is reflected in the 2012 estimates of overall usage of animals in the United States (891 161 nonrodents total) as published by the US Department of Agriculture (USDA), which showed that only about 10% of the animals used in general research for that year were either NHPs (7.2%), pigs (6.3%), or dogs (7.6%). It is estimated that 93% of the animals used in research are not included in this count. The smaller number of nonrodents used is related

TABLE 14.1 Comparison of Rodent and Nonrodent Experimental Design

Duration of Study	The Total Number of Animals on Study (No./Group/Sex)			
	Rat	Dog	Pig	Monkey
4 weeks	360 (20) ^a	40 (4)	40 (4)	32 (4)
13 weeks	280 (20) ^{a,b}	48 (6) ^b	48 (6) ^b	48 (6) ^b
52 weeks/9 months	360 (10) ^{a,b}	64 (8) ^b	64 (8) ^b	48 (6) ^b

^a Includes satellite animals for pharmacokinetic evaluation.

^b The number of animals/group includes several animals.

in part to the higher costs associated with their purchase, housing, and maintenance and in part to their limited use in other areas of research.

14.3 DIFFERENCES IN STUDY ACTIVITIES

14.3.1 Blood Collection

In rodent studies, many satellite animals (often close to the number used in the main study phase) are usually needed for pharmacokinetic blood sampling, whereas with most nonrodent species adequate, blood samples can be collected from the main study animals without compromising their health status or study results (Diehl et al., 2001).

14.3.2 Dosing

Capsule dosing is probably the most appropriate route of oral administration for dogs and pigs and gavage for monkeys and ferrets. Nasogastric gavage is also occasionally used for dogs and primates.

14.3.3 Handling of Animals

Once rodents are acclimated to handling, they are generally relatively easy to work with. In contrast, some nonrodent species, such as NHPs and pigs, are often difficult to handle because of their size, strength, emotionality, and aggressiveness. This can make the conduct of routine study activities (such as dosing, blood collection, and recording electrocardiograms [ECGs]) relatively time-consuming, as well as stressful to the animals (Gad, 2015).

14.3.4 Behavioral Evaluation

Behavioral assessment of nonrodents is generally more difficult than evaluation of rodents because of their larger size, difficulties associated with handling and manipulation, and their greater awareness of and reactivity to the experimenter.

Such factors can confound detection and/or interpretation of more subtle test compound-related behavioral changes. However, there is now a published and validated functional observational battery (FOB) for neurological exams of dogs, and it is widely used (Gad et al., 2003).

14.4 NONRODENT MODELS

This section is devoted to the definition and comparison of the four nonrodent animal models (dog, NHP, pig, and ferret) in terms of experimental procedures, environmental and dietary requirements, and advantages and disadvantages of use in safety assessment testing. The dogs (beagles in toxicology) and pigs and ferrets are purpose bred for use in research. Indeed, contrary to PETA, it is no longer legal to use dogs sourced otherwise from “class B” sources. NHPs are generally wild caught.

14.5 DOG

14.5.1 Environmental and Dietary Requirements

Typical housing for laboratory dogs consists of stainless steel (of dimensions appropriate to the dog’s size) or indoor pens (typical dimensions are 3 ft, 8 in. wide, 8 ft high, and 10 ft long). The two important aspects of the laboratory dog’s environment are the need for exercise and socialization. Recent amendments to the USDA’s Animal Welfare Act require that an exercise and socialization program be established for dogs maintained in a laboratory environment (APHIS, 1989). Difficulty often arises in establishing a program that will be truly beneficial to the animals. One important consideration is whether dogs should be exercised as a group or individually. Studies have demonstrated that dogs exercised alone tend to spend most of their time walking or investigating the area rather than jumping or running (Campbell et al., 1988), which suggests that group exercise is more beneficial.

The need for a certain degree of socialization is also important in terms of both dog–dog and dog–human contact. If at all possible, dogs should share a cage or pen with another animal. One on-study approach undertaken by some laboratories has been to allow dogs of the same sex and treatment group to have daily contact with each other, usually from early evening to early morning. If study dictates do not make this approach feasible, efforts should be made to ensure the animals are housed in such a way that they have visual, auditory, and olfactory access to each other.

The recommended dry-bulb temperatures and relative humidity ranges for dogs are 64.4–84.2°F (16–27°C) and 30–70%, respectively (National Research Council [NRC], 2011). Increases in temperature and high humidity are

of particular concern because of the dog's limited capacity to dissipate heat (primarily through panting and, to a lesser extent, through radiation and conduction). Dogs would likely not survive exposure for extended periods of time to environments where the temperature is in excess of 40°C and there is 40% relative humidity (Norris et al., 1968).

While the dog is a carnivore, it is able to adapt to an omnivorous diet. Requirements for dietary sources of energy, amino acids, glucose precursors, fatty acids, minerals, vitamins, and water have been established based on recommendations by the National Research Council (NRC, 2006). Adult beagles maintained in a laboratory environment function well with one feeding of standard laboratory chow per day. In safety assessment testing, however, some compounds may induce serious dietary deficiencies through induced loss of appetite, malabsorption, or vomiting, and, in these cases, it may be advisable to provide a dietary supplement.

The dog's requirement for water appears to be self-regulated and depends on factors such as the type of feed consumed, ambient temperature, amount of exercise, and physiological state; therefore, in most cases, dogs should have free access to water.

14.5.2 Common Study Protocols

The dog is the most commonly used nonrodent species in safety assessment testing (i.e., acute, subchronic, and chronic studies and cardiovascular safety pharmacology studies). The exception to this is its use in developmental toxicity and reproductive studies. For developmental toxicity studies, the dog does not appear to be as sensitive an indicator of teratogens as other nonrodent species such as the monkey (Earl et al., 1973) and the ferret (Gulamhusein et al., 1980), and, for reproductive studies, the dog is not the species of choice because fertility testing is difficult to conduct (due to prolonged anestrus and the inability to predict the onset of proestrus) and there is no reliable procedure for induction of estrus or ovulation.

Examples of experimental designs and suggested timing of various study activities for 4- and 13-week dog studies are shown in Tables 14.2 and 14.3, respectively. Beagles are generally in the age range of 6–9 months at study start, and the number of animals per sex per treatment group (*N*) will depend on the duration of the study. For a 2- to 4-week study without a reversal phase, *N* will likely be 4, whereas for a 26-week or 1-year study, *N* will be larger (e.g., *N* may be 9 including 3/sex/group for the reversal phase); it should be noted that it has become an Food and Drug Administration (FDA) expectation for high-dose and control groups to include animals to allow the assessment of recovery.

Dogs should be selected for study use on the basis of acceptable body weights, urinalysis, and clinical pathology findings, as well as physical, ophthalmic, and electrocardio-

TABLE 14.2 Four-Week Dog or Primate Toxicity Study

Experimental design
 Four to five groups (including a control group)—4/sex/group main groups, plus extra in high-dose and control groups to evaluate recovery
 Repeated daily dosing for 28 or 29 days
 Necropsy starting on day 29

Study activities
 Daily observations: pretreatment and twice daily during the study period
 Physical examinations: pretreatment and after dosing during weeks 2 and 4
 ECG: pretreatment and after dosing during weeks 2 and 4

graphic evaluations. To minimize familial effects, efforts should be made to ensure that no two littermates of the same sex are assigned to the same treatment group.

Because most, if not all, study-related activities are conducted in the same dogs, the stress induced by repeated manipulation of dogs for activities such as blood collection, ECG, and physical examinations needs to be taken into consideration. Efforts should be made wherever possible to separate study activities by several days.

14.5.3 General Study Activities

14.5.3.1 Dosing Techniques The most frequently used route of administration in dog safety assessment studies is oral. Dosing by capsule is usually the preferred oral route in the dog. Gavage is also used, but is a more labor-intensive technique, and there is always the possibility of gavage error or aspiration. Since dogs have a natural tendency to vomit, it is recommended that they be sham dosed with empty capsules or gavaged with a water solution for several days prior to starting a study so that they can become acclimated to the dosing procedure. If the test substance is irritating (and therefore proemetic), the use of enterically coated capsules should be considered. Attention should be paid, however, to the time course of emesis. If it follows dose administration by more than 4–6 h, the cause will not have been due to the gastric irritation, as the material will have already exited the stomach.

Next to oral dosing, the most common dosing route for dogs is intravenous. For bolus or limited infusion intravenous dosing, the femoral, cephalic, and saphenous veins are commonly used. For continuous infusion, the jugular is often the vein of choice, and the procedure will require surgical preparation for either a direct line catheterization or subcutaneous insertion of a vascular access port (a rigid, multipuncturable reservoir equipped with an indwelling catheter).

Other routes of administration used less commonly in dog safety studies are subcutaneous, intramuscular (IM), intraperitoneal, rectal, and vaginal and dermal.

14.5.3.2 Clinical Observations and Physical Examinations

Daily clinical observations in dog safety studies, usually conducted pretreatment (prior to cage cleaning) and at a specified time(s) after dosing, consist of a home cage observation with notation of clinical signs indicative of poor health (such as salivation, weight loss, abnormal feces, and vomitus) or abnormal behavior (such as reduced activity or increased aggression).

Physical examinations are conducted less frequently and generally involve the evaluation of gait, mobility, demeanor, and reflexes (pupillary, corneal, patellar, wheelbarrowing, hopping, etc.), as well as an examination of the head (eyes, ears, mouth, teeth, gums, and tongue), body (palpation for

signs of masses and nodal swellings), and urogenital and anal regions.

14.5.3.3 Feed Consumption Feed consumption is relatively easy to measure in the dog, since dogs do not usually spill much of their feed. Generally, the full feed bowl is weighed at the beginning and the empty bowl at the end of the feeding period (usually a 4 h period). This is repeated over two or three consecutive days and the average daily feed consumption calculated from the numbers.

14.5.3.4 Electrocardiograms The collection of recorded ECGs in test dogs has become increasingly of interest due to the concurrence to the QT prolongation by drugs and International Conference on Harmonization (ICH)/FDA/EMA-mandated evaluation studies. Traditionally, a 10-lead system, consisting of the bipolar leads (I, II, and III), the augmented unipolar leads (aVR, aVL, and aVF), and the unipolar precordial leads (V10, CV6LL (V2), CV6LU (V4), and CV5RL (rV2)), has been recommended for dogs in the conscious state (Detweiler et al., 1979; Detweiler, 1981). For toxicity studies, dog ECGs are usually recorded by technical personnel and read at a later time by a veterinary cardiologist. Depending on the length of the study and the pharmacological–toxicological profile of the test compound, ECGs may be recorded as frequently as every day or as infrequently as every 3 months. Dog ECGs can also be highly variable. Factors that can affect the quality of the tracing include the positioning of the electrodes, the positioning of the dog, and the degree of nervousness and excitability of the animal. Conditioning the dogs to the electrode clips and the recording position (usually sphinx or right lateral recumbency) during the pretreatment period will help improve the quality of the recording.

The use of surgically implanted sensors to be able to remotely monitor electrophysiology, heart rate, blood pressure, and blood gases has become very common for cardiovascular safety pharmacology studies. It should always be the case using such dogs that a concurrent evaluation of baseline and vehicle effects be performed prior to that of acute drug grounds. Such sensors allow us to effectively monitor an increasing number of physiological and biochemical biomarkers in a continuous manner.

14.5.3.5 Blood and Urine Collection

As mentioned previously, serial blood samples can be fairly easily collected from the dog. The jugular vein is probably the most commonly used vein because of its size and accessibility. Other veins used less frequently are the cephalic, femoral, brachial, and saphenous.

Due to the difficulty in obtaining sufficient volumes of urine in dogs over short collection periods, urine is usually collected overnight (~16–17 h period) in stainless steel metabolism cages. It is recommended that a sample for urinalysis be

taken early in the collection process and that all samples be collected in light-resistant containers to help avoid problems such as dissolution of urine casts, increased bacterial activity, and breakdown of bilirubin with exposure of the sample to light.

14.5.4 Advantages and Disadvantages

Some of the advantages and disadvantages of using the dog in safety assessment studies are listed in Table 14.4. With respect to its medium size and even temperament, the beagle is certainly a desirable nonrodent model. The relative ease in handling beagles makes them suitable for activities such as serial collection of blood samples and recording of ECGs.

Disadvantages include a wide variation in size and body weight and a loud, penetrating bark. The large amount of space required to house dogs and the current emphasis on regular exercise may also be disadvantages. Test compound requirements are generally higher for the dog than for either the NHP or ferret when these are alternatives to nonrodent species used in safety testing. This may be a problem in the early period of drug development when compound availability is often limited. Other problems center around the dog's tendency to vomit, which can be a disadvantage when compounds are orally administered, and the fact that, unlike rodents, studies requiring a large number of dogs need careful advance planning to ensure that a sufficient number of animals of the appropriate age can be obtained in a timely manner.

14.6 THE FERRET

The ferret, *Mustela putorius furo*, is a small carnivore that has become an increasingly popular species in various areas of research including anatomy, virology, bacteriology, physiology (gastrointestinal, pulmonary, and cardiovascular), pharmacology, neurology, teratology, and, to some extent, toxicology. The reader is referred to the excellent review by Fox (1988) on the biology and diseases of the ferret and to

TABLE 14.4 Use of the Beagle in Safety Assessment Studies

<i>Advantages</i>
Medium size
Moderate length of hair coat
Adaptability to living in group housing
Ease of handling (e.g., dosing, blood collection, and ECG)
<i>Disadvantages</i>
Variation in size and body weight
Loud, penetrating bark
Greater test compound requirements than smaller nonrodent species
Availability
Exercise and housing requirements

the chapter in Gad (2015) or the recent paper by Gad (2000) on the ferret as an animal model in toxicology. Since 1990, the literature has reported on work done by Pfizer, Hoffman-La Roche, Gilead, Bristol-Myers Squibb, Merck, Yamanouchi, Procter & Gamble, Abbott, and Glaxo Wellcome using ferrets in pharmaceutical development. The ferret is also the species of choice for respiratory virus (especially influenza) efficacy studies. Most recently, Fox and Marini (2014) published a comprehensive volume on biology and disease of the ferret.

14.6.1 Environmental and Dietary Requirements

For reasons of environmental control, ferrets used in safety assessment studies should be housed indoors. It has been suggested that an optimal temperature range for the ferret is 40–65°F (4–18°C), while relative humidity should be maintained in the range of 40–65% (Fox, 1988). The ferret does not tolerate heat well due to its lack of well-developed sweat glands; the primary method of regulating heat loss appears to be through panting (Moody et al., 1985).

Since ferrets are seasonal breeders, the female being monestrous and an induced ovulator, the breeding cycle can be controlled by varying the length of exposure to artificial light. For safety studies, it is desirable to prevent both estrus in females and increased sexual activity in males; thus, it has been recommended that the light period be kept short (Fox, 1988). In this laboratory, a 9 h light/15 h dark cycle has been used successfully for this purpose.

Ferrets should be housed in well-ventilated rooms that provide at least 10–15 air changes per hour. Good ventilation is important, since ferrets are susceptible to respiratory viral infections. Additionally, there is a need to dissipate the musky odor of the animals. While housing standards for ferrets are not specified in the NRC (2011), space requirements of 49×46×46 cm have been defined by other groups (Wilson and Donnoghue, 1982). Stainless steel cat or rabbit cages equipped with a drop pan to catch feces and urine are a suitable form of primary housing for ferrets. Ferrets are more content when they have access to a small, secluded nesting area within their cage in which they can sleep, such as hammocks. The use of paper to line the cage or drop pan is not recommended, since the ferrets are likely to eat it. For socialization purposes, ferrets should be housed as a group or have visual access to neighboring ferrets if housed individually.

Since ferrets eat only their caloric requirements, and since their gastrointestinal transit time is short (3–5 h), it is recommended that they receive diet ad libitum. Only one of the available standardized ferret chows commercially available should be fed. The most important dietary variable is the quality of the protein, and ferrets appear to do best with a high percentage of animal protein in their diet (Morton, 2010). Feed consumption will be higher in the fall and winter and lower in the spring and summer. Hairball laxative is essential

during the spring and summer months when the animals experience considerable hair loss. Water should be available at all times.

14.6.2 Study Protocols

Historically, the ferret was used more often in teratology, reproductive (Hoar, 1984), and acute safety studies than in repeated-dose studies (4–52 weeks in duration). This has changed since 2000, however, and the use of the ferret in pivotal repeated-dose safety assessment testing (Thornton et al., 1979; Hart, 1986; Haggerty et al., 1989) has increased particularly for vaccines.

An example of the experimental design for a 4-week pivotal study in ferrets is shown in Table 14.5. Young adult ferrets are usually in the age range of 9–11 months at study start, and there should be a sufficient number of animals in each group for statistical confidence (generally in the range of six to eight animals per sex per group reflecting the high degree of intergroup variability in the species). For longer-term studies, the number of animals per group would be increased to include reversal group animals (three to four animals per sex per dose group).

Assignment of ferrets to a study should be based on evaluation of pretreatment clinical signs and body weights, as well as physical, electrocardiographic, and ophthalmological findings.

For longer-term studies, females should be spayed to avoid the development of aplastic anemia, which will occur if the animals come into heat and are not bred (Morton, 2010).

As with dogs, efforts should be made to separate study activities as much as possible to minimize the stress of multiple activities being performed in the same animals.

TABLE 14.5 Four-Week Ferret Toxicity Study

Experimental design

Five groups (including a control group)—7/sex/group

Repeated daily dosing for 28 or 29 days

Necropsy starting on day 29

Study activities

Daily observations: pretreatment and twice daily during the study period

Physical examinations: pretreatment and after dosing during weeks 1, 2, and 4

ECG: pretreatment and after dosing during weeks 2 and 4

Ophthalmic examinations: pretreatment and during week 4

Body weight: pretreatment, twice weekly, and prior to scheduled necropsy

Feed consumption: pretreatment and weekly during the study

Clinical lab: pretreatment, week 2, and prior to scheduled necropsy

Urine collection: pretreatment and during weeks 2 and 4

Pharmacokinetic samples: blood collected at specified times after dosing on days 1 and 28

14.6.3 General Study Activities

14.6.3.1 Dosing Techniques Oral dosing of ferrets is usually done by gavage. One method is to hold the ferret perpendicular to the floor and insert the appropriate size stainless steel gavage needle into the animal's mouth, back into the esophagus, and down toward the stomach. Confirmation of correct positioning of the tube can be determined by visual inspection of the aspirate. As with dogs, ferrets have a tendency to retch or vomit, and daily gavage with a water solution for several days prior to starting a study (for adaptation purposes) is recommended.

Repeated daily intravenous dosing in the ferret is generally considered to be technically difficult and time-consuming; the use of an indwelling catheter is recommended (Moody et al., 1985). There are, however, reports in the literature of subchronic intravenous dosing (three times weekly for 3 months) of the ferret via the caudal vein (McLain et al., 1987).

Dosing techniques, such as intramuscular, intradermal, subcutaneous, and intraperitoneal administration, can be used for the ferret. Care needs to be taken, however, when administering lipophilic compounds by the subcutaneous or intradermal routes to avoid inadvertently injecting compounds into the ferret's thick layer of subcutaneous fat, which can result in poor absorption (Moody et al., 1985).

14.6.3.2 Clinical Observations and Examinations Daily clinical observations will usually begin the week prior to study start and continue twice daily (pre- and postdosing) throughout the study. Ferrets are observed in their home cage for signs of physical debilitation (such as abnormal feces and vomitus), behavioral abnormalities, hair loss, swelling of the vulva (females), and testicular prominence (males). A physical examination should periodically be made and should include measurement of rectal temperature; observation of general demeanor and activity; palpation of the head, thorax, and abdomen; examination of the eyes, ears, and body orifices; and testing of the pupillary and patellar reflexes.

14.6.3.3 Feed Consumption Feed consumption can be measured over two to three consecutive days, and the average daily intake calculated. A problem with measuring feed intake in ferrets is their tendency to dig through their feed bowl, which often results in an unacceptable amount of spillage. Use of a feed follower may help reduce the spillage.

14.6.3.4 Electrocardiograms Most electrocardiographic evaluation in the ferret has been previously done in the anesthetized animal, though sensors may be surgically implanted. This allows ECGs to be recorded using the bipolar (I, II, and III) and augmented (aVR, aVL, and aVF) leads. It is quite possible to obtain fairly good-quality ECGs in the conscious

ferret using leads I, II, and III. The standard position used for recording ECGs in the conscious or anesthetized ferret is right lateral incumbency. ECGs have also been measured in the ferret using surface electrodes placed between two points on the chest, with the signals being led off to an amplifier by a long, flexible cable and recorded on magnetic tape for later analysis (Andrews et al., 1979). The advantage of such a system is that the animals are allowed to move freely during the recording.

14.6.3.5 Blood and Urine Collection About 5–10 mL of blood can be collected from adult ferrets using retro-orbital blood collection techniques. Other methods of blood collection include cephalic and jugular veins and caudal tail venipuncture, as well as bleeding via the ventral tail artery. Cardiac puncture is also used, but in the opinion of this and other (Hart, 1986) laboratories, the procedure is traumatic and can cause myocardial scarring. Blood collection from the tail can be difficult, because the ferret tail is short and the tail veins and arteries cannot be seen. For all the aforementioned collection techniques, some form of pharmacological or mechanical restraint is required. To facilitate serial blood collection, methodology has been developed for a tethered restraint system with an implanted indwelling venous jugular catheter, which does not interfere with the normal activities of the ferrets and allows blood sampling to occur from outside the cage (Jackson et al., 1988).

For urine collection, glass or plastic rat metabolism cages work well for short-term or overnight collection. Care needs to be taken to avoid contamination of the urine with feces.

14.6.4 Advantages and Disadvantages

Two advantages to using the ferret are its cost and its size (Table 14.6). The cost of the ferret is approximately one-tenth that of the dog. The ferret's smaller size means that it is easier to maintain and more economically housed and fed than the dog (Hart, 1986). Smaller size also means that test compound requirements for the ferret will be considerably less than those for larger nonrodent species (e.g., on the

TABLE 14.6 Use of the Ferret in Safety Assessment Studies

Advantages

Small size
Significantly lower cost than most other nonrodents
Lower test material requirements (relative to larger nonrodents)
Adaptability to an exercise program

Disadvantages

Pervading musky odor
Rodents' inherent fear of ferrets
Can be difficult to handle
Background disease profile with resulting "background noise" and increased variability in clinical and anatomical pathology

order of one-tenth of that needed for the dog). Another advantage is that if exercise requirements are ever established for the ferret, it will be an easier species than the dog for which to design an acceptable exercise program.

Disadvantages associated with the ferret include its pervading musky odor and its background disease profile. While the scent glands can be removed, 90% of the animal's odor is derived from sebaceous secretions onto the skin. However, neutering the males and spaying the females, in addition to descenting, will markedly reduce the odor. Rats should be housed as far away from ferrets as possible because of their inherent fear of ferrets (triggered by olfactory stimulation), which can interrupt breeding cycles or disturb other physiological functions (Fox, 1988). In this laboratory's experience, ferrets, which are generally less docile than dogs, can be difficult to handle and prone to bite, especially when restrained for activities such as ophthalmic and ECG examinations. The lack of easily accessible veins for intravenous dosing and serial blood collection is also a disadvantage.

The major disadvantage in the use of the ferret in safety studies is the profile of diseases associated with the species and the resulting variability in background clinical and anatomical pathology. Pneumonitis and hepatic lymphoid accumulation, associated with chronic parvovirus infection, have been observed in ferrets in this laboratory (Haggerty et al., 1989). Submucosal lymphoid nodules of the intestines are also a common finding (Hart, 1986). Additionally, a relatively high incidence of electrocardiographic anomalies (atrial or ventricular premature depolarization and atrial and ventricular extrasystoles) and ophthalmological anomalies (optic nerve hypoplasia and cataracts) has been found in ferrets in this laboratory. While it may be possible to work with the animal suppliers to reduce the chances of receiving animals with background ECG or ocular abnormalities, at the present time there is no supplier of a disease- and viral-free ferret.

14.7 THE PIG

14.7.1 Background

The use of pigs (*Sus scrofa*) in biomedical research is well established. In toxicology, whereas the use of pigs in the United States is largely limited to dermal studies, in Europe they have become very popular for pharmaceutical studies in place of dogs and primates. They have been extensively used for surgical (Swindle et al., 1988) and physiological (primarily cardiovascular, renal, and digestive) research (Khan, 1984; Clausing et al., 1986) for years. Prior to the last 10 years, the pig's use in toxicity testing was uncommon, except in the testing of veterinary or herd management drugs intended for use in swine or in dermal toxicity and absorption studies (McAnulty et al., 2010). Because of their well-accepted

physiological similarities to humans, minipigs are becoming increasingly attractive toxicological models (Table 14.7). In fact, they long have been more frequently used in nutritional toxicology studies (Clausing et al., 1986). Among the more common experimental animals, pigs are the only ones whose use is on the increase (Khan, 1984). Their expense (in both procurement and maintenance) and their relatively large size have mitigated against their use in more general toxicity testing. The development of minipigs has resulted in a strain of more manageable size. In addition, the increase of expense in the use of dogs and the perceived lay opposition to their use make minipigs (in Europe and Israel) much more attractive as a nonrodent species for general toxicity studies. The dog is a far more common companion animal, and many of the recent developments in animal care and use laws have made specific provisions about the care of dogs. Minipigs have been shown to be more sensitive to a wide variety of drugs and chemicals (e.g., carbaryl and methylmercury) than dogs (Khan, 1984). The FDA has kept its own breeding colony of minipigs since the early 1960s. In short, there are scientific, economic, and sociological reasons that make minipigs good toxicological models. The reader is referred to an excellent short review by Phillips and Tumbleson (1986) that puts the issue of minipigs in biomedical research into the context of modeling in general. Table 14.8 presents the advantages of the minipig.

Several breeds of miniature swine have been developed. These include, in the United States, the Yucatan microand minipigs, the Hanford, the Sinclair, the Pitman-Moore, and the Hormel. The Yucatan and the Sinclair tend to be the most commonly used, though the Göttingen (widely used in Europe) is seeing increasing use (Ellegaard et al., 1995; Koch et al., 2001). Panepinto and Phillips (1986) have discussed the characteristics, advantages, and disadvantages of the Yucatan minipig in some detail. In Europe, the Göttingen minipig is extensively used. At sexual maturity (4–6 months) the typical minipig weighs 20–40 kg, as compared to 102 kg for the more common pig and 8–15 kg for the dog. Micropigs weigh about 14–20 kg at sexual maturity. The minipig and the dog have comparable life spans; for example, Peggins et al. (1984)

TABLE 14.7 The Minipig in Toxicity Testing

Due to the many advantages, mini- and micropigs are real alternatives to the use of nonrodents (dogs, ferrets, and primates)
Minnesota minipig introduced in 1949
Body weights at age 2 years
Yucatan minipig: 70–90 kg
Yucatan micropig: 40–45 kg
Göttingen micropig: 35–40 kg

reported that the average life span for miniature swine is 15–17 years. The average beagle dog may have a life span of 8–12 years. Most of this discussion will focus on the purpose-bred minipigs, primarily the Yucatan and the Sinclair.

The greatest area of use of the pig in pharmaceutical safety assessment is for dermal agents. It should be noted that there are differences in skin thicknesses, and these differences are not well characterized.

14.7.1.1 Restraint and Dosing In general, minipigs are docile and easily socialized and trained. Barnett and Hensworth (1986) recommended a socialization regimen of 2 min of gentle interaction. Pigs, like most experimental animals, are simply kept and fed (Hunsaker et al., 1984) but have to be occasionally restrained so samples can be taken and other measurements made. Restrain methods designed for commercial swine should not be used for laboratory swine. Panepinto (1986) have described a sling method that provides restraint with minimal stress. The most frequently mentioned dosing routes in the literature are dietary admix, dermal (topical), gavage, and intravenous injections. Generally, minipigs are restrained in a sling while being dosed by the active route such as gavage. If the experiment requires the implantation of, for example, an indwelling catheter, minipigs can be anesthetized with ketamine (20 mg kg⁻¹ IM) as described by Swindle et al. (1988).

14.7.2 Clinical Laboratory

Clinical chemical and hematologic parameters for minipigs have been studied. Ranges for some of the more commonly examined parameters from Yucatan minipigs are summarized in Tables 14.9 and 14.10 (from Radin et al., 1986). Parsons and Wells (1986) have published similar data on the Yucatan minipig. Brechbuler et al. (1984), Oldigs (1986), Ellegaard et al. (1995), and Koch et al. (2001) have published on the Göttingen minipig. Middleton and coworkers

Source: Data from Burks et al. (1977) (12 months old, sexes pooled); Radin et al. (1986).

have published extensive lists (organized by age and sex) on the hematologic parameters (Burks et al., 1977) and serum electrolytes (Hutcheson et al., 1979) for the Sinclair minipig. In general, the clinical laboratory picture of the various strains is quite similar. No real differences between sexes have been identified, but age can be very much a factor. For example, serum creatinine can be 33% higher in 3-month-old as compared to 18-month-old Sinclair minipigs (based on data reported by Burks et al., 1977). As with other species, health status, feed composition, feeding regimen, fasting state, season, time of day, and so on can affect clinical laboratory results in the minipig. Toxicological experiments should not be run without concurrent controls.

14.7.3 Xenobiotic Metabolism

Some critical parameters of hepatic microsomal drug metabolism in the minipig, common swine, and rats are given in Table 14.11. As most investigators tend to use younger minipigs, the values reported in this table are for young (<4 years old) minipigs. Relatively few papers have examined the mitochondrial mixed functional oxidase (MMFO) in a broad age range (10 months to 14 years) of Hanford minipigs. They identified definite age-related differences. The amounts of cytochrome P450, the MMFO activity with aniline and *p*-chloro-*N*-methylaniline, and glucuronosyltransferase activity were all significantly higher in middle-aged (5–8 years) versus young (<4 years) minipigs. Freudenthal et al. (1976) examined Hanford minipigs in the 2- to 8-month age range and obtained somewhat different cytochrome P450 (~0.95 nmol mg⁻¹) values than did Peggins et al. (1984) (~0.50 nmol). The reported ranges for aniline hydroxylase (about 0.70 nmol min⁻¹ mg⁻¹) and UDP-glucuronosyltransferase (about 50 nmol min⁻¹ mg⁻¹) were similar in the two papers. Hence, the available data on the MMFO of young Hanford minipigs are fairly consistent. P450 (CYP) isoenzymes 1A, 2A, 2B, 2C, 2D, 2E, and 3A have all been well characterized in the pig (Gad, 2015).

The flavin adenine dinucleotide (FAD) containing mono-oxygenase (FMFO) has traditionally been studied in hog liver obtained from slaughterhouses (Tynes and Hodgson, 1984). Interestingly, when FMFO activity is compared between species, substrate specificities are found to be generally very similar (Tynes and Hodgson, 1984). Rettie et al. (1990) isolated and studied the FMFO from Yucatan minipig liver. As with the enzyme studied from other species, the hepatic enzyme exists as a single isozymic species, is active with both dimethylaniline (*N*-oxide formation) and alkyl *p*-tolyl sulfides (sulfoxidation) and is enantioselective in metabolite formation. It would thus appear that the minipig does not differ appreciably from regular swine in the presence or activity of FMFO.

Perhaps some aspects of minipig xenobiotic metabolism can be inferred from studies in regular swine. For example, Rendic et al. (1984) demonstrated that cimetidine and ranitidine are

TABLE 14.11 Comparison of Xenobiotic Metabolism Systems in Rat and Pig

excellent inhibitors of the porcine MMFO *in vitro* and are probably also inhibitory in microsomal preparations from minipigs (Van Ryzin and Trapoid, 1980). Walker et al. (1978) reported on epoxide hydratase activity in various species, including the pig. Depending on the substrate, the pig had activities equivalent to or greater than those of the rat. This was confirmed by Smith et al. (1984) and Watkins and Klaassen (1986). The MMFO, epoxide hydrolase, UDP-glucuronosyltransferase, *N*-acetyltransferase, glutathione *S*-transferase, and sulfotransferase activities in regular swine may be used to help infer the expected activity in minipigs until more complete and specific information appears in the literature on minipigs.

There are relatively few papers that compare *in vivo* pharmacokinetic behavior of a specific chemical in the minipig versus another animal. Schneider et al. (1977) reported on the toxicology and pharmacokinetics of cyclotrimethylenetrinitramine in the rat and minipig. Rats convulsed within the first several hours after receiving this chemical, whereas minipigs convulsed 12–14h later. This is consistent with the observation that at 24h postdosing (100 mg kg⁻¹ po), the plasma levels were 3.0 μg mL⁻¹ in rats and 4.7 μg mL⁻¹ in minipigs. Other differences in pharmacokinetics and metabolism between the two species were described. The latent period for convulsion development was more similar between minipigs and humans than between rats and humans. The implication in this chapter

is that the minipig is a more suitable model for the study of the toxicity and metabolism of the nitramines than rats.

14.7.4 Dermal Toxicity

Although rabbits are commonly used for the assessment of primary (and even cumulative) dermal irritation (and in some cases accepted by regulators as a nonrodent species), pigs are now generally being considered to be better models for the more sophisticated study of dermal permeability and toxicity. As reviewed by Sambuco (1985), human and porcine skin are similar with regard to sparsity of the pelage, thickness and general morphology, epidermal cell turnover time, size, orientation, and distribution of vessels in the skin. The particularly thin hair coat and lack of pigments in the Yucatan minipigs make it particularly ideal for dermal studies. The size of the animal also provides the additional practical advantage of abundant surface area for multiple site testing.

Sambuco (1985) has described the sunburn response of the Yucatan minipig to ultraviolet (UV) light, suggesting that this species would also make a good model in phototoxicity as well as photocontact dermatitis studies. Thirty 12 cm sites were demarcated, permitting the study of 15 different dermal dosages of UV radiation.

Mannisto et al. (1984) have published a series of articles on the dermal toxicity of the anthralins in the minipig. In one

experiment, 24 sites per minipig were used to assess the acute dermal irritation of various concentrations to four different chemicals per site. The range of concentrations tested permitted them to calculate the median erythema concentration and median irritation concentrations with relatively few animals. They were able to show clear differences between anthralin congeners (antipsoriatic drugs) with regard to irritation. When compared to other species (mouse and guinea pig), the response of the minipig was the most similar to humans in that in both species these chemicals are delayed irritants, and several days postexposure may pass before the maximal irritant response is presented.

Likewise, Hanhijarvi et al. (1985) studied the chronic, cumulative dermal effects of anthralin chemicals in minipigs. Using only 12 animals, they were able, by having 32 sites per animal, to study the effects of two different chemicals (dithranol and butantrone; both anthralins) in three different formulations at three different concentrations each. The protocol also included observations for systemic toxicity, clinical laboratory measurements, plasma drug analyses, and gross and histopathological examinations.

In a third report (very similar to the second), Hanhijarvi et al. (1985) clearly demonstrated that the type of vehicle can greatly influence irritation in that dithranol was clearly more irritating when applied in paraffin than when applied in a gel. They were also able to demonstrate that although dithranol was less irritating than butantrone acutely, the cumulative irritations (mean scores at the end of 6 months of six times per week applications) were quite similar (Mannisto et al., 1984). There was neither evidence of systemic toxicity nor evidence of test article in plasma with either species.

14.7.5 Cardiovascular Toxicity

In general, the published literature consistently maintains that the cardiovascular systems of swine and humans are very similar (McAnulty et al., 2010). For example, as reviewed by Lee (1986), swine, including minipigs, have a noticeable background incidence of atherosclerotic lesions, and swine fed with high lipid diets will develop even more extensive atherosclerotic lesions. High lipid diets will produce lesions similar to advanced atheromatous lesions seen in humans. Although few drugs or chemicals have been shown to cause atherosclerosis, this information has three general applications to toxicology and pharmacology. First, the feeding regimen of minipigs should be carefully controlled in general toxicity studies to minimize the incidence of arterial disease, especially in long-term studies. Second, the pathologist should be aware of the natural background of this disease when preparing a diagnosis. Third, the minipig could provide a convenient model for the study of atherosclerotic disease and the screening of potential therapies.

The minipig has been used to study cardiotoxicity, particularly with medical device and drug/device combination products. Van Vleet et al. (1984) reported that minipigs were the

only other species studied other than dogs to develop cardiac damage in response to large doses of minoxidil. In both the pig and the dog, minoxidil cardiotoxicity is characterized by vascular damage (with hemorrhage in the arterial epicardium) and myocardial necrosis (mostly of the left ventricular papillary muscles). Interestingly, in the dog the atrial lesion is largely restricted to the right atrium, whereas in the pig it is restricted to the left atrium. These lesions can be produced in roughly 50% of the minipigs given 10mgkg^{-1} of minoxidil for 2 days and sacrificed 48 h after the last dose (Herman et al., 1988, 1989). Herman et al. have published extensive descriptions of minoxidil-induced lesions in minipigs in comparison to those produced in dogs (Herman et al., 1988, 1989). The right versus left arterial difference is believed to be due to differences in the anatomical pattern of coronary circulation between two species (Herman et al., 1989).

Minipigs are also sensitive to the cardiotoxic effect of doxorubicin. When given six intravenous injections of either 1.6 or 2.4mgkg^{-1} of doxorubicin at 3-week intervals, minipigs develop cardiac lesions similar to those seen in dogs, rabbits, and other experimental animals (Herman et al., 1989). The lesion is characterized by cytoplasmic vacuolation and varying degrees of myofibrillar degeneration and loss. Thus, the minipig is sensitive to the cardiotoxic effect of two well-known and extensively studied chemicals. Therefore, it is a suitable nonrodent species for the general assessment of cardiotoxicity.

14.7.6 Advantages and Disadvantages

There is one disadvantage to the use of minipigs. The first is their size. Although minipigs are smaller than regular swine, they typically gain weight and at maturity they are generally larger than beagle dogs. Among the advantages is the fact that they are long-lived, cooperative animals with well-defined physiological and metabolic characteristics. As they are not either popular companion animals (like dogs) or do not physically resemble humans (like monkeys), minipigs are not specifically discussed in animal “welfare” laws like the other two species. Depending on their final form, new animal welfare regulations have made the space and maintenance costs for dogs and monkeys very prohibitive. This had made minipigs increasingly more attractive as a nonrodent species for general toxicity testing. In an increasing number of cases, administration of a drug to a target site may require a surgical intervention. The size of the minipig makes such surgeries feasible.

14.8 THE RABBIT

A number of size, shape, and color variations derived from centuries of selective breeding constitute the more than 50 well-established breeds recognized by the rabbit breeders’ associations. Representatives of the small breeds (under 2 kg

or 5 lb) include the American Dutch and Polish breeds, the medium-sized breeds (2–5 kg or 5–10 lb) are the California and New Zealand White (albino) rabbits, and the large breeds (5 kg or 10 lb and over) are the Flemish and Checkered Giants. The New Zealand White albino is the rabbit most commonly used for research purposes and is the focus for this section. The Dutch Belted is commonly used in evaluating ocular drugs for which potential effects on pigmented eyes are a concern.

Rabbits are relatively inexpensive (compared to other non-rodent species), hardy, small, clean, and more easily housed and handled. Thus, they are readily used for a wide variety of experimental procedures and testing situations, including immunology (they are good antibody producers and blood is relatively easy to collect from their large and accessible ear veins), teratological (where their sensitivity to thalidomide made them a required species), dermal, ocular, and implant studies. Specific study designs are discussed later in this chapter and are outlined in Table 14.13.

Because the distribution of intestinal microflora within the gut (and hence, their potential metabolic activity) is more similar in rabbits to that of humans than that of the guinea pig, rat, or mouse (Williams, 1972; Peiffer et al., 1994), an orally administered compound is less likely to be metabolized, possibly into a toxic or active metabolite, in a manner irrelevant to humans in the rabbit than in these other laboratory species. However, since gastric emptying time for the rabbit can vary anywhere from 20 min to 20 h in contrast to the human rate of 1.0–1.5 h (Digens et al., 1980) the rabbit is a poor species for evaluating the absorption of orally administered compounds (Maeda et al., 1977).

Although rabbits are frequently used to study dermal toxicity, they may not be the best species. Because human skin has a thicker stratum corneum, it is more resistant to the dermal absorption of foreign substances and is penetrated much less easily by xenobiotics than the skin of the most widely used animal models, including the rabbit and the rat (Calabrese, 1984). *In vitro*, skin permeability to ionic and covalent substances in aqueous solution and organic solutes increases in the following order: human, pig, guinea pig, rat, and rabbit (Tregear, 1966). When Bartek et al. (1972) compared the *in vivo* skin permeability of several compounds, they also found that the absolute dermal absorption rate for the rabbit was higher than that of the rat, pig, or human (in a descending order). It appears that because the permeability of the skin of miniature swine is close to that of human skin, for studies in which dermal toxicity data are to be used to predict toxicity in humans, in some respects the miniature swine appears to be a more suitable test animal than the rabbit. However, despite the considerable species difference between rabbit and human skin, rabbits are routinely employed in dermal toxicity tests. Thus, when interpreting data generated using rabbits, the researcher must consider the following (Bartek et al., 1972). In general, for a single

dermal dose, total exposure of the outer surface of the skin to the applied compound will be of shorter duration in the rabbit than in humans. However, because of the higher penetration rate in the rabbit, temporarily higher concentrations of compound might occur within the rabbit skin as compared to human skin. In addition, the time course of systemic exposure to the compound will also be markedly different in the two species.

14.8.1 Excretion

Rabbits have two types of feces: soft, moist nighttime feces and firm, dry daytime fecal pellets. The nighttime feces, which are covered with mucus and consist primarily of secretion from the cecum, are produced by the initial ingestion of food; hard feces are produced by reingestion of the soft feces. The soft feces are protein and vitamin rich, and their ingestion (coprophagy) directly from the anus improves the utilization of nitrogen (Thacker and Brandt, 1955), provides an abundance of certain B vitamins, plays an important role in the incorporation of sulfur in the soft tissues, and conserves water (Kulwich et al., 1953, 1954). Wild rabbits are able to survive up to a week without food because of reingestion of feces.

Because of their diet, rabbit urine is cloudy and ranges in color from light yellow to deep orange or red brown and may resemble purulent discharge. It contains carbonate and phosphate crystals, which cause a scale to accumulate on cage surfaces.

14.8.2 Husbandry

As with other laboratory animals, the facilities, equipment, and husbandry procedure used for rabbits should be designed to afford maximum environmental control (i.e., minimal variation in temperature, humidity, and ventilation); optimal conditions for that animal's comfort, health, and welfare; and minimal exposure to injury and disease (Clarke et al., 1977).

14.8.2.1 Facilities Rabbits should be maintained in an area that is clean and dry, with adequate ventilation, away from excessive noise, and within a specified range of temperature and humidity.

Temperature, Relative Humidity, and Ventilation Because the thermal environment can influence the severity, duration, and variability of toxic responses to chemical by influencing the physiology of the animal and the metabolism and disposition of test materials (Fuhrman and Fuhrman, 1961; Weihe, 1973; Clough, 1982), the temperature, humidity, and ventilation of the animal facilities must be strictly controlled (Rao, 1986). The thermoneutral zone of resting laboratory animals (and humans) is very small (Weihe, 1973).

When exposed to temperatures outside their thermoneutral zone, laboratory animals adapt behaviorally (unless they are prevented from doing so by experimentally enforced restrictions) and/or metabolically (by increasing or decreasing their metabolic rates). Thus, marked variations in the environmental conditions of the animal room may alter the animal's rate of metabolism, and, ultimately, the potential toxicity of a test material.

Ambient relative humidity is also a major factor in maintaining the heat balance of an animal (Clough, 1982). It is a very important consideration with dermal absorption studies, particularly when shaved animals are used. In these situations, the relative humidity will directly affect the rate of evaporation, the viscosity of the test material, and the animal's peripheral circulation, thus having a major impact on the potential toxicity of the applied material.

For rabbits, animal room temperatures should be maintained between 60 and 70°F (16 and 20°C) and relative humidity should be between 40% and 60% (ILAR, 2018). This temperature range is lower (vs. 64.4–78.8 or 84.2 and 18 to 26 or 29°C) and the relative humidity range is narrower (vs. 30–70%) than that required for other common laboratory animals (ILAR, 2018). With rabbits, elevated temperatures in particular can result in lower male fertility, lower conception rates for the does, and reduced litter sizes.

The recommended ventilation rate is 12 cu ft/min/animal (up to approximately 5.6 kg)/day (Runkle, 1964) or at least 10 complete air changes/hour (ILAR, 2018), preferably with 100% fresh air. Recirculation of air is not recommended. If the air is recirculated, more efficient filtration will be required to remove odors and contaminants.

14.8.2.2 Feed and Water Feed and water systems should be clean and designed so that they cannot become easily contaminated. Metal feeders that attach to the front of the cage and can be filled outside without opening the cage door are commercially available and should be used in preference to crocks or other open containers. Likewise, water bottles (if an automatic water system is not available) are usually mounted on the outside on the front of the cage. Sipper-tube watering devices are preferred.

Rabbits should be provided access to food *ad libitum* with a plentiful supply of fresh, clean water. Nonpregnant does drink approximately 10 mL/100 g of body weight per day, and lactating does may drink up to 90 mL/100 g/day (Harkness and Wagner, 1983). If water bottles are used, they should be filled with fresh water daily and sanitized at least once weekly.

Malnutrition is uncommon in rabbits. Other relatively uncommon nutritional problems include vitamin D, calcium, and phosphorus imbalances (atherosclerosis); vitamin A (hydrocephalus, prenatal death) and vitamin E (muscular dystrophy, prenatal mortality, seminiferous tubal degeneration) deficiencies; and some specific mineral or amino acid deficiencies.

14.8.2.3 Handling and Restraint Rabbits must be picked up and held correctly to prevent both animal and human injuries. They should be handled firmly but gently. Because they are very shy animals and are easily frightened, they may often struggle and try to escape. With the exception of older bucks and primiparous does with strong territorial instincts, rabbits seldom bite people.

14.8.3 Dosing Techniques

Compounds may be administered to rabbits by a variety of routes. The more commonly used routes and specific techniques are described as follows.

14.8.3.1 Oral Administration The simplest method of administering compounds orally is by incorporating them in the feed or water. However, as with other species, rabbits may not voluntarily consume the material if it has an unpleasant odor or taste, or if it is in a form that cannot be easily consumed. In addition, rabbits tend to spread their feed around and “play” with their water bottles. Thus, because of potential palatability problems, spillage, and wastage these methods may not be satisfactory if it is important that precise amounts of the material be administered.

Very small volumes of liquid materials may be administered by placing the tip of a ball-tipped syringe in the corner of the rabbit's mouth and slowly introducing the material. However, the most accurate method of administering compounds orally is to deliver the material by gavage. This may be done using a stainless-steel ball-tipped needle (13 gauge) or a latex catheter (size 14 French, 16 in. long). The needles are attached to a syringe with a locking end, the head and neck of the animal are manually restrained to avoid injury if the animal should struggle, and the needle is inserted into the back of the mouth and into the esophagus.

When using a latex catheter for gavage, the animal is also restrained. The animal may be manually restrained, or a cat bag can be used for restraint. The mouth is held open and the catheter is inserted into the back of the throat, being careful to avoid the teeth, and then gently introduced into the esophagus and into the stomach. To establish that the catheter is in the stomach and not the bronchi, there should be no air passage in the tube that corresponds to respiratory movements. If the animal struggles, the catheter should be removed and reinserted. After the catheter is inserted, a ball-tipped needle which is attached to a syringe is inserted into the open end of the catheter, and the plunger of the syringe is gently pushed to administer the dose. Depending on the nature of the material and the dose volume, it may be advisable to flush the catheter by leaving the catheter in place and affixing another syringe with water or the appropriate vehicle. The catheter, attached to the empty syringe, is then removed, again being careful to avoid the teeth. The volume of material administered is based on the vehicle used. In general, rabbits should not be given

more than 2 mL kg^{-1} of corn oil; water or a water-based solution may be given at volumes up to 6 mL kg^{-1} .

14.8.3.2 Dermal Administration Materials are applied topically on the dorsal area of the trunk. The fur is removed with an electric clipper before dosing and as needed thereafter. Care should be taken to avoid abrading the skin and only animals with healthy, intact skin should be used. If the dosing material is a liquid, it may be applied diluted or undiluted. If the dosing material is a solid, it should be slightly moistened with saline, deionized water, or another suitable vehicle before application to ensure good contact with the skin. The dosing material is then applied uniformly over the exposure area (from approximately 5 cm^2 to an area estimated to constitute approximately 20% of the total body surface area). The exposure area may be left uncovered, or it may be held in contact with the skin by a gauze dressing secured with tape, covered with cellophane wrap, and overwrapped with elastic tape. The animals should be fitted with flexible “Elizabethan”-type plastic collars to prevent them from removing the dosing material or coverings (Barnett, 1958). At the end of the treatment period, the bindings and collar are removed, and the exposure area may be washed with water and/or wiped clean with a towel moistened with water or a mild soap solution as thoroughly as possible without irritating the skin. The volume of material given is based on the size of the animal and the area of skin that is available for application.

14.8.3.3 Ocular Administration Animals should be examined before the administration of the dose material and any that show preexisting ocular defects, irritation, or corneal injury should not be used. If a solid or granular material is to be administered, it should be finely ground into a dust or powder. The material is placed in the conjunctival sac and the upper and lower lids are then gently held together for a second before releasing to prevent loss of the dose material. The amount given should not exceed $10\text{ }\mu\text{L}$ or the equivalent weight.

14.8.3.4 Intravenous Administration Materials are usually administered intravenously into the marginal ear vein (along the posterior edge on the outside of the ear). The animal is restrained, the hair is gently plucked from the area of the vein, and a disinfectant is applied. If the vein is not readily apparent, the area can be rubbed with alcohol, or the vein can be occluded by gently pressing on the base of the ear or by placing a paper clip at the base of the ear. For intravenous injections, the needle should be sharp (prepackaged, sterile, disposable needles are the best) and should be the smallest size possible (1 in., 25 gauge, or smaller). The needle should first be inserted into the skin beside and parallel to the blood vessel, and then inserted into the vein

with the beveled edge up. The syringe should only contain the dosing solution and no air. If there are signs of engorgement or swelling at the injection site, indicating that the needle is outside the vein, reposition the needle. After the material has been injected, withdraw the needle, and apply digital pressure to the puncture site for a short time to prevent bleeding.

14.8.3.5 Subcutaneous Administration Subcutaneous injections are made under the skin of the neck or back, using a 1-in., 23- to 27-gauge needle. The skin is grasped with one hand and the material is injected into the tented skin. If large volumes are to be injected, the needle can be withdrawn slightly and redirected to spread the fluid over a wider area.

14.8.3.6 Intramuscular Administration Intramuscular injections are made into the lateral aspects of the large muscles in the hindquarters, e.g., the gluteal or thigh muscles. Care must be taken to avoid hitting large blood vessels, nerves, and bone. First, the area of the injection site is immobilized, cleaned with disinfectant, and the needle is then inserted $\frac{1}{2}$ to $\frac{3}{4}$ in perpendicularly, depending on the muscle thickness. After the needle is inserted, the plunger of the syringe should be withdrawn slightly to confirm that no blood can be aspirated, i.e., the needle has not inadvertently entered a blood vessel. If blood appears in the syringe, the needle should be carefully repositioned or withdrawn and reinserted. After the needle is placed properly, the fluid is injected slowly, and the needle is withdrawn. The smallest gauge needle possible (1 in., 23–27 gauge) should be used for this procedure.

14.8.3.7 Intradermal Administration Intradermal injections are given in the loin and flank areas where it is difficult for the rabbit to reach with its hind feet. The hair should first be removed from the site with clippers and depilatory cream. An antiseptic is then applied. The skin is stretched, and the needle is inserted only into the dermis, forming a small bleb, and the injection is made using a 25-gauge needle attached to a syringe containing the dosing material. When the needle is removed, the site should be examined for seepage of the dosage material. If this occurs, the needle should be inserted further into the skin during the injection.

14.8.3.8 Intraperitoneal Administration The rabbit is manually restrained with the hindquarters elevated and the needle ($\frac{5}{8}$ in., 23–25 gauge) is inserted bevel up into an area just lateral to the midline and just posterior to the area of the umbilicus at a steep angle toward the spine. The insertion is made up with a quick thrust through the subcutaneous tissue and ventral abdominal muscles and abdominal wall, and into the peritoneal cavity. Using this procedure, up to 20 mL of fluid may be given in a single injection.

14.8.3.9 Vaginal Administration The doe is placed in a restraining stock, and the tail is gently grasped between the thumb and forefinger while the rest of the hand is pressed firmly on the hip region of the animal. As the animal relaxes, the tail is pulled upward to expose the vaginal opening. A catheter (size 8 French, or a ball-tipped stainless steel 1½ in., 18-gauge needle) is gently inserted approximately 1 in. into the vagina, the dose is administered, and the catheter or needle is withdrawn. The animal is kept in the restraining stock for 1–2 min after the procedure is complete to ensure that the dose material is retained.

14.8.3.10 Implantation The rabbit is widely used for subcutaneous and intramuscular implantation studies of both drugs (particularly those formulated into faster release direct delivery) and medical devices.

14.8.4 Collection Techniques

14.8.4.1 Blood Collection Ear Vein Blood is usually collected from the large, readily accessible marginal ear veins. To facilitate collection procedures, the animal is placed in a restraint box that allows access to the ears. A small amount of petroleum jelly is spread along the marginal vein. This causes the hair to lay flat in a natural direction toward the edge of the ear. A disinfectant such as 70% ethyl alcohol is applied, and a paper clip may be applied as a tourniquet proximal to the intended bleeding site. Using a lamp as a heat source, the ear is warmed, which causes the vein to become engorged with blood. Slight digital irritation of the tip of the ear will also increase blood flow and facilitate blood collection. Although xylene is sometimes used for this purpose, it should not be used if the sample is to be used to determine white blood cell counts because of its severe inflammatory properties. While keeping the ear over the lamp, the vein is incised midway between the tourniquet and the tip of the ear, and blood is collected directly in appropriate tubes or containers. Alternatively, a needle attached to a syringe may be used and the blood drawn into the syringe by slow, steady manual pressure.

Auricular Artery When larger blood samples are required, they may be collected from the centrally located auricular artery using a 20- or 23-gauge needle that is inserted into the artery toward the base of the ear.

Catheterization Techniques for obtaining multiple blood samples from rabbits over short or extended period of time, which are not traumatic, do not cause hematomas, and do not require anesthesia, invasive surgery, or sophisticated expertise involve implanting a flexible catheter into the

auricular artery (Smith et al., 1988; Heim, 1989). The site of the arterial puncture is depilated, or the entire ear is shaved. A 2% nitroglycerin ointment may be applied over the artery to prevent arterial spasms, which can interfere with successful catheterization, and the area is stroked with the forefinger until the artery becomes engorged with blood. A 1-in, 22-gauge catheter is inserted into the artery approximately 3 cm from the tip of the ear with the needle at a 25° angle and the bevel up. The appearance of blood in the flash chamber confirms arterial entry. The catheter is then advanced into the arterial lumen until the hub meets the surface of the skin (the hub of the catheter should be below the tip of the ear) and an injection cap is attached to the hub of the catheter. Approximately 0.3 mL of heparinized (5 μmL⁻¹) saline should be injected into the catheter to determine if the placement is correct. This is followed by rapidly infusing an additional 1 mL of heparinized saline and then aspirating blood until adequate blood flow is established. Tissue adhesive may be used to adhere the catheter hub to the skin surface. A piece of rolled gauze is placed inside the ear and then the ear and catheter hub are wrapped with adhesive tape, binding the ears together to prevent the rabbit from removing the injection cap and catheter. For longer sampling periods, gauze or bandaging tape should be used under the adhesive tape to prevent skin irritation.

For all these methods, blood flow from the puncture site is easily stopped by applying firm digital pressure at the site with a gauze pad. Alternatively, after the blood sample is collected, direct pressure may be applied to the incised area and a paper clip applied as a tourniquet to control bleeding until clotting takes place. The use of a surgical lubricant with the paper clip facilitates clotting.

Cardiac Puncture Cardiac puncture may be used to collect larger quantities of blood or multiple blood samples from anesthetized or sedated rabbits. However, cardiac puncture is traumatic and can result in death. The rabbit should be anesthetized and placed in right lateral recumbency or dorsal recumbency on a restraining board. The heartbeat may be used to directly locate the heart or the needle (1½ in, 18–21 gauge) is inserted at approximately a 30° angle immediately behind the xiphoid cartilage.

Posterior Vena Cava/Iliac Bifurcation When large volumes of blood are needed at terminal sacrifice and known enzyme alterations caused by cell trauma from other bleeding techniques are contraindicated, blood may be obtained from the posterior vena cava or iliac bifurcation of anesthetized animals (Gad, 2015).

14.8.4.2 Urine Collection The most common method used to collect urine is by placing the animals in stainless steel metabolic cages, where the urine and feces are separated

by a cone-shaped device (the urine drains off the collecting walls into a tube and the feces drop into an inverted cone). Food and water are provided in such a way that the urine will not be contaminated. However, some hair and fecal contamination of the urine may occur.

If contamination of the sample with fecal and other material not acceptable, urine samples may be obtained by urethral catheterization (practicable in males only) or by direct puncture of the bladder (cystocentesis).

14.8.5 Study Designs

The rabbit remains the most commonly used to evaluate dermal toxicity in numerous study designs to evaluate toxicological responses to pesticides, drugs, and industrial chemicals. Depending on the type of material to be evaluated, these tests are done according to the U.S. FDA, Environmental Protection Agency (EPA), Federal Hazardous Substances Act (FHSA), Department of Transportation (DOT), or the Organization for the Economic Cooperation and Development (OECD) guidelines and range from short-term acute studies to 90-day toxicity studies.

14.8.5.1 Dermal Toxicity The rabbit is also used to evaluate the dermal toxicity of a test material. This study may be a short-term, 14-day study or may be up to 90 days in duration. The animals are clipped, treated, and wrapped like an acute dermal study, but the duration of treatment is daily, for 6 h per days per week. Clinical observations, body weights, and food consumptions are recorded weekly and dermal irritation scores are recorded daily. The animals are necropsied, and microscopic examinations are done. Animals are bled before the terminal sacrifice and hematology and clinical chemistry data are obtained. Specific tissue lists, clinical pathology test, and other specific requirements and tests for the 21-day and 90-day toxicity studies are listed in Table 14.13.

14.8.5.2 Teratogenicity Rabbits are frequently used as the nonrodent species for teratogenicity studies (Table 14.12). In this study design, the pregnant doe is treated during fetal organogenesis, days 7–19 of gestation. The day of breeding or artificial insemination is gestation day 0. The doe is euthanized prior to term (gestation day 29) and the uterine contents are examined for implantation sites, early and late resorption sites, and live or dead fetuses. The fetuses are weighed, sexed, and examined for external, soft-tissue, and skeletal development.

14.8.6 Metabolism

Hepatic microsomal CYP-450 (cytochrome P-450) activity in the rabbit has been studied and compared with those in other laboratory animals such as the mouse, rat, hamster, and guinea pig (Davies et al., 1969; Chhabra et al., 1974; Litterst

TABLE 14.12 Selected Normative Data for New Zealand White Rabbits

<i>General adult body weight</i>	
Male	4–5 kg
Female	4–6 kg
Life span	5–13 years
Surface area	2.5 kg: 1270 cm ² 4.8 kg: 3040 cm ²
Chromosome number (diploid)	44
Water consumption	50–100 mg kg ⁻¹ day ⁻¹
Food consumption	50 g kg ⁻¹ day ⁻¹
Rectal temperature	102.0–103.5°F
Basal metabolism	110 cal kg ⁻¹ day ⁻¹
GI transit time	4–5 h
<i>Reproduction</i>	
Puberty	
Breeding age	3–8 months
Male	6–10 months
Female	5–9 months
Breeding season	All year (controlled conditions)

et al., 1975, 1976), as have the levels and activities of its substrates. The cytochrome P-450 content (1.05–1.09 nmol mg⁻¹) and the activity of NADP:cytochrome c reductase (130–150 nmol min⁻¹ mg⁻¹) in the rabbit were similar to those in the other species examined (Table 14.13). While CYP-450 reductase activity is much lower in the rabbit (3.0–3.4 nmol min⁻¹ mg⁻¹) compared with that in the mouse and rat, the full range of CYP-450 isoenzyme activities is present (Table 14.1).

Souhaili-El Amri et al. (1986) conducted a similar study in six laboratory animal species and humans. Although the values for the CYP-450 concentrations were somewhat lower in this study compared with those in the previous studies, the value in the rabbit (0.67 nmol mg⁻¹) was generally similar to those in the other animals, which is consistent with earlier findings. The CYP-450 content in the rabbit was somewhat higher than the value in humans (0.31 ± 0.09 nmol mg⁻¹).

Studies of rabbit CYP-450 using SDS-acrylamide gel electrophoresis have demonstrated at least 15 separable forms from liver microsomes other than P-450. The PB-induced form, P-450 LM₂, and β-naphtho-flavone (BNF)/3-methylcholanthrene (3-MC)-induced form, P-450 LM₄, are the most active, although all of the P-450 isozymes displayed enzymatic activities. P-450 LM₂ was most effective in the metabolism of benzphetamine, whereas P-450 LM₄ was specific for acetanilide hydroxylation. However, they displayed comparable activity toward *p*-nitrophenetole, *p*-nitroanisole, and 7-ethoxycoumarin. The isozyme LM₃, which is similar to cytochrome P-450_p in the rat, was also found in the rabbit treated with macrolide antibiotics such as erythromycin and triacetyloleandomycin (Bertault-Peres et al., 1987; Fabre

TABLE 14.13 Typical Study Design for Dermal Toxicity Studies with Rabbits

<i>21-Day toxicity</i>	
Duration	21 days
Dose levels	4 groups of 10 males and 10 females each; dose mL kg ⁻¹ based on most recently recorded weight
Number/age of animals	80 (40 males and 40 females) rabbits; 10–12 weeks of age
Area of exposure	Approximately 10% of total body surface
Length of exposure	6 h day ⁻¹ , 5 days week ⁻¹
Dose administration	Applied uniformly over exposure area
Body weights	Weekly and at sacrifice
Food consumption	Monitor quantitatively or qualitatively, depending on specific guidelines
Observations	At least twice daily for signs of moribundity, mortality, toxicity, and abnormal behavior or poor health
Dermal irritation	Scored daily, before each application of test material and on the day of necropsy Score using scale presented in Table 14.5
Clinical pathology	Before terminal sacrifice
Hematology	Red blood cell count, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, platelet count, white blood cell count, differential blood cell count, blood cell morphology, reticulocyte count smear
Clinical chemistry	Glucose, urea nitrogen, creatinine, total protein, albumin, globulin, total bilirubin, cholesterol, aspartate, aminotransferase, alanine aminotransferase, γ -glutamyl transferase, calcium, inorganic phosphorus, sodium, potassium
Moribund sacrifices/deaths	Gross necropsy, save tissues
Scheduled sacrifice	Gross necropsy, record organ weights, save tissues
Tissues weighed	Brain, kidneys, liver, ovaries, or testes
Tissues saved	Skin (treated and untreated); target organs; lesions
Microscopic examination	Tissues saved from control and high-dose rabbits and macroscopic lesions from all rabbits
<i>90-Day toxicity</i>	
Duration	90 days
Dose levels	4 groups of 10 males and 10 females each; additional rabbits (10/sex) may be added to the control and high-dose groups and used as recovery animals; dose mL kg ⁻¹ based on most recently recorded weight
Number/age of animals	80 (40 males and 40 females) rabbits; 10–12 weeks of age
Age of exposure	Approximately 10% of total body surface
Length of exposure	6 h day ⁻¹ , 5 days week ⁻¹
Dose administration	Applied uniformly over exposure area
Body weights	Weekly and at sacrifice
Food consumption	Monitor quantitatively or qualitatively, depending on specific guidelines
Observations	At least twice daily for signs of moribundity, mortality, toxicity, and abnormal behavior or poor health
Dermal irritation	Scored daily, before each application of test material and on the day of necropsy Score using scale presented in Table 14.5
Ophthalmic examination	Before initiation of treatment and before terminal necropsy
Clinical pathology	Before terminal sacrifice
Hematology	Red blood cell count, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, platelet count, white blood cell count, differential blood cell count, blood cell morphology, reticulocyte count smear
Clinical chemistry	Glucose, urea nitrogen, creatinine, total protein, albumin, globulin, total bilirubin, cholesterol, aspartate, aminotransferase, γ -glutamyl transferase, calcium, inorganic phosphorus, sodium, potassium
Moribund sacrifices/deaths	Gross necropsy, save tissues
Scheduled sacrifice	Gross necropsy, record organ weights, save tissues
Tissues weighed	Brain, kidneys, liver, ovaries, or testes
Tissues saved	Adrenals, aorta, bone marrow smear, brains, cecum, colon, duodenum, epididymides, esophagus, eyes, femur and bone marrow, gallbladder, heart, ileum, jejunum, kidneys, lacrimal gland, liver, lungs, mammary gland, mesenteric lymph node, muscle, ovaries or testes, pancreas, pituitary, prostate, rectum, sciatic nerve, seminal vesicles, skin (both treated and untreated), spinal cord, spleen, sternum and bone marrow, stomach, submandibular salivary glands, thymus, thyroid with parathyroid, trachea, urinary bladder, uterus, and lesions
Microscopic examination	Tissues saved from control and high-dose rabbits and macroscopic lesions from all rabbits

et al., 1988). This isozyme specifically mediates metabolism of cyclosporin. The isozymes LM₅ and LM₆ exclusively mediate the metabolism of 2-aminofluorene and 7-ethoxyresorufin, respectively.

The distribution pattern of mixed function oxidases for xenobiotics between smooth and rough microsomal membrane is known to be highly species dependent. In the rabbit, concentrations of all components of the mixed function oxidase system are four to five times higher in the smooth endoplasmic reticulum than in the rough endoplasmic reticulum of the hepatic microsomal fractions (Gram et al., 1971), whereas some animals (e.g., the rat and mouse) showed even distribution between the smooth and rough membranes.

As reported for other species, the drug-metabolizing enzymes in newborn rabbits are not fully developed. For example, phenobarbital was more toxic to newborn than to adult rabbits and produced longer loss of the righting reflex in newborn rabbits (Weatherall, 1960).

The content of CYP-450 and other electron transport chain components are highest in the rabbit liver among the organs examined, being approximately 2.5- to 5.0-fold higher than those in the lung and kidney (Uehleke, 1969; Oppelt et al., 1970). However, comparison of mono-oxygenase activity toward various substrates undergoing the same route of metabolism shows considerable variation in the ratio of lung to liver.

Distribution of mono-oxygenase activities among the tissues is dependent on the substrates employed. For example, when benzpyrene hydroxylase activity was examined in the small intestinal mucosa preparations of the rabbit, mouse, cat, guinea pig, and rat, the rabbit had medium benzpyrene hydroxylase activity in the small intestine, although the hydroxylase activity in the liver microsomes was least active in the rabbit (Hietanen and Vainio, 1973). The UDP-glucuronyl transferase measured using *p*-nitrophenol as a substrate was highest in the small intestinal mucosa of the rabbit, although the transferase activity of the rabbit liver was intermediate and similar to the activity of rat and mouse liver.

Neither the concentrations of CYP-450 and the activities of CYP-450 reductase and NADPH:cytochrome c reductase were similar between the male and the female rabbit (Davies et al., 1969), nor in the N-demethylation of ethylmorphine and aminopyrine or hydroxylation of phenobarbital (Davies et al., 1969; Testa and Jenner, 1976). An exception is found in rabbit lung metabolic response to ozone which was found to be more sensitive in females (Delaunoy et al., 1999).

Strain differences in drug-metabolizing ability could account for varying biological responses to such compounds as hexobarbital, adrenal cortex hormones, and 2-naphthylamine. In contrast to two- to threefold variation in drug-metabolizing ability seen in the mouse and rat strains, up to 20-fold variations were observed between various rabbit strains. California rabbits, wild cottontails, and jack rabbits exhibited the most striking difference, each being deficient in some enzymes. For

example, the *in vitro* hepatic microsomal metabolism rate of hexobarbital and amphetamine was 19 and 8 nmol/mg protein/h, respectively, in the cottontail rabbit, whereas the metabolism rate of hexobarbital in the New Zealand rabbit was 254 nmol/mg/h and the metabolism rate of amphetamine in the Dutch rabbit was 154 nmol/mg/h (Cram et al., 1965).

The capacity for aromatic hydroxylation in the rabbit appears to be medium to high in general as illustrated with aniline, biphenyl, and coumarin. After intravenous administration of aniline, about 50% of the dose was excreted as *p*-aminophenol (Parke, 1960). While 4-hydroxylation of biphenyl was observed in the rabbit as in humans, 2-hydroxylation was not observed. Biphenyl 2-hydroxylation was limited to a few species such as the mouse and hamster. When the *in vitro* metabolism of *N*-benzyl-4-substituted anilines were studied using the rabbit, mouse, hamster, and guinea pig, ring hydroxylation was the major pathway in the rabbit and guinea pig, whereas in the mouse and hamster, *N*-debenzylation was the major pathway (Gorrod and Gooderham, 1987). The rat used both pathways to an equal extent. Coumarin 7-hydroxylase was present in rabbit hepatic preparations but absent in the rat and mouse preparations (Kulkarni and Hodgson, 1980).

In contrast to the above examples, the aromatic hydroxylation activity in the rabbit was low with benzpyrene, amphetamine, and ethyl biscouarnacetate. The hepatic benzpyrene hydroxylase activity of the rabbit was two- to fivefold lower compared with that of the rat and mouse (Hietanen and Vainio, 1973; Gregus et al., 1983) and also somewhat lower than that in humans with a variation of about sixfold (Pelkonen et al., 1975). The range of aryl hydrocarbon hydroxylase activity in humans was approximately 20 to 320 pmol/g liver/min with no sex difference. In the rabbit, ethyl biscouarnacetate, an anticoagulant drug, was exclusively deesterified and no aryl hydroxylation was observed whereas in humans and dogs, aryl hydroxylation of the drug was observed.

In the metabolism of amphetamines, aromatic hydroxylation was minor and deamination was the major pathway in the rabbit (Caldwell, 1976, 1981). Only small amounts were excreted as the unchanged drugs. In humans, deamination and unchanged drug excretion were equally important. In addition, substantial amounts of aromatic hydroxylated metabolites were excreted. *N*-Dealkylation of amphetamines was a minor pathway in humans as observed in the rabbit (Brodie, 1962). Green et al. (1986) have studied amphetamine metabolism using isolated hepatocyte suspension from the rabbit, rat, dog, squirrel monkey, and human livers. As observed in the *in vivo* studies, rabbit hepatocytes metabolized amphetamine almost exclusively to the products of the oxidative deamination pathway, whereas rat hepatocytes primarily metabolized by aromatic hydroxylation. Metabolism of the drug by the hepatocytes from three other species (dog, monkey, and human) was mixed but oxidative deamination was somewhat more active than aromatic hydroxylation.

N-Dealkylating activity in the rabbit was highly variable, ranging from low to high depending on the substrate. For example, N-demethylation of benzphetamine by the rabbit was about twofold higher than that in the rat and mouse, about fourfold higher than that in the dog (Gregus et al., 1983), and more than 10-fold higher than that in humans (Souhaili-El Amri et al., 1986). The maximum velocity (V_{\max}) of N-dealkylase activity for aminopyrine in the rabbit was slightly lower compared with the mouse and male rat (SD strain), similar to that of the monkey and female rat, and about twofold higher than that of humans (Souhaili-El Amri et al., 1986). N-Demethylase activity of ethylmorphine in the rabbit was less than half that of the mouse and male rat, similar to that in the dog and female rat, and about twofold higher than that in humans (Gregus et al., 1983; Souhaili-El Amri et al., 1986). In contrast, N-dealkylation of benzyaniline in the rabbit was minor and ring hydroxylation was the major pathway. Similar results were also observed with tolbutamide, an antidiabetic drug. Tolbutamide is metabolized via methyl hydroxylation and N-dealkylation pathways. In rabbits as well as in humans, monkeys, and rats, the methyl hydroxylation was the major pathway (Thomas and Ikeda, 1966; Tagg et al., 1967; Gee and Green, 1984). In dogs, N-dealkylation was the major pathway (Remmer et al., 1964).

N-Hydroxylase activity is predominately mediated via the polycyclic hydrocarbon-inducible cytochrome P450 (Felton et al., 1976) and is of great importance for toxicity evaluation. For example, acetaminophen-induced hepatic injury was found to be related to the rates of N-hydroxylation of the drug by the hepatic microsomes (Davis et al., 1974). In the rabbit, N-hydroxylation activity was medium to high as illustrated with 4-aminobiphenyl and 2-acetylaminofluorene (2-AAF). The major metabolic pathway of 4-aminobiphenyl was N-hydroxylation in the rabbit, mouse, guinea pig, and hamster (McMahon et al., 1980). Interestingly, the N-hydroxylase activity in the rabbit was not induced by methylcholanthrene or Aroclor 1254, a potent cytochrome P450 inducer, although it was induced by phenobarbital. N-Hydroxylation of 4-aminophenyl in the rat, mouse, and guinea pig was enhanced more than fivefold by Aroclor 1254.

The N-hydroxylase activity of 2-acetylaminofluorene in rabbit liver microsomes was higher than that in the mouse, rat, and guinea pig (Lotlikar et al., 1967). The N-hydroxy metabolite was practically undetectable in the guinea pig, which explains resistance of the guinea pig to hepatoma induction by 2-acetylaminofluorene. When *in vitro* metabolism of dibenzylamine was studied using hepatic microsomes of the rabbit, rat, mouse, hamster, guinea pig, chick, and cat, N-oxidase activity in rabbit microsomes was highest ($86.9 \text{ nmol mg}^{-1} 30 \text{ min}$) and approximately five and seven times greater than the activity of mouse and rat microsomes (Beckett and Gibson, 1975). *In vitro* metabolism of N-benzyl-4-substituted anilines were studied using rabbit, rat, mouse, hamster, and guinea pig liver homogenates (Gorrod and

Gooderham, 1987). In contrast to the findings with dibenzylamine, the rabbit had the lowest N-oxidase activity, which was followed by the rat, mouse, guinea pig, and hamster in increasing order. In the rabbit, ring hydroxylation was the major pathway.

Hepatic microsomal levels of epoxide hydrolase activity in rabbits have been compared with those of humans and several commonly used animal models, including the mouse, rat, guinea pig, and rhesus monkey (Oesch, 1973, 1980). With benzo(a)pyrene 1,1-oxide as a substrate, the hydrolase activity in the rabbit was similar to that in the rat but approximately half that in humans and guinea pigs. The monkey had the highest activity, and the mouse had the least activity. When the activity of epoxide hydrolase was measured with styrene oxide as a substrate, the enzyme activity in rabbit liver ($4.2\text{--}10.1 \text{ nmol min}^{-1} \text{ mg}^{-1}$) was similar to that in rat liver as observed with benzo(a)pyrene 1,1-oxide but three- to sixfold lower than that in human liver (Pacifci et al., 1981; Gregus et al., 1983; Oesch and Wolf, 1989). As observed with other enzyme activities, the styrene oxide hydrolase activity in the rabbit kidney and lung (1.5 and $0.4 \text{ nmol min}^{-1} \text{ mg}^{-1}$) was lower compared with that in the liver.

The N-acetyltransferase enzyme system is important in understanding the toxicity induced by arylamines. This enzyme system can be viewed as a component of activation pathways with respect to arylamine hepatocarcinogenesis and as a component of detoxification pathways with respect to arylamine bladder carcinogenesis, whereas N-hydroxylating enzyme systems can be viewed as components of activation pathways with respect to both arylamine bladder carcinogenesis and arylacetamide hepatocarcinogenesis. The rabbit is known as the best acetylator of aromatic amines and sulfonamide with low arylacetamide deacetylase activity. For example, consistently high levels of N-acetyl transferase activity were observed in the rabbit toward *p*-aminobenzoic acid, isoniazid, sulfamethazine, 2-aminofluorene, and *O*-naphthalylamine, whereas the rat and mouse showed markedly different activity depending on substrate (Gregus et al., 1983). When acetylase activity was studied with sulfanilamide (Williams, 1967) and various mono- and dimethoxy-6-sulfanilamidopyrimidines (Bridges et al., 1969) in various species (such as rabbit, human, monkey, and rat) the major metabolites in the rabbit urine were N^4 -acetyl derivatives except in the case of the 2,5-dimethoxy compound, which was excreted largely unchanged. The rat also favored the formation of N^4 -acetyl derivatives, but overall excreted more unchanged drug than the rabbit. Comparable results were apparent in humans with a lesser degree of N^4 -acetylation compared with the rabbit. Rabbits display a genetic polymorphism with respect to acetylation, as do humans. This leads to speculation that the rabbit may be a predictive animal model for population-based acetylation of aromatic amines (Calabrese, 1988).

Glowinski et al. (1978) compared rates of acetylation in both fast and slow acetylator phenotypes in rabbits and

humans for seven compounds, sulfamethazine, *p*-aminobenzoic acid, and five arylamine carcinogens (α -naphthylamine, 8-naphthylamine, benzidine, 2-aminofluorene, and methylenebis-2-chloroaniline). In general, the fast acetylators rabbits displayed a 10- to 50-fold greater rate of activity than the fast acetylators humans. For all compounds except *p*-aminobenzoic acid, the acetylation activity for the fast acetylators rabbits was 90- to 580-fold higher than that of the slow acetylators rabbits, whereas in humans the activity in fast acetylators was approximately 4- to 13-fold higher. Therefore, for some compounds, the levels of acetylation activity in the slow acetylators rabbits were in the range of the fast or slow acetylators humans. For example, the slow acetylators rabbits were very similar to the slow acetylators humans for 2-aminofluorene (0.013 vs. 0.021 $\mu\text{mol mg}^{-1} \text{h}^{-1}$) and benzidine (0.016 vs. 0.019 $\mu\text{mol mg}^{-1} \text{h}^{-1}$), but more closely comparable to the fast acetylators human for β -naphthylamine (0.28 vs. 0.23 $\mu\text{mol mg}^{-1} \text{h}^{-1}$).

Many studies have been conducted to determine UDP-glucuronyltransferase activity in the rabbit. However, the enzyme activity appears to be highly substrate specific, and no general conclusion could be drawn. For example, the transferase activity in the rabbit was high toward 1-naphthol, *p*-nitrophenol, estrone, morphine, and chloramphenicol when compared to the activity in other species such as the mouse, rat, guinea pig, and cat (Gregus et al., 1983). The transferase activity was medium or low toward phenolphthalein, diethylstilbestrol, testosterone, digitoxigenin, valproic acid, and bilirubin. In the rabbit, the concentration of hepatic UDP-glucuronic acid, which is required in the glucuronidation reaction as a glucuronic acid donor, was about half the values of the rat and guinea pig and similar to that of the dog. Therefore, UDP-glucuronic acid did not appear to be a limiting factor for glucuronidation metabolic pathway.

Emudianughe et al. (1978, 1987) studied glucuronidation and other conjugation reactions of radiolabeled naphthylacetic acids. Following 1-naphthylacetic acid administration, the majority of urinary radioactivity (88%) was accounted for by a glucuronide conjugate, whereas only a small amount (6%) of glycine conjugate was present in the rabbit. However, with 2-naphthylacetic acid the majority of urinary radioactivity was accounted for by amino acid conjugates (glycine, glutamine, and taurine), whereas the glucuronide conjugate represented about 24% of the urinary radioactivity. This was explained by the steric hindrance of 1-naphthylacetic acid for activation in amino acid conjugation (Caldwell, 1981). The amino acid conjugations require that the carboxylic group of the xenobiotic acid should be readily accessible for activation to the essential acyl CoA intermediate.

Interestingly, solubilized rabbit liver microsomes had relatively high UDP-glucuronyl transferase activity toward estrone and G-estradiol but not testosterone (Falany et al., 1983). Glucuronidation observed at the 3-OH position of β -estradiol is 20-fold greater than at the 17-OH position. In

contrast, solubilized liver microsomes from female rats possessed approximately fourfold more activity toward testosterone (17-OH) than estrone (3-OH). Rat liver microsomes formed 2.5-fold more β -estradiol 17-glucuronide than 3-glucuronide. The highly substrate- and species-specific UDP-glucuronyltransferase appears to be due to, at least in part, multiple forms of the enzyme.

Sisenwine et al. (1982) studied *in vivo* and *in vitro* stereoselective effects in the glucuronidation of oxazepam in various species. They reported that conjugation of *S*(+)-oxazepam was favored in rabbits as well as in humans, dogs, rats, and miniature swine. In rhesus monkeys, conjugation of *R*(-) isomer was favored. In contrast to oxazepam, glucuronidation of propranolol was stereoselective for (*R*)-propranolol in the rabbit and for (*S*)-propranolol in humans and dogs (Yost et al., 1981; Von Bahr et al., 1982). These workers also found that glucuronic acid conjugation of 4-hydroxypropranolol, a metabolite of propranolol, was not stereoselective. After administration of racemic 2-arylpropionic acid, the formation of the glucuronide was enantioselective for the *S*(-) isomer in the rat and mouse but showed no stereoselectivity in the rabbit (Fournel and Caldwell, 1986). These findings demonstrated complex stereoselectivity of UDP-glucuronyl transferases among different species and broad generalization could not be made for the suitability of animal models for evaluating stereoselectivity of the enzyme.

Hydrolysis of glucuronide conjugates is carried out by the lysosomal enzyme β -glucuronidase, which is present in most tissues, particularly liver, kidney, spleen, intestinal tract, and endocrine and reproductive organs. The level of β -glucuronidase in multiple tissues has been studied in a variety of animal species as well as in humans. When β -glucuronidase activity was measured with phenolphthalein glucuronide, the enzyme activity in the rabbit liver (5000 $\mu\text{g/g liver/h}$) was about 1.7-fold higher than that of human liver, similar to that of guinea pig and hamster liver, and three- to sixfold lower than that of rat liver (Calabrese, 1988). In contrast to liver enzyme activity, the enzyme activity in the kidney was lower in the rabbit (300 $\mu\text{g/g liver/h}$) than in humans (2000 $\mu\text{g/g liver/h}$).

Gastrointestinal tract levels of β -glucuronidase activity may markedly affect the response to some carcinogenic agents. Many carcinogenic agents such as benzo(*a*)pyrene are conjugated with glucuronic acid and excreted via the bile. Low β -glucuronidase activity in the small intestine is expected to reduce enterohepatic circulation, thereby reducing the residence time of the carcinogens in the body. Rabbits are estimated to have approximately 120- and 50-fold higher β -glucuronidase activity in the proximal and distal small intestine, respectively, compared with humans (Calabrese, 1988). Mice and rats are estimated to have approximately 60 000- and 15 000-fold, respectively, higher β -glucuronidase activity in the proximal small intestine than humans. Such findings suggest that the rabbit model may offer a closer

approximation to the human even though the rabbit far exceeded the human values.

Glutathione transferase activity in rabbit liver was highly variable depending on the substrate. For example, glutathione transferase activity toward 1-chloro-2,4-dinitrobenzene was approximately five- and twofold higher in the rabbit than in the rat and mouse, respectively (Gregus et al., 1983; Igarashi et al., 1986). However, toward 1,2-dichloro-4-nitrobenzene, the enzyme activity in the rabbit was less than one-sixth of the activity in the rat and mouse. Gregus et al. (1985) studied glutathione transferase activities in the 60-day-old rabbit and other commonly used laboratory animals, such as rat, mouse, and guinea pig, toward seven substrates. The rabbit was the least active in the conjugation of six substrates (3,4-dichloronitro-benzene, sulfobromophthalein, *p*-nitrobenzyl chloride, ethacrynic acid *trans*-4-phenyl-3-butene-2-one, and 1,2-epoxy-3-(*p*-nitrophenoxy propane) out of seven, yet it was the most active in the conjugation of 1-chloro-3,4-dinitrobenzene. 'Glutathione transferase activity toward styrene oxide in rabbit liver ($36 \text{ nmol min}^{-1} \text{ mg}^{-1}$) was two- and fourfold lower than that in rat and mouse liver, but about 1.9 and 1.4 times higher than that in dog and human liver (Pacifici et al., 1981). This high variation of the enzyme activity appears to be in part due to different substrate specificities and subunit composition of the enzymes among the different species (Igarashi et al., 1986). The glutathione transferase activities toward styrene oxide in the rabbit kidney and lung (18.0 and $6.5 \text{ nmol min}^{-1} \text{ mg}^{-1}$ respectively) were lower than that in the liver (Pacifici et al., 1981).

Oesch and Wolf (1989) determined glutathione transferase activity in liver microsomes and cytosol from various species, including rabbits and humans. The glutathione transferase activity toward the microsomal specific compound, hexachloro-1,3-butadiene in rabbit liver microsomes ($0.14 \text{ nmol min}^{-1} \text{ mg}^{-1}$) was about one-tenth of that in human liver. The transferase activity toward the cytosol enzyme-specific compound, 1-chloro-2,4-dinitrobenzene, in rabbit liver cytosol fractions ($4091 \text{ nmol min}^{-1} \text{ mg}^{-1}$) was more than twofold higher than that in human liver cytosol fractions.

When perinatal development of glutathione *S*-transferase and epoxide hydrolase was studied in rabbit liver and extrahepatic organs, activity of glutathione *S*-transferases toward 1,2-dichloro-4-nitrobenzene and styrene oxide was different in liver, intestine, lung, and kidney (James et al., 1977). In the liver, which has higher activity compared with the other organs, the transferase activity toward both substrates was within the adult range at 70 days after birth. The transferase activity toward styrene oxide in fetal rabbit liver was $1\text{--}2 \text{ nmol mg}^{-1} \text{ min}^{-1}$. This activity increased sharply and reached about 50% of the adult value between 1 and 6 days after birth. However, the age development of glutathione transferase activities in rabbits was highly substrate specific (Gregus et al. 1985). For example, the glutathione transferase activity in rabbit liver for ethacrynic acid increased only 1.8-

fold from the neonatal value during the first 120 days after birth, whereas the enzyme activity toward 1,2-epoxy-3-(*p*-nitrophenoxy)-propane increased about 18-fold.

Depletion of glutathione in the liver was found to be directly correlated with acetaminophen hepatotoxicity (Green et al., 1984). After treatment of acetaminophen, hepatocytes of acetaminophen-resistant species such as the rabbit retained higher amounts of glutathione, produced no detectable covalent adducts, and metabolized more extensively to polar metabolites compared to hepatocytes from other species. In contrast, hepatocytes of acetaminophen-susceptible species such as the hamster were depleted of glutathione more rapidly, produced more covalent adducts of acetaminophen, and formed polar metabolites at a slower rate than the rabbit hepatocytes.

Although information on *S*-methyl reactions in the rabbit is limited, a membrane-bound enzymatic activity has been found in rabbit liver microsomes which catalyzes the transmethyl-ation from *S*-adenosylmethionine to a series of C1–C3 alkane thiol (Hollaway et al., 1979). Methane and ethane thiols are known to be endogenous toxins, which may play an important role in the pathogenesis of hepatic coma, and methylation could provide an important pathway for metabolic detoxification through neutralization of the highly reactive sulfhydryl group.

The rabbit appears to have low to moderate sulfate conjugation capability. After administration of dopamine about 1% of the dose was excreted as sulfate conjugate in the 0 to 72-h rabbit urine, whereas about 61%, 5.3%, and 7.0% of the dose were excreted as sulfate conjugates in the dog, rat, and mouse urine, respectively, over the same time periods. Following administration of phenacetin, the sulfate conjugate was a minor metabolite (4–9%) and *N*-acetyl-*p*-aminophenylglucuronide was the major metabolite in the rabbit, whereas in humans glucuronide and sulfate conjugates were about equally important (36–42% and 23–31%, respectively) (Smith and Timbrell, 1974). However, with phenol, the percentage of the total sulfate conjugate excreted in rabbit urine was 54% of the administered dose (Capel et al., 1972). This value is comparable to those in the rat (55%) and mouse (51%) but somewhat lower than that in humans (78%).

The formation of arylsulfoconjugates is known to be rate limited by the endogenous sulfate ion, and thus the extent of conjugation is dose dependent. Liver concentrations of adenosine 3'-phosphate-5'-phosphosulfate (PAPS), which is required for sulfation reactions as the sulfate donor, was 32.7 nmol g^{-1} of tissue in the rabbit. This concentration was about half the value in the rat, similar to that in the hamster and mouse, but about twofold higher than that in the dog ($16.1\text{--}17.3 \text{ nmol g}^{-1}$). The concentrations of PAPS in the rabbit kidney, lung, and intestine were approximately one-third of the value in the rabbit liver.

The rabbit utilizes the glycine conjugation pathway in the metabolism of many arylacetic acid compounds, such as

phenylacetic acid, indoleacetic acid, and phenylcysteine. In contrast, humans did not form any substantial amount of glycine conjugate with these compounds. Interestingly, 1-naphthylacetic acid was conjugated only with glycine in addition to glucuronic acid in the rabbit, whereas 2-naphthylacetic acid formed conjugated metabolites with glycine, glutamine, and taurine as well as glucuronic acid (Emudianughe et al., 1978, 1979).

The drug-metabolizing enzymes in the rabbit are generally induced or inhibited with the known enzyme inducers or inhibitors in the other species, respectively. However, the effects of some inducers and inhibitors have been reported to differ in rabbits from those in the other species. When differential inductive effects in the rabbit liver were studied after treatment with phenobarbital, BNF, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), and 3-MC, metabolism of 2-AAF to the mutagenic metabolite *N*-hydroxy 2-AAF was increased from 7- to 13-fold after treatment with 3-MC, BNF, or TCDD (Atlas et al., 1975). The *N*-hydroxylation of 2-AAF increased twofold with phenobarbital in the rabbit but not in the rat, mouse, hamster, and guinea pig. A more detailed study revealed that in the rabbit, a significant portion of the microsomal metabolism of 2-AAF to the mutagenic metabolite was initiated by deacetylation to aminofluorene followed by *N*-hydroxylation, which was catalyzed by phenobarbital-inducible cytochrome P-450 LM₃ as well as by 3-MC-inducible cytochrome P-450 LM₄.

Acetanilide hydroxylation in the rabbit was induced from 2.4- to 3.9-fold with BNF, TCDD, 3-MC, and phenobarbital (Atlas et al., 1975). However, arylhydrocarbon hydroxylase (AHH) activity toward benzo(*a*)pyrene was increased only by phenobarbital but not by any of the other inducers in this study. Furthermore, Aroclor 1254 and methylcholanthrene, which were potent inducers of *N*-hydroxylation of 4-aminophenyl in the rat and guinea pig, were not inducers in the rabbit (McMahon et al., 1980). Interestingly, TCDD stimulated the demethylase activity for *p*-nitroanisole in the rabbit after 3 days of treatment, but the effect was lost after 6 days.

Cytochrome P-450 LM₅, which is found in rabbit liver and extrahepatic tissues, does not appear to be similar in all properties to any cytochrome P-450 isozymes isolated from other species. Although phenobarbital induces the synthesis of both isozyme LM₅ and LM₂ in rabbit liver, the relationship between these isozymes is not comparable to that between P-450₆ and P-450_e, highly related isozymes that are induced by phenobarbital in rat liver.

Vanderslice et al. (1987) examined the presence of homologs of rabbit cytochrome P-450 LM₅ in pulmonary and hepatic preparations from the rat, mouse, hamster, guinea pig, and monkey. Homologs of isozyme LM₅ were detected in pulmonary preparations from all five species. However, only hepatic preparations from the hamster, in addition to those from the rabbit, contained detectable levels of this isozyme. Although LM₅ isozyme in rabbit liver was induced by pheno-

barbital, treatment of other animals with phenobarbital did not increase the hepatic or pulmonary content of isozyme LM₅ homologs or the amount of 2-aminofluorene metabolism which was inhibited by antibodies to isozyme LM₅. Subchronic treatment of phenobarbital induced renal cortical microsomal monooxygenase and arylhydrocarbon hydroxylase and cytochrome P-450 content in rabbits but did not induce these renal enzyme systems in the rat (Kuo et al., 1982).

In addition to cytochrome LM₅ isozyme, rabbit pulmonary cytochrome P-450 comprises two other isozymes, LM₂ and LM₆. In the untreated rabbit lung, cytochrome LM₂ and LM₅ isozymes are present in approximately equal proportions. However, the isozyme LM₆ has been identified only after treatment with TCDD. In the liver, the isozymes LM₂ and LM₅ make up a small fraction of the total complement, which comprises at least nine forms. Phenobarbital, an inducer of forms 2 and 5 in liver, has no inductive effect in the lung. Induction of form 4 by aromatic hydrocarbons occurs in the liver but not in lung, except perhaps in the neonate. Pulmonary concentrations of isozyme 2 were decreased to trace levels by the administration of Aroclor 1260 (Ueng et al., 1980, Ueng and Alvares, 1981; Serabjit-Singh et al., 1983). The pulmonary content of isozyme 6 was also decreased twofold by treatment with phenobarbital but increased 5- and 10-fold by administration of Aroclor 1260 and TCDD, respectively.

It has been reported that metabolism of stereoisomers was selectively induced by pretreatment with different inducing agents. For example, when the stereoselective glucuronidation of oxazepam was studied using rabbit liver microsomes with a series of inducing agents, the ratio of diastereomeric products produced varied dramatically relative to noninduced animals (Yost and Finley, 1985). The *R/S* enantiomer ratio for noninduced rabbits was 0.76, but this was reversed to 1.41 after treatment with β -naphthoflavone. These data clearly suggest that various forms of glucuronyltransferase with different stereoselectivities were present in rabbit liver.

α -Naphthoflavone has been reported to be a potent inhibitor of reconstituted rabbit liver P-450 IA2 (LM₄) biphenyl 4-hydroxylation (IC₅₀ = 27 nM) and 7-ethoxy-resorufin-*O*-demethylation (IC₅₀ = 10 nM) (Johnson et al., 1979). In contrast, P-450 IIB4-dependent activity (rabbit LM₂) was only inhibited to a minor extent at an α -naphthoflavone concentration of 240 nM. Thorgeirsson et al. (1979) also studied the *in vitro* effect of α -naphthoflavone on four hepatic mono-oxygenase activities (arylhydrocarbonhydroxylase, 2-acetylaminofluorene *N*-hydroxylase, biphenyl 2-hydroxylase, and biphenyl 4-hydroxylase) before and after methylcholanthrene treatment of the rabbit and other laboratory animals (mice, rat, hamster, and guinea pig). *In vitro* addition of α -naphthoflavone selectively inhibited 2-AAF *N*-hydroxylase and biphenyl 4-hydroxylase activity in the methylcholanthrene-treated rabbit, which is consistent with the findings of Johnson et al. (1979). However, *in vitro* addition of α -naphthoflavone enhanced the activities of aryl hydrocarbon hydroxylase and

biphenyl 2-hydroxylase in liver microsomes from both control and methylcholanthrene-treated rabbit. The enhancement of mono-oxygenase activities by the *in vitro* addition of α -naphthoflavone may be caused by an interaction with the allosteric binding site(s) on the heme proteins. In contrast to the rabbit, *in vitro* addition of α -naphthoflavone selectively inhibited all four monooxygenase activities from the 3-MC-treated rat, mouse (C57BL/6N strain), and hamster.

Species differences in toxicity of a compound may be due to factors other than differences in its metabolism. Some of these factors include protein binding and biliary excretion in addition to absorption and renal elimination of drugs. When protein binding of some drugs (clofibrac acid, etodolac, tolrestat, perrinone, benoxaprofen) was examined in the rabbit and other laboratory animals (rat, mouse, dog, rhesus monkey) as well as in humans, the binding in the rabbit appeared to be medium. In general, the binding was highest in human serum and weakest in the mouse. However, when the protein binding of prednisolone was studied in serum from rabbits, dogs, rats, and humans, the binding characteristics of the drug in rabbit serum were most similar to those in human serum (Rocci et al., 1980). A similar phenomenon was observed with a new cephalosporin, CL284635 (Bialer et al., 1986).

14.9 NONHUMAN PRIMATES

NHPs are often the nonrodent species of choice for safety assessment studies. There are over 500 species of NHPs that differ widely from each other in size and physical characteristics. Most of the monkeys used in experimental research belong to the suborder Anthroidea and especially to the superfamilies of Ceboidea (marmoset and squirrel monkey) and Cercopithecoidea (macaque, *Papio* species, and rhesus). These have been popular because of (i) assumed better concordance of effects seen to those in man and (ii) smaller weights (and therefore reduced compound requirement). However, predominant factors leading to a decision whether or not to select primates as the nonrodent species for safety evaluation are summarized as follows (Hobson, 2000; Bluemel et al., 2015):

Primates Are Selected for Safety Studies Because

- They are the only species which exhibit the human response to the test article.
- Due to smaller body size, they conserve rare or expensive test articles.
- They don't form neutralizing antibodies to the test article.
- They are physiologically more similar to man.
- Regulatory agencies require their use.
- Prior development history dictates species choice.
- Known class effects have previously been seen in primates.

Primates May Not Be Selected for Safety Studies Because of

- Perceived expense
- Facility and logistic concerns
- Limited supplies
- Biosafety concerns
- Perceived animal rights or animal welfare concerns or pressures
- Tradition and prior development history
- Regulatory agency direction
- Data suggesting that other animal models are the "most sensitive species"

Tradition and cost are the two most frequently quoted reasons for selecting dogs as the second toxicology species instead of NHPs. Many pharmaceutical companies, especially those that primarily work with small molecules, have many years of background data in dogs and do not choose to venture into NHP research without a compelling reason to do so. Secondary concerns often center on perceived biosafety or animal rights issues. Contrary to conventional wisdom, NHP studies are often more cost efficient than studies in dogs. Although the purchase cost for NHPs is approximately twice that of dogs, many other factors suggest that the total cost of a NHP safety study may be less than the cost for a similar-sized dog study. Husbandry costs are higher in dogs because of the USDA requirement for exercise. Approximately fourfold more building space is required for a dog study due to the larger cages needed. Perhaps most importantly, the smaller body size of macaques means that the requirement for expensive or scarce test article in a primate study is approximately a third of that of a dog study.

Clearly, the amount and cost of test article and the length of the study determine which species is the most cost efficient.

Because NHPs are phylogenetically closer to man than other species, there is less chance that they will recognize human protein, peptide, or antibody-based biopharmaceuticals as foreign. Thus, they are often selected for safety studies of these materials. Although highly conserved proteins may not be immunogenic in lower species, clearly the formation of neutralizing antibodies to less conserved proteins during a safety study can confound experimental results (Dean et al., 1990). The formation of neutralizing antibodies to human biopharmaceuticals almost never occurs in chimpanzees (which no longer may be used in pharmaceutical research) but occurs more and more frequently as the NHP phylogenetic tree is descended. It is generally believed that NHPs' phylogenetic difference from man is ranked as follows: great apes, baboons, other old-world primates (including macaques), and new-world primates. Clearly, as proteins are modified, they can become immunogenic in all NHP species, including man (Konrad, 1989).

The physiological similarity and phylogenetic proximity of NHPs to man are often cited as rationale for NHP selection for safety studies, especially when mechanisms of toxicity or pharmacological action are expected to be closely related to potential physiological reactions in man. Likewise, species selection is often based on the demonstration of pharmacological activity of the test article. Many biopharmaceuticals do not exhibit their intended activity in nonprimate species, whereas small molecules may have activity across all species.

Regulatory agencies sometimes suggest (read dictate) the use of NHPs for certain study designs or drug classes. These requirements are often a surprise to companies when they are first presented. Usually, they are derived from confidential data that the regulatory agencies have previously reviewed. Often the regulatory bodies are privy to data that suggest that a class effect is seen in NHPs and not in other species or that NHPs are the most sensitive species. An example was regulatory agency encouragement to perform cardiovascular evaluations of oligonucleotide pharmaceutical candidates in NHPs (Black et al., 1993, 1994). This was based on background information that suggested that oligonucleotides induced complement activation, and the attendant hemodynamic and cardiovascular changes were observed in NHPs but not in other species (Galbraith et al., 1994).

Animal welfare and conservative issues have frequently led to decisions to avoid primate use. Through the mid-1980s many NHPs used in medical research came from wild populations. This led to strong conservationist concerns with the use of monkeys in research. Now, however, almost all NHPs used in research are purpose bred and the conservationist concern has abated. Although there is some animal rights pressure specifically directed against primate use, it is not as formidable as the well-financed and sophisticated efforts to prevent the use of cast-off dogs (pound or shelter dogs or dogs from other class B sources in research). As a consequence, a few pharmaceutical companies are considering switching to NHPs for their second toxicology species.

14.9.1 Environmental and Dietary Requirements

For most NHP species, room temperatures should be maintained in the range of $75 \pm 5^\circ\text{F}$ with a relative humidity of 40% or greater. These temperature and humidity ranges have been found to be beneficial to the prevention of pneumonia and bloody nose syndrome. Rooms in which monkeys are housed should have 10–15 air changes per hour and be kept under negative pressure in relation to other parts of the building. Where there is significant risk of airborne infection, it is necessary to contain infected animals in units designed to remove the air away from personnel (Mazue and Richez, 1982).

Physical comfort should be an important consideration when determining the appropriate housing for NHPs. For individually housed NHP, the floor area and height of cages

should be about $0.28 \text{ cm}^2 \times 76.20 \text{ cm}$ for animals in the weight range of 1–3 kg and $0.40 \text{ cm}^2 \times 76.20 \text{ cm}$ for monkeys weighing 3–10 kg (NRC, 2011). Probably the most common form of commercially available housing is mobile stainless steel rack-mounted cages. Group housing of NHPs used in safety studies is likely to become more common in the future as a result of the USDA's current animal welfare regulations, which require that NHPs have the opportunity for socialization.

Another requirement of the new animal welfare regulations is that any cage or pen in which NHPs are housed must also contain toys, food, or other objects that animals can manipulate, as they would objects in their natural environment. From experience, laboratories have found that toys in themselves are not sufficient since the animals quickly lose interest. Effective enrichment materials include foraging boards (fur-covered objects under which food is buried) and puzzle feeders for more complex foraging.

In many laboratories, monkeys are often fed with commercial pelleted chow *ad libitum* supplemented with fresh fruits and bread. Like man and the guinea pig, the NHP cannot synthesize vitamin C and, thus, has a dietary requirement for this vitamin. Powdered chow is an inefficient form for feeding NHPs, because a high percentage of the diet is wasted. Also, dust associated with the chow can cause respiratory problems in some species (NRC, 2003). Even with pelleted or extruded food, monkeys will waste about 50% of the ration sorting through the pellets (Mazue and Richez, 1982). Monkeys should have *ad libitum* access to water, and it is important that the device (either a water bottle equipped with a sipper tube or an automatic watering system) be fixed securely to the cage to avoid detachment by the animal.

14.9.2 Common Study Protocols

Group sizes and numbers of animals per group for NHP toxicology studies vary slightly from country to country and from company to company; however, with the movement for international harmonization, there is a trend toward less variation in study design. Selection of group size is a compromise among regulatory guidelines, cost, statistical power, and conservation of animals.

An example of a protocol for a 4-week safety study in cynomolgus monkeys is shown in Table 14.2. Cynomolgus monkeys are generally in the age range of 1–3 years at study start. A 2- or 4-week study will usually have about four animals per sex per group, not including the mandatory extra animal for evaluating recovery. For the longer-term studies, the number of animals per group will be larger in order to include recovery animals. As with dogs and ferrets, monkeys should be selected for study use based on acceptable pretreatment body weights, clinical laboratory profiles, and physical, ECG, and ophthalmic examinations.

One aspect of study design in NHPs that is not well understood is caused by the variability in the age at which monkeys

undergo puberty. Although age at the onset of puberty is highly variable within macaque species, there is a remarkable correlation between body weight and sexual maturity in macaques. Rhesus females undergo menarche at 3000±200 g irrespective of age, whereas males tend to become sexually mature around 4500 g. This means that a “typical” study is initiated with sexually mature females and sexually immature males. This practice is debatable and is certainly not universally adopted. A few pharmaceutical companies require mature animals of both sexes. Because sexual maturation in males occurs many months later than in females, rearing costs are higher for males and animal numbers may be limited because the younger males may have already been sold with their female birth year counterparts.

14.9.3 General Study Activities

14.9.3.1 Common Dosing Techniques Dosing routes and permissible volumes for NHPs vary between laboratories. The volume limitations from our laboratory are presented in Table 14.14.

Primates offer all of the possible dosing routes available in man, but body size often limits dosing volumes. If volumes for subcutaneous or intramuscular injections exceed those suggested previously, enzyme elevations (particularly alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) are frequently observed (unpublished results). Continuous infusion techniques in alert animals are available in some laboratories through the use of either programmable backpack pumps or jacket-and-tether systems (Perkin and Stejskal, 1994).

Probably the most common oral route is gavage. This procedure usually requires some degree of physical restraint of the animal (by one or more persons) while a stomach tube for dosing is inserted either orally or intranasally. Other oral dosing methods include buccal, capsule, or addition of the test compound to the drinking water. It is also possible to prepare a modified diet admixture consisting of test compound, diet meal, water, agar, and a jelling agent. This type of preparation will reduce both the feed spillage and the dust normally associated with powdered chow; however, it is susceptible to microbial growth and must be kept frozen or refrigerated (NRC, 2003).

Bolus intravenous, intramuscular, or subcutaneous injections can be administered by a single person by securing the animal’s arm through the cage bars (Mazue and Richez, 1982). For safety considerations, many investigators prefer to have the animal physically restrained by a second person before the injection is given. Arterial injections (via the femoral artery) as well as limited or continuous intravenous infusion (via catheterization of the femoral or jugular vein) are other less commonly used parenteral routes in the monkey.

TABLE 14.14 Summary of Hepatic Xenobiotic Drug Metabolizing Enzymes in the Rabbit

Enzyme	Concentration or Activity
Cytochrome P-450 (nmol/mg protein)	1.1 ^a , 0.779 ^b , 1.05 for M and 1.09 for F ^c , 0.720 ^d , 0.67 ^e , 0.81 ^{e,f}
Cytochrome b ₅ (nmol/mg protein)	0.3 ^g , 0.84 ^b
NADPH:cytochrome c reductase (nmol/mg protein)	185 ^a , 152 ^f , 130 for M and 150 for F ^c
NADPH:cytochrome P-450 reductase (nmol/mg protein)	3.0 for M and 3.4 for F ^c
Hydroxylase (nmol min ⁻¹ mg ⁻¹)	
Aniline hydroxylase	0.65 ^a , 0.542 ^b , 0.6 ^f , 0.72 ^h
Benzo(a)pyrene hydroxylase	0.061 ^d , 0.11 ⁱ
Biphenyl 4-hydroxylase	3.9 ^a , 1.7 ^f , 1.1 ^e , 2.0 ^j
Styrene oxide hydroxylase	5.6 ^j , 5.8–6.4 ^k , 4.2 ^l , 2.3 ^m , 10.1 ⁿ
<i>O</i> -Dealkylase (nmol min ⁻¹ mg ⁻¹)	
Ethoxycoumarin <i>O</i> -dealkylase	2.3 ^e
<i>p</i> -Nitroanisole <i>O</i> -dealkylase	5.4 ^e
<i>N</i> -Demethylase (nmol min ⁻¹ mg ⁻¹)	
Aminopyrene <i>N</i> -demethylase	15.0 ^b , 9.8 ^f , 8.0 ^h
Ethylmorphine <i>N</i> -demethylase	4.0 ^a , 4.0 for M and 4.3 for F ^c , 2.0–2.2 ^o
<i>N</i> -Hydroxylase (nmol min ⁻¹ mg ⁻¹)	
Dibenzylamine <i>N</i> -hydroxylase	2.9 ^p
2-Acetylaminofluorene <i>N</i> -hydroxylase	0.2 ^r , 0.1 ⁱ
Glutathion <i>S</i> -transferase (nmol min ⁻¹ mg ⁻¹)	
1-Chloro-2,4-dinitrobenzene	4091 ⁿ (cytosol), 81 ⁿ (microsomes), 156 ^q microsomes
Hexachloro-1,3-butadiene	0.14 ⁿ (microsomes)
Ethacrynic acid	5.81 ^r
Styrene oxide	30.5 ^j , 21.3–26.9 ^k , 36 ^l
Protein estimates (mg g ⁻¹)	
Microsomal	24.1 ^f , 13.8–22.8 ^k , 18.1 ^d
Cytosolic	72.7–82.0 ^k , 86.5 ^d

Other routes of administration sometimes used in monkey safety assessment studies are intravaginal dosing, topical application, inhalation, and nasal administration.

14.9.3.2 Clinical Observations and Examinations As with other species, it is important to have a good understanding of the types of normative behaviors and clinical signs that can be seen in normal, untreated monkeys before attempting to make observations in drug-treated animals. Cage-side observations in the monkey should be conducted at least two times daily to monitor general health and behavior. The first observation should be made before cages are cleaned in the morning, and the floors of the cages should be critically examined for signs of blood, abnormal feces, or vomitus. Clinical signs to which investigators should pay particular attention include reduced activity and lethargy, excessive excitation, reduced feed consumption, vomiting, and abnormal feces. If at all possible, the same people should work on a study for its entirety. The behavior of more timorous monkeys can be affected by the presence of unfamiliar personnel, resulting in undesirable clinical signs such as a loss of appetite and lethargy (Evans, 1982). To circumvent these kinds of problems, isolated observation using a video camera system may be a preferable approach.

Physical examinations of monkeys are usually conducted no more than once a week and generally consist of the measurement of rectal temperature; observation of general demeanor; palpation of the head, thorax, and abdomen; examination of the eyes, ears, and bodily orifices; and testing of the pupillary and patellar reflexes.

14.9.3.3 Feed Consumption As mentioned previously, monkeys tend to scatter their feed, which can make feed consumption difficult to measure. It may be possible to successfully monitor feed consumption in monkeys by using the larger chow biscuits and counting the number of biscuits (or fractions of biscuits) consumed over two consecutive 24 h periods.

14.9.3.4 ECGs and Cardiovascular Measurements The availability of excellent good laboratory practice (GLP)-validated telemetry systems has led to recent increases in the number of cardiovascular safety pharmacology studies conducted in primates. In addition, telemetry is now sometimes included as a design element in standard safety studies. Because of the ability to collect large amounts of high-quality data over an extended time, the total number of animals can often be reduced by appropriate application of telemetry. Indeed, it is often difficult to avoid statistical and reporting problems caused by the temptation to collect too much data using telemetry. Implanted transmitters can function continuously for up to a year without battery replacement while providing data such as blood pressure, heart rate, ECG, body temperature, and activity.

For safety assessment studies, it is preferable to record monkey ECGs in the conscious animal, which, if using standard ECG techniques, requires chairing the animal. Electrocardiographic leads used in this laboratory include II, aVL, and V10. To help reduce emotional tachycardia, it is recommended that there be pretreatment habituation (no more than 10–30 min at least twice before study start) to the chairing and attachment of the surface electrodes. Probably the best and least stressful approach to monitoring ECG activity in conscious monkeys is automatic monitoring using a biotelemetry system. With this system, a transmitter, surgically implanted subcutaneously along the dorsal midline, broadcasts a radio signal encoding the ECG to a receiver mounted on top of the animal's cage, and a computer records the signal at 2 min intervals (Line et al., 1989).

14.9.3.5 Blood and Urine Collections For blood collection, the rhesus can be bled from the saphenous or femoral vein. For female rhesus monkeys, it may not be possible to use the saphenous vein because of the swelling of the sex skin (i.e., the edematous thickening and reddening of the skin over the external genital region, rump, and tail that often extends down the leg to the knee). For the cynomolgus and squirrel monkeys, the veins are very small, and the femoral vein is usually the one of choice. Depending on the species, 2 (marmoset) to 24 (cynomolgus) mL may be collected.

However, experimental designs in primates are often constrained by the limitations in the amount of blood that can be safely and humanely obtained during the course of a study (Walker et al., 2015). With increasing emphasis on obtaining toxicokinetic data during safety studies, these constraints have become more vexing. A guideline for maximum blood withdrawal is 10 mL kg⁻¹ day⁻¹ (Heiser, 1970). More blood can be collected, but hematocrit should be monitored (Schalm, 2010). These amounts do not approach maximum amounts allowable for humane considerations but do represent the maximum that can be collected without causing anything more than slight decreases in hematologic parameters (notably hematocrit, hemoglobin, and red cell count). Currently, modern catheter material and vascular access ports support long-term frequent blood collection without the catheter clotting and emboli problems experienced in the past. The new vascular access ports remain patent for over a year with routine maintenance. Vascular access ports are particularly useful in NHPs where frequent samples are required because blood sample collection through ports appears to be far less stressful than collection by needle stick. We have also found them useful when evaluating anticoagulant test articles because venipuncture is contraindicated. Sample quality is also superior with ported collections.

Urine collection in NHPs can be measured using either a metabolism cage or a collection pan (equipped with a screen to catch the feces), which is inserted under the floor grid of the home cage. The advantage of the latter system is that the

animals do not need to be removed from their home cage; however, care needs to be taken to avoid contamination of the urine with drinking water.

14.9.4 Advantages and Disadvantages

Advantages of using NHP in safety assessment studies include their phylogenetic proximity, as well as their physiological, behavioral, and, often, metabolic similarities to humans (Table 14.13). An example is the similarity between the ovarian cycle of female monkeys and women (Mazue and Richez, 1982), which makes the monkey the ideal animal model for reproductive studies. Another advantage associated with most species of monkeys used in safety assessment studies is that they are much smaller than nonrodents such as the dog and, thus like the ferret, require less test compound.

The most significant disadvantage to working with monkeys is the serious spontaneous diseases they can carry that are transmissible, and often life threatening, to humans. An example of one such disease is *Herpesvirus simiae* (B virus). B virus is widespread, especially among wild-caught, and to some extent laboratory-bred, rhesus monkeys, including cynomolgus monkeys. Human exposure to B virus occurs during handling of monkeys and monkey tissues (via contact with tears, blood, or saliva of infected animals) and is associated with a high incidence of human mortality (DiGiacomo and Shah, 1972). Other serious to very serious diseases that can be transmitted from monkey to man are Marburg disease, viral hepatitis, tuberculosis, and monkeypox.

14.10 ISSUES IN ANIMAL MODEL SELECTION

Historically the most common species for use as the model to meet regulatory requirements are the dog and the NHP, generally for use with small molecules or proteins, respectively. However, the range of potential species is much broader, and the relevant considerations are more complex. A starting place should be to determine which species is metabolically and pharmacologically/pharmacodynamically the best model for humans.

The metabolism “fit” is usually addressed by screening metabolites formed by incubation of the drug with a range of species-specific hepatocytes. While the metabolites formed are generally not identified but rather the peaks formed at different retention times are compared to those formed by human metabolites. A second metabolic consideration is the stability of the drug in the presence of species-specific hepatocytes. The rate of metabolism and half life of parent compound when incubated with species-specific hepatocytes is compared with those of humans.

Pharmacologic relevance is assessed by comparing finding characteristics at the target receptor site and by assessing the

potential for off target hits in a panel of potential binding sites. Other aspects to be considered are:

1. *Route*: for a dermal drug, the minipig is broadly considered to be the best model for absorption.
2. *Tolerance*: Some species are not tolerant to exposure by the oral route to some classes of structures. The dog for a broad range of compounds, for example. These are covered in Gad (2015).

14.11 STATISTICS IN LARGE ANIMAL STUDIES

Large animal toxicology studies, typically ranging from 14 days to generally a maximum of 52 weeks, pose different types of statistical problems and open new possibilities in terms of statistical evaluations. Standard statistical methods used for chronic toxicology studies, such as one-way designs, often do not provide any meaningful insights because of small sample sizes used in large animal studies. The designs for such studies are nonoptimal. Consequently, an investigator must attempt to use optimal statistical methods to evaluate such studies. Fortunately, for many of the relevant parameters for such studies, there are fewer to no dropouts (if one is careful), and there are repeated measurements on the same parameters of interest, both pre- and posttreatment intervals. Optimality of statistical methods for such studies is then achieved by making use of the longitudinal observations in the analysis. The optimality can be further enhanced by introducing sex as a factor in the evaluation of the data in many such studies.

Many of the standard assumptions in both parametric and distribution-free statistical methods cannot be meaningfully tested in large animal studies because of extremely small sample sizes (which are not necessarily dictated by scientific doctrine but by economic and minimum regulatory requirements). Fortunately, by making use of solid biological as well as statistical judgments, we seem to have made many discoveries in terms of human safety and efficacy in large animal toxicology.

Instead of a conventional textbook-type layout, this discussion will try to focus on various issues in large animal toxicology experiments with plausible examples. One word of caution before we get deeper into our discussion: like in most areas of applied statistics, there really is no gospel in what we will be discussing today. Many statisticians may have variations of the theme to be brought out here.

14.11.1 Reasons for Small Sample Sizes in Large Animal Toxicology

The following are some of the main reasons for having only three to five dogs or monkeys per sex in a typical large animal study:

1. These studies are very expensive. A typical full-fledged study may cost as much as US\$ 30 000 to US\$ 500 000 (for 26 weeks).
2. There is tremendous pressure from the animal rights groups to look for alternatives rather than using dogs and monkeys for investigating purposes.
3. Regulatory agencies throughout the world recognize these two facts and recommend such small sample sizes as minimum requirements. Consequently, the pharmaceutical and chemical industries are reluctant to expand the scopes of such studies.

14.11.2 Cross-Sectional or Longitudinal Analysis?

Many of the studies we deal with have various parameters, such as body weight, food consumption, clinical chemistry, and hematology, that are collected repeatedly at various pre-treatment and posttreatment intervals. Unfortunately, many investigators in the field do not take advantage of this important design feature of such studies. Instead, one finds the literature is full of simple parametric or distribution-free one-way techniques, such as Student's *t*-test, Wilcoxon–Mann–Whitney rank test, one-way analysis of variance (ANOVA) methods, and so on, widely being used, sometimes without satisfaction. The argument then is given that “although there is apparent biological effect (or lack of it), because of small sample sizes and poor statistics, no significant effects can be determined from these data” or something like that. If truth be known, the small sample size part of this argument may be correct; however, no attempts were made to optimize on the statistical methods above using the various pieces of the particular design. The repeated sampling part of the design (repeated measures) is very important for such studies and therefore should be incorporated in the analysis of the data. After all, design of experiment and analysis of data are inseparable. There are advantages and disadvantages of such analyses (the advantages generally outweigh the disadvantages) as described in the following.

14.11.3 Repeated Measures: Advantages

1. Between-subject variations are excluded from the experimental and stochastic errors.
2. Only the within-subject variation is included in the mean square error (*MSE*) term.
3. Each subject becomes its own control.
4. Economizes on the number of subjects in an experiment.
5. Minimizes both type I (false positive) and type II (false negative) error rates, thereby increasing power of the test statistic to be employed while decreasing inconsistent significant effects.

14.11.4 Repeated Measures: Disadvantages

1. Order of the treatment may cause interference which can be avoided by appropriate randomization.
2. There is the possibility of carry-over effects. This is more crucial in Latin square and other crossover designs. Knowledge of pharmacokinetics and metabolism of a compound under study generally helps in avoiding this problem.
3. Exact permutation and distribution-free techniques are not as widely developed as in the cases of one-way methods.
4. Power and sample size computations are a little more difficult to compute than one-way designs.
5. Generally requires computers for performing the analyses using specialized software (not a major issue in most societies nowadays).
6. A little more difficult to interpret the results than their one-way counterparts.

14.11.5 Common Practices in Large Animal Toxicology

Older (and some newer) literature in large animal toxicology is full of two-sample, one-way parametric, and distribution-free techniques. Some of the newer works use repeated measures and even multivariate techniques. The following is a brief exposé of various methods used in the field:

1. One-way ANOVA/analysis of variance covariance (ANCOVA)/regression and preplanned and post hoc group comparisons
2. Two-sample Student's *t*-test, Wilcoxon–Mann–Whitney rank test, and so on
3. Graphic display of response over time (as two- or three-dimensional plots)
4. Univariate repeated measures ANOVA/ANCOVA techniques
5. Multivariate analysis of variance (MANOVA)/multivariate analysis of covariance (MANCOVA) techniques

Methods 1 and 2 in the preceding text should not be preferred in global analyses. Graphic displays have tremendous values as exploratory data analysis (EDA) techniques with the type of data one encounters in these studies. For formal analyses, one could weigh univariate repeated and other factorial designs against their true multivariate counterparts.

14.11.6 Univariate (Repeated Measures) Techniques: Advantages

1. Easier to compute.
2. Less susceptible to violation of normality.

3. Exact and distribution-free tests are easier to compute.
4. Require smaller sample sizes; there is more power.
5. Very few test statistics to deal with: classical ANOVA F , Greenhouse–Geisser and Huynh–Feldt adjusted degree of freedom (df), and ANOVA F .
6. Biologically meaningful and easier to resolve contrasts and multiple comparison tests.
7. Missing values are easily handled.

14.11.7 Univariate (Repeated Measures) Techniques: Disadvantages

1. Susceptible to heteroscedasticity (heterogeneity of variances)
2. Less fancy compared to multivariate techniques

14.11.8 Multivariate Techniques: Advantages

1. Less susceptible to heteroscedasticity
2. Handles multiple dependent variables
3. Real fancy compared to univariate ANOVA/ANCOVA techniques

14.11.9 Multivariate Techniques: Disadvantages

1. More susceptible to violation of normality
2. Less power than univariate ANOVA, particularly with small sample sizes
3. Contrasts and multiple comparisons that are difficult to construct
4. Missing values that are more difficult to handle
5. Computationally more difficult (a mute point nowadays with personal computers)
6. Too many test statistics, sometimes giving contradictory answers, to deal with

14.11.10 Some Other Design Factors to Be Considered in Analysis

Most of the toxicological studies are designed to evaluate efficacy and safety in both sexes. With small sample sizes, one can increase the power efficiency of the particular test statistic by including sex as a factor in a full factorial analysis (not combining the two sexes) where appropriate. The factorial analysis will reveal whether there is any need to separate the two sexes. The other design fact that should be weighed carefully is the presence of any concomitant variables or covariates. For example, most large animal studies will involve collection of data both prior to the beginning of the experiments as well as after. Thus pretreatment values and other characteristics that control variables (e.g., body

weights) may be important covariates in the analysis of the data. There are both advantages and disadvantages in including covariates in the analysis.

14.11.11 Covariates: Advantages

1. Increases precision of an analysis (indirect or statistical control of variability)
2. Correction of bias
3. Elimination of extraneous variation in the data

14.11.12 Covariates: Disadvantages

1. Unequal intra- and intergroup covariate slopes may actually introduce bias as a consequence.
2. Nonlinearity of covariate slopes may have the same effect as in the preceding text.
3. In some cases, the covariates may be affected by treatment.

An example is shown in Table 14.14. A two-factor ANOVA for the covariate, as shown in Table 14.15, clearly indicates that the two sexes started with approximately the same means ($p = 0.5598$). Moreover, there were no differences between the group means in either sex as indicated by the large tail probabilities for treatment ($p = 0.8823$) and sex \times treatment interaction ($p = 0.6532$). These facts justify using sex as a factor in the analysis, as was done here.

There are various other ways of examining the variate in question in this case. Let us first examine simple one-way ANOVA of the variate by sex as in Table 14.16. In neither of the two cases was there any indication of significant treatment differences at any reasonable level. Because the two sexes did not show any pretreatment differences based on the two-factor analysis of the covariate, let us combine the two sexes and analyze the data by one-way ANOVA as in Table 14.17. In this case, because of the increased sample sizes for combining the two sexes, there was an indication of some treatment differences ($p = 0.0454$). Unfortunately, this analysis assumes that because there were no pretreatment differences between the two sexes, that pattern will hold during the posttreatment period. That often may not be the case because of biological reasons.

The earlier analysis establishes that there was no significant sex difference, as indicated by the tail probabilities for sex ($p = 0.2667$) and sex \times treatment interaction ($p = 0.9784$) (Table 14.18). There was also some indication that there may have been some treatment effect across the treatment groups in both sexes ($p = 0.0559$). Examination of the variate means indicated that both sexes seemed to have lower means than their respective controls. The picture was clouded by the fact that there was such a slightly lower tendency, though not very

consistent, in the covariate means as well. Under this circumstance, it is more appropriate to take both the covariate and the variate into any optimal analysis. Table 14.19 shows an ANOVA for the factorial model.

As the ANCOVA table indicates, there was a definite significant treatment effect ($p = 0.0104$), but this effect was not sex specific because there was no significant sex \times treatment interaction ($p = 0.7613$). Furthermore, there was a significant difference between the two sexes in terms of magnitude but not in the direction of the effect. These findings are apparent in the covariate-adjusted means in all groups in both sexes.

TABLE 14.16 Comparison of Costs for Typical 90-Day Studies Conducted with Nonhuman Primates or Dogs

Animal cost (assume 40 animals)	
Cost of dogs	40 \times US\$ 900 = US\$ 36 000
Cost of primates	40 \times US\$ 2 200 = US\$ 88 000
Per diem	
Dogs	90 days \times US\$ 11 \times 40 = US\$ 39 600
Primates	90 days \times US\$ 7 \times 40 = US\$ 25 200
Test article (at US\$ 400 mg ⁻¹)	
Dogs	10 kg \times 90 days \times 40 animals \times 100 μ g kg ⁻¹ day ⁻¹ = US\$ 1 440 000
Primates	4 kg \times 90 days \times 40 animals \times 100 μ g kg ⁻¹ day ⁻¹ = US\$ 576 000

TABLE 14.17 Permissible Dosing Volumes for Nonhuman Primates

Route	Maximum Permissible Dose ^a
Intravenous	Varies with duration of administration and character of test article
Subcutaneous	2 mL site ⁻¹ and 5 mL kg ⁻¹
Intramuscular	0.25 mL site ⁻¹ and 0.5 mL kg ⁻¹
Oral/nasogastric	5 mL kg ⁻¹

^a Values are given for single or infrequent administration. Smaller volumes are appropriate for repeated dosing.

TABLE 14.18 Use of the Nonhuman Primate in Safety Assessment Studies

Advantages

Small size of many species
 Less test material needed than for other nonrodent species
 Physiological, behavioral, and, often, metabolic similarities to man

Disadvantages

Limited availability
 Cost
 Need to develop environmental enrichment programs
 High potential for spontaneous diseases

The magnitude of the treatment effect became amplified by introducing the covariate in the model. As can be seen from the two ANOVA and ANCOVA tables in the preceding text, despite the fact that the ANCOVA error term lost 1 degree of freedom ($df = 23$) as opposed to the ANOVA error term ($df = 24$), the former gains some edge over the latter because of increased precision. Precision in this context is defined as the ratio between the *MSEs* of ANOVA and ANCOVA (Tables 14.20–14.25). For this example,

TABLE 14.19 Example 1

Standard error	2.293 98	2.293 98	2.309 85

$$\begin{aligned}
 \text{Precision} &= \frac{1/\text{MSE}_{\text{ANCOVA}}}{1/\text{MSE}_{\text{ANOVA}}} \\
 &= \frac{\text{MSE}_{\text{ANOVA}}}{\text{MSE}_{\text{ANCOVA}}} \\
 &= \frac{59.38333}{26.10642} \sim 2.3
 \end{aligned}$$

In other words, we have gained about 2.3-fold precision by ANCOVA over ANOVA in resolving treatment effect.

With the advent of powerful personal computers and the availability of sophisticated “do-it-all” statistical packages, there is a trend among nonstatisticians (even some statisticians) to accept the results from these packages without contemplating twice. Many of these packages have flexible features that allow one to perform different types of analyses with the same data set, inappropriately or appropriately sometimes. What popular statistical packages give is not necessarily correct statistics or they may not be correct under specific designs. Some programs, for example, BMDP’s 2V (1992), have “intelligence” built into them whereby they can identify the design based on the data matrix. By following the data matrix setup specified in the manual correctly, one can simply press the button and get the appropriate analysis needed. On the other hand, incorrect specification of the data matrix will produce incorrect results (although some programs, such as 2V, will often give an error message or prompt to make sure one wants what one is asking for; some such as SAS’s PROC GLM may not and give results that are not even remotely related to the design). In other words, one must know some statistics and must be well versed in the features of the

particular package before using them. The one-time famous mathematician, statistician, composer, pianist, singer, producer, and recording artist Tom Lehrer (1959), in one of his famous monologues, said, “Life is a sewer; what one gets out of it depends on what one puts into it.” Statistical packages are exactly like that.

14.11.13 Missing Values

All investigators know that missing values are a nuisance. They also create statistical nightmares. Classical statistical techniques were not geared toward having missing values in experiments. Unfortunately, in real-life situations, it just happens. Animals may die or are censored for various reasons. There are various techniques of calculating missing values for specific designs (Miller, 1981) just like there are for extreme values or outliers (SAS, 2015). In neither case there is a unique way of handling them that is completely agreed upon by statisticians. One should remember that every time a missing value is computed and used in statistical analyses, one loses a degree of freedom. In large animal toxicology, with small sampling sizes, one must be very careful about dealing with missing values. In a repeated measures analysis, if one observation is missing from an animal during one interval, classical techniques automatically will exclude observations from that animal for all remaining intervals. Newer techniques based on regression or imputation have been developed in recent years and have been implemented in popular packages such as BMDP (5V) or SAS (PROC MIXED). Within a single package, there may be various techniques based on assumptions on covariance structures (unstructured, compound symmetry, etc.) and statistical

algorithms (maximum likelihood, restricted minimum likelihood, etc.). The results sometimes could be very different under the same assumptions and algorithms. As a result, given the same compound symmetry assumption and using the same restricted maximum likelihood (REML) algorithm, two well-known programs give different quantitative results. These methods are still experimental in nature and should not be taken for granted. Actually, the BMDP manual clearly warns users about the nature of this method. Consequently, the best way to avoid confusion is to try to make sure that missing values do not occur in key parameters in *large animal* studies (Thakur, 2000).

14.12 READ ACROSS FOR CROSS SPECIES DATA INTEGRATION

While a well executed nonclinical safety study generates a great deal of data, all too often a great deal of the potential value of the data is not used—data from different species (and even from individual studies) are considered only on their own, and not rather as part of a matrix of data. What is needed is an integrated evaluation produced by a form of read-across analysis. What do we know of dose–response and the trends across these species? Are target organs and effects common across all or most of the species? These are just some of the questions that should be addressed.

14.13 SUMMARY

While there are advantages and disadvantages associated with all three of these nonrodent species, the dog is probably the nonrodent species most frequently used in safety assessment studies. This is because dogs are relatively docile and even tempered, they are generally easier to obtain and relatively less expensive than monkeys, they carry less serious diseases than the ferret and the monkey, and they have a more extensive historical database in safety studies. It should be noted, however, that if the technical and health problems associated with the ferret can be overcome, its small size in terms of compound requirements, cost, and housing may make it an ideal nonrodent species for future use in safety assessment studies.

DEVELOPMENTAL AND REPRODUCTIVE TOXICITY TESTING

15.1 INTRODUCTION

The objective of evaluating the potential developmental and reproductive toxicity of drug candidates in laboratory animals is to predict which agents would adversely affect the ability to achieve and maintain pregnancy/interfere with the normal development of offspring, humans and to allow evaluation of the potential risks to patients and their offspring at levels of clinical use. An additional concern being seriously addressed is the existence of qualitatively different and quantitatively greater sensitivity to adverse effects in juvenile and pediatric populations. No longer is it accepted as adequate to simply select doses based on body sizes to be able to predict the safety of a drug product in these vulnerable populations (Tassinari et al., 2013; Faqi, 2017). The need for specific developmental testing of drugs evolved over a period of more than 60 years, with four historic events heightening concern:

- 1941: Human malformations linked to rubella virus.
- 1950s: Methylmercury recognized as developmental toxicant (from Japanese environmental exposure).
- 1960s: Thalidomide (a sedative and antinausea drug) found to cause human malformations.
- 1970s: Alcohol related to developmental effects—fetal alcohol syndrome (FAS). Lead came to be a similar concern.
- Twenty-first century: increase in diagnoses of autism in children in the US

This testing involves an extensive battery of studies based on experience with animal models (see Table 15.1), historically on guidelines promulgated by the Food and Drug Administration (FDA) of the United States in 1966 (see Food

and Drug Administration, 1966, 1984, 2000a,b; D’Aguanno, 1973), and subsequently modified by ICH. These guidelines established three basic types of studies, segments I, II, and III, that are based on dosing during sequential phases of the reproductive cycle. These guidelines represented a dramatic increase in the extent and sophistication of testing expected of new drug candidates. The impetus for this intensified interest was the tragic epidemic of phocomelia and other congenital malformations caused in the early 1960s by the exposure of pregnant women to the sedative thalidomide (for an excellent discussion of the history of the thalidomide tragedy, see Schardein, 2000). Table 15.2 presents the most recent guidelines.

The types of developmental and reproductive toxicity studies performed prior to 1993 and the methods used have been extensively documented (see Palmer, 1981; Christian, 1983; Persaud, 1985; Schardein, 1988; Christian and Hoberman, 1989; Khera, 1991; DeSesso and Willhite, 2009; Makori et al., 2009; Cooper and Goldman, 2010; Kapp, 2010; Hood, 2012; Klinefelter and Veeramachaneni, 2014; York et al., 2014). Since June 20, 1979, the FDA has required that these studies be conducted according to Good Laboratory Practice (GLP) regulations (see FDA, 1978, 2007, 2020). The conduct of these studies had been complicated by the need to satisfy worldwide regulatory guidelines that varied from country to country. As a result, studies were conducted for regulatory purposes that, from a scientific viewpoint, were redundant, superfluous, and/or unnecessarily complex. This situation was changed in 1993 when the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) standardized worldwide requirements in the guideline “Detection of Toxicity to Reproduction for Medicinal Products” (S5 A and B).

TABLE 15.1 Teratological Classification in Animal Species of Groups of Substances Universally Recognized as Human Teratogens: Summary of Classifications by Animal Species

Species	Substance Group											Results	
	Androgenic Hormones	Anticancer Antimetabolites	Anticancer Alkylating Agents	Anti-convulsant Hydantoins	Anti-convulsant Diones	Coumarin Anticoagulants	Antithyroid Drugs	Aminoglycoside Antibiotics	Vitamin A Analogs	PCBs	Tetracyclines	+/-	%+
Mouse		±	+	+	+	-	+	±	+	-	±	5/3/2	50
Rat	+	+	+	+	±	+	±	+	+	-	±	7/3/1	64
Rabbit	+	±	+	+		-	±	-	+	-	-	4/2/4	40
Hamster	+	+		-					+			3/0/1	75
Primate	+	±	+	+	±			-	+	±		4/3/1	50
Dog	+	±		-					+	+	-	3/1/2	50
Cat		±		-								0/1/1	0
Pig	+	+							+	±		3/1/0	75
Ferret			+						+			2/0/0	100
Guinea pig	+	+					+	±	+	-	+	5/1/1	71
Sheep	-	+					+					2/0/1	67
Cow	+						-			-		1/0/2	33
Total												39/15/16	Mean = 56%

Eleven groups of substances known to be teratogenic in humans are listed above, along with their teratogenic classifications in 12 species of animal (Schardein, 2000). + = teratogenic; ± = variably teratogenic; - = not teratogenic. No entry = no classification available. The number of positive, variable, and negative results in each species for all groups of substances is summarized, along with the combined percentage of positive results for all groups of substances in each species. The maximum and minimum concordance of results with respect to human classifications are 100 and 0% in the ferret and the cat, respectively, although only 2 results are listed for both of these species. While positive predictability is 75% for the hamster, it is just 40% for the rabbit, which also exhibits a false-negative rate of 40%. The mean positive predictability rate in those species tested for at least 9 of the 21 agents (viz., the first six categories, i.e., mouse, rat, rabbit, hamster, primate, dog) was under 55%, and the number of equivocal results remained high across these six species at just under 25%. Taking all 70 results into account leads to an overall positive rate of only 56%, only slightly better than by chance.

FDA	International Conference on Harmonisation: Guideline on Detection of Toxicity to Reproduction for Medicinal Products; Addendum on Toxicity to Male Fertility. Federal Register, April 5, 1996, Vol. 61, No. 67

This chapter briefly describes the current standard study designs and then focuses on current and continuing issues in developmental and reproductive toxicity testing.

15.2 ICH STUDY DESIGNS

The ICH S5 A and B guideline allows for various combinations of studies. The studies conducted must include evaluation of the following components:

1. Male and female fertility and early embryonic development to implantation
2. Embryo–fetal development
3. Pre- and postnatal development including maternal function.

These components would normally be evaluated in a rodent species (preferably rats) and, in addition, embryo–fetal development would be evaluated in a second species, typically the rabbit. The “most probable option” in the ICH guideline is the case where three rodent studies would be conducted that separately addressed each of the components listed in the preceding text. These study designs are described in the succeeding text. Table 15.3 presents a comparison of ICH, FDA, European, and Japanese guidelines. The day of insemination or detection of evidence of mating is considered day 0 of gestation, and the day of birth is considered postpartum and postnatal day 0. Figure 15.1 presents line charts for the ICH stage study designs.

15.2.1 Male and Female Fertility and Early Embryonic Development to Implantation

The purpose of this component is to assess the effects that result from treatment during maturation of gametes, during cohabitation, and, in females, during gestation up through the time of embryo implantation (typically the last dose on day 6 of gestation) (DeSesso and Willhite, 2009; Gupta, 2011; York et al., 2014). Assuming that the findings from a toxicity

TABLE 15.3 Comparison of ICH Stages and Study Types with Similar Observations Made

ICH Stage	FDA Guidelines	Great Britain and EEC Guidelines	Japanese Guidelines	EPA OPPTS, OECD, and FDA Redbook Guidelines
A—Premating to conception: reproductive functions in adult animals, including development and maturation of gametes, mating behavior, and fertilization	Segment I	Segment I	Segment I	Multigeneration One generation
B—Conception to implantation: reproductive functions in the adult female and preimplantation and implantation stages of the conceptus	Segment I	Segment I	Segment I	Multigeneration One generation Developmental Toxicity
C—Implantation to closure of the hard palate: adult female reproductive functions and development of the embryo through major organ formation	Segment I Segment II	Segment I Segment II	Segment II	Multigeneration One generation Developmental Toxicity Developmental Neurotoxicity
D—Closure of the hard palate to the end of pregnancy: adult female reproductive function, fetal development, and growth and organ development and growth	Segment I Segment II Segment III	Segment I Segment II	Segment II	Multigeneration One generation Developmental Toxicity Developmental Neurotoxicity
E—Birth to weaning: adult female reproduction function, adaptation of the neonate to extrauterine life, including preweaning development and growth (postnatal age optimally based on postcoital age)	Segment I Segment III Pediatric	Segment I Segment II Segment III	Segment II Segment III	Multigeneration One generation Developmental Toxicity Developmental Neurotoxicity
F—Weaning to sexual maturity: (pediatric evaluation when treated) postweaning development and growth, adaptation to independent life, and attainment of full sexual development	Pediatric	Segment I	Segment II Segment III	Multigeneration Developmental Neurotoxicity Developmental Immunotoxicity

Bolded information indicates treatment interval.

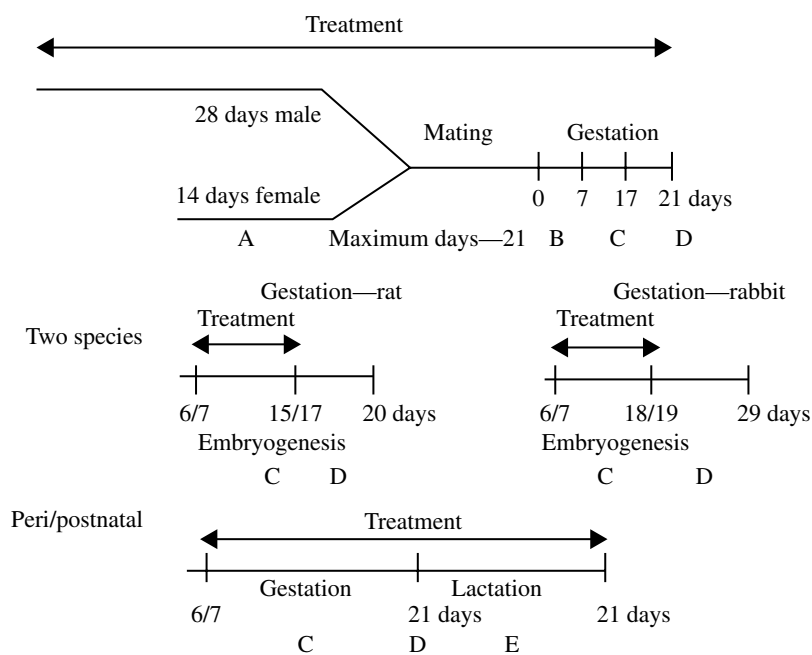

FIGURE 15.1 ICH line charts of nonclinical reproductive and developmental toxicology studies. A, B, C, D, and E here refer to ICH stages as explained in Table 15.3.

study of at least 1 month in duration do not contraindicate, the treatment period begins in males 4 weeks before male/female cohabitation and, in females, 2 weeks prior to cohabitation. A group size of 16–24 litters would generally be considered acceptable.

Minimal in-life observations include:

1. Clinical signs and mortality daily
2. Body weight twice weekly
3. Food consumption weekly
4. Vaginal cytology daily during cohabitation
5. Valuable target effects seen in previous toxicity studies

Females are sacrificed after the middle of the gestation period. Males are sacrificed at any time after the end of the cohabitation period, but it is generally advisable to retain the males until after the outcome of the first mating is known, to ensure that a repeat cohabitation with untreated females will not be needed to determine if an observed effect on mating performance is a male effect. Males are treated until termination. Terminal examination of adults includes:

1. Necropsy
2. Preservation of organs with gross changes and sufficient control organs for comparison
3. Preservation of testes, epididymides, ovaries, and uteri

4. Sperm count and sperm viability
5. Count of corpora lutea and implantation sites
6. Count of live and dead conceptuses

Among the study designs conducted before the ICH guidelines, the segment I fertility study conducted according to Japanese guidelines is most similar to this ICH study design. The major differences are the shortening of the treatment period of males prior to cohabitation from the duration of spermatogenesis (60–80 days) to 4 weeks and the addition of sperm evaluation. The justifications given for shortening the treatment period of males are the following:

1. Careful organ weight and histopathological evaluation of testes in general toxicity studies will detect most testicular toxins.
2. Fertility is an insensitive measure of testicular effects.
3. Compounds known to affect spermatogenesis generally exert their effects during the first 4 weeks of treatment.

Sperm counts can be performed with sperm from either the testis or the epididymis. Sperm motility is commonly being treated as a measure of sperm viability. The addition of sperm evaluation greatly increases the sensitivity of the study to detect effects on sperm maturation, and the current study design will likely detect more male effects than previous designs even though the treatment period has been shortened.

15.2.2 Embryo–Fetal Development

The purpose of this component is to detect anatomical effects on the developing conceptus by treating during the period of organogenesis from implantation to closure of the secondary palate. The study design is very similar to the historical segment II developmental toxicity study. A group size of 16–24 litters would generally be considered acceptable. The following is demonstrated in Table 15.4.

Minimal in-life observations include:

1. Clinical signs and mortality daily
2. Body weight twice weekly
3. Food consumption weekly
4. Valuable target effects seen in previous toxicity studies

Females are sacrificed at the end of the gestation period, about one day prior to parturition (day 20 or 21 for rats, day 28 or 29 for rabbits, and day 17 or 18 for mice). Terminal examinations include:

1. Necropsy
2. Preservation of organs with gross changes and sufficient control organs for comparison
3. Count of corpora lutea and live and dead implantations
4. Fetal body weight
5. External, visceral, and skeletal examination of fetuses
6. Gross evaluation of placenta

A minimum of 50% of fetuses are to be examined for visceral alterations and a minimum of 50% for skeletal abnormalities. When a fresh tissue microdissection technique is being used for the visceral examination of rabbit fetuses, all fetuses should be examined for both visceral and skeletal abnormalities.

Interpretation of results requires understanding and utilizing the following definitions:

Malformation: Structural change that is likely to be permanent and detrimental to the survival or well-being of the fetus, in the species/strain of animal being tested

Alternation: Change that is, in isolation, unlikely to be detrimental to the survival or well-being of the fetus, in the species/strain of animal being tested

TABLE 15.4 Recommendations for Acceptable Group Size (Litters)

	Rat	Rabbit	Mouse
Treatment period (gestational days)	6–17	6–18	6–15
Group size (mated or inseminated)	16–24	16–24	16–24

Variant: Observation occurring frequently in a particular strain of animal

15.2.3 Adverse Effects

The following definitions should be referred to when considering whether an observed effect of treatment is adverse or not:

1. Treatment-related trend in incidence of specific or related malformations
2. Treatment-related increase in alterations, the cumulative effect of which is considered to be detrimental to the well-being of the fetus
3. Treatment-related increase in alterations, which are related in nature or derivation to treatment-related malformations evident on the study
4. Treatment-related marked change in the incidence of a group of alterations, in which although their form is normal for a previous or future stage of development, that is, their occurrence suggests precocious or delayed development, their presence in a marked degree suggests some permanent change in the rate of development of the fetus and could be detrimental to its future development
5. Marked treatment-related increase in the occurrence of a specific alteration, in which the form is not predictive of the normal chronological order of development (e.g., bent scapula)

15.2.4 Pre- and Postnatal Development

The purpose of this component is to detect effects of treatment from implantation through lactation on the pregnant and lactating female and on the development of the conceptus and offspring through sexual maturity. The study design is similar to the previous segment III study design except that dosing begins on day 6 of gestation instead of day 15. A group size of 16–24 litters would generally be considered acceptable (with 25 mated females being recommended).

Minimal in-life observations for parental (F₀ generation) females include:

1. Clinical signs and mortality daily
2. Body weight twice weekly
3. Food consumption weekly
4. Valuable target effects seen in previous toxicity studies
5. Length of gestation
6. Parturition

Parental females are sacrificed after weaning of the F₁ generation. The age of sacrifice of the F₁ generation animals is not specified in the ICH guideline and varies among laboratories.

Typically, they are sacrificed intermittently with some laboratories reducing litter size on postnatal day 0, 3, or 4, on postnatal day 21 or at weaning, at male/female cohabitation to produce an F₂ generation, and at the terminal sacrifice, after production of the F₂ generation. Terminal examinations for maternal animals and offspring include:

1. Necropsy of all parental and F₁ adults
2. Preservation of organs with gross changes and sufficient control organs for comparison
3. Count of implantations

Additional observations of the F₁ generation include:

1. Abnormalities
2. Live and dead offspring at birth
3. Body weight at birth
4. Pre- and postnatal survival, growth, maturation, and fertility
5. Physical development including vaginal opening and preputial separation
6. Sensory function, reflexes, motor activity, learning, and memory

15.2.5 Single-Study and Two-Study Designs for Rodents

Except for the embryo–fetal development component in rabbits, the components described previously can be combined into fewer, larger studies instead of conducting each component separately. Acceptable alternatives include the “single-study design” and “two-study design.” The choice may be made based on when study results are needed (how soon are females to be incorporated in clinical studies) and compound availability.

In the “single-study design,” all of the aforementioned components are combined into one study. The dosing period, extending from before mating to lactation, is a combination of that for the fertility study together with that for the pre- and postnatal development study. Subgroups of animals are terminated at the end of gestation for fetal examination.

There are a variety of possible “two-study designs.” One is to conduct the single study described in the preceding text except that, instead of having subgroups for fetal examination, a separate embryo–fetal development study in rodents is conducted. Another two-study design consists of combining the embryo–fetal development study with the pre- and postnatal development study such that the two studies to be conducted would be (i) the fertility study and (ii) the pre- and postnatal development study with subgroups terminated at the end of gestation for fetal examination. A third possible two-study design is to combine the fertility study with the embryo–fetal

development study. In the first study, treatment would extend through the end of organogenesis, and then, at termination at the end of gestation, there would be a complete fetal examination. The second study would be the pre- and postnatal development study.

For all the options described earlier, effects on male and female fertility can be evaluated separately by conducting separate studies in which only one sex is treated. The treatment periods are the same, but the treated animals are cohabited with untreated animals of the opposite sex. In the male fertility study, the untreated females are terminated after the middle of gestation, and terminal observations include embryo survival and possibly external examination of fetuses (if terminated at the end of gestation) (Tanimura, 1990). The advantage of conducting separate male and female studies is that, if there are effects, it is clear which sex was affected by treatment. Often when effects are seen in a combined male and female study, additional work is required to resolve which sex was affected. Either a second cohabitation of the treated males with untreated females is added, or studies with only one sex treated must then be conducted.

With the possible exception of combining the female fertility component with the embryo–fetal development component, the combined-study approach is used often. The female fertility and embryo–fetal development components are needed to support clinical trials in women of childbearing potential in most countries and thus will be conducted early in the development of a drug. However, since the pre- and postnatal development component is not routinely required for clinical studies of women of childbearing potential and represents a large commitment of resources, it will not generally be conducted until late in the drug development process.

15.2.6 Preliminary Studies

According to the ICH guideline, “some minimal toxicity is expected to be induced in the high dose dams” in the reproductive and developmental toxicity studies. In some cases, particularly for the fertility and early embryonic development study, available information from general toxicity studies in the selected rodent species may be sufficient to allow the selection of dosage levels for a reproductive toxicity study with the goal of achieving minimal toxicity in high-dose dams. However, pregnant females sometimes respond differently to toxins than nonpregnant females, the duration of dosing for reproductive toxicity studies is different than for general toxicity studies, and toxicity may not have been achieved in the subacute toxicity studies. Thus, it is often necessary to conduct a range-finding study in pregnant rodents prior to the embryo–fetal development study. A range-finding study in rabbits is almost always required since only rarely are results available from other toxicity studies.

The range-finding study in pregnant animals (rodents or rabbits) is similar to the embryo–fetal development study discussed previously except that there may be more dosage groups, group size is smaller (6–10 inseminated or mated females per group), and there is generally no need to examine fetuses for visceral or skeletal abnormalities. Evaluating litters from range-finding studies for resorption, fetal weight, and external abnormalities is valuable for providing an early indication of marked developmental toxicity. This is particularly important if conceptus survival at a particular dosage level would be inadequate to evaluate effects on development in the subsequent embryo–fetal development study. Once it has been determined during a range-finding study that a particular dosage level causes toxicity exceeding the minimal toxicity desired for the embryo–fetal development study, it is best to terminate that dosage group since continued treatment and evaluation unnecessarily expose animals to toxicity, any subsequent data collected are not useful for risk assessment (since it is known that excessive maternal toxicity itself causes developmental toxicity), and investment of resources is therefore unwarranted.

15.2.7 Potential Male Mediated Developmental Effects

Developmental effects on offspring (including adult-onset diseases) due to genetic or chemical carryover from males via their sperm has been of concern for at least 30 years but has only risen to the level of active regulatory concern and guidelines since 2015 (FDA, 2015a). After male mediated developmental toxicity being of concern for some decades, occupational cases such as in leukemia in children of workers and animal study data contributed to our current understanding of male-mediated effects. Animal studies in the 1980s and 1990s suggested that genetic damage after radiation and chemical exposure might be transmitted to offspring. With the increasing understanding that there is histone retention and modification, protamine incorporation into the chromatin and DNA methylation in mature sperm and that spermatozoal RNA transcripts can play important roles in the epigenetic state of sperm, the need for heritable studies began to be viewed differently. Recent reports using molecular approaches have demonstrated that DNA damage can be transmitted to babies from smoking fathers, and expanded simple tandem repeats minisatellite mutations were found in the germline of fathers who were exposed to radiation from the Chernobyl nuclear power plant disaster. In epidemiological studies, it is possible to clarify whether damage is transmitted to the sons after exposure of the fathers. Paternally transmitted damage to the offspring is now recognized as a complex issue with genetic as well as epigenetic components. (Anderson and Briskworth, 2007; Anderson et al., 2014; Brinkworth and Anderson, 2007)

Putative mechanisms of male-mediated developmental toxicity include those based on the induction of genetic damage or mutations in the male germ cell before conception (Olshan and Faustman 1993; Olshan and Mattison, 2012; Harrouk et al., 2000; Robaire and Hales 2003). Genotoxic agents present in the seminal fluid may also have direct effects on the conceptus. Various adverse developmental outcomes, including embryo/fetal mortality, structural defects, growth impairment, and behavioral abnormalities have been reported in animals after paternal exposure to known genotoxins; and epidemiological studies have reported associations between paternal genotoxin exposure and increases in adverse pregnancy outcomes in humans (Anderson and Briskworth 2007; Anderson et al., 2014). In addition to genotoxic mechanisms, other forms of heritable sperm damage (e.g., epigenetic modifications may be involved in paternally mediated developmental toxicity [Doerksen et al., 2000; Barton et al., 2005]).

Studies of male reproductive toxicity can identify a range of effects relevant to the assessment of potential male-mediated developmental toxicity, including effects on sperm quality, implantation, and the early embryo (Safarinejad 2008; Lewis and Aitken 2005). In the event that an API has been identified as having the potential to affect male reproduction based on either the mechanism of action or through demonstrated animal toxicity (e.g., in a repeat dose toxicity study or study evaluating fertility), appropriate contraception should be considered until the possible implications for developmental risk have been assessed.

Seminal transfer of a developmentally toxic pharmaceutical may result in direct adverse effects on the conceptus. A number of developmental toxicants present in seminal fluid have been reported to affect pregnancy outcomes adversely in animals by this mechanism (Robaire and Hales 1994). For example, the presence of thalidomide in semen was associated with evidence of developmental toxicity, including fetal malformations, in the progeny of treated male rabbits (Lutwak-Mann et al. 1967), and increased preimplantation loss after mating cyclophosphamide-treated male rats with untreated females was attributed to the presence of the drug in seminal fluid (Hales et al. 1986). Thalidomide has been measured in human semen after oral dosing, with an apparent correlation between semen and plasma levels (Teo et al., 2001)

The FDA (2015a,b) guidance calls on four principal factors to be considered in preclinical evaluation of the potential for developmental toxicity:

1. The known reproductive and developmental toxicity of the intended therapeutic and related (by structure or mode of action) compounds.
2. The cytotoxic/genotoxic properties of the drug
3. Pharmacologic and other mechanism of action (or off target hits) that suggest the potential for adverse effects.

4. The absorption, distribution, metabolism, and excretion (ADME) profile of the drug, particularly as related to male reproductive tissues or partitioning into semen.

Suggested studies to assess these potentials include first *in vitro*, then follow up with *in vivo* and ADME studies.

in vitro Studies: Nonclinical *in vitro* studies relevant to the assessment of potential male-mediated developmental toxicity include the standard genotoxicity assays (ICH S2(R1)) and any miscellaneous studies of pharmaceutical effects on the sperm (e.g., spermicidal assays and various tests of sperm genetic integrity) (Sawyer et al., 1998; Liu et al., 2014) or conceptus (e.g., whole embryo culture). Based on the strength of an *in vitro* signal, precautionary measures or follow-up *in vivo* studies may be warranted using reproductive outcome as a more definitive measure of paternally mediated effects.

in vivo Studies: The *in vivo* nonclinical studies of interest for assessment of potential male-mediated developmental toxicity include general toxicity studies with appropriate histopathology and/or semen analysis in adult males and the standard battery of reproductive and developmental toxicity studies (Chatterjee et al., 2000; Doerksen et al., 2000). When maternally mediated developmental toxicity has been identified in the nonclinical studies, a risk assessment should be performed to assess the potential for exposure to fetuses through seminal transfer and vaginal uptake, particularly for potent developmental toxicants

15.2.8 Toxicokinetics

The ICH guidelines do not require that toxicokinetic studies be conducted except that “at the time of study evaluation further information on kinetics in pregnant or lactating animals may be required according to the results obtained.” In addition, the guidelines state that “it is preferable to have some information on kinetics before initiating reproduction studies.” In practice however, at least some degree of toxicokinetic sampling and analysis is performed to verify exposure and allow risk assessment.

The major toxicokinetic issue for reproductive toxicity studies is whether systemic exposure in the selected species and route is adequate relative to the systemic exposure with the clinical regimen. Often, this information is available for the selected rodent species from studies conducted independently from the reproductive toxicity studies. For rabbits, though, there is rarely toxicokinetic information available from other studies. Accordingly, it is advisable to conduct at

least a crude evaluation of systemic exposure in the rabbit. It is best if these data are available prior to the embryo–fetal development study so that, if the rabbit is found to have inadequate systemic exposure, an alternative species may be selected before the investment of resources in a large rabbit study. The collection of blood samples for toxicokinetic evaluations may be incorporated into the range-finding study in pregnant rabbits. However, rabbits stressed by multiple bleedings should not be retained for evaluation of developmental toxicity, and satellite groups of toxicokinetic animals for bleeding only may be needed.

It would be ideal to have data from five to eight time points following the first and last doses to examine accumulation and other changes in kinetic parameters during pregnancy and, since physiology changes rapidly during gestation, to have data periodically during gestation as well. However, from a practical point of view, the question being asked (what is the approximate systemic exposure?) does not justify a comprehensive kinetic evaluation. When circumstances dictate that a toxicokinetic evaluation be performed, determining maternal plasma levels at a few postdosing intervals during a single 24 h period of gestation, preferably during the period when serious adverse effects are most likely to be induced (days 9 through 12 of gestation), will generally provide adequate information.

Only in special circumstances will the determination of embryo levels of drug add meaningfully to the assessment of human risk from a drug. In such studies, even if it is found that the embryo is not exposed, the lack of exposure of the embryo would not necessarily indicate an invalid study or increased human risk since there may also be no exposure in human embryos. When embryo level studies are conducted, the selection of day(s) of gestation to harvest embryos is severely restricted by the sensitivity of the assay. Often, the earliest day that allows the collection of sufficient tissue for assay is gestational day 10 or 11.

15.2.9 Timing of Studies

The definition of which studies need to be performed in advance of clinical trials has not been harmonized yet by the ICH process and is currently determined by the regulatory agencies of individual countries and institutional review boards (IRBs) (or ethics committees [ECs]). Embryo–fetal development studies in two species are almost universal prerequisites prior to clinical studies in women of childbearing potential. Some regulatory agencies also request that a fertility study in female rodents be conducted before clinical trials in women of childbearing potential. A fertility study in male rodents is required before clinical trials in men in Japan. Some pharmaceutical companies have internal guidelines that specify compliance with all the guidelines listed earlier, regardless of the location of the clinical trials.

The most conspicuous exception to the policy described in the preceding text is the position of the US FDA (1993). The FDA withdrew the restriction on the participation of women of childbearing potential in early clinical trials, citing “(i) exclusion of women from early trials is not medically necessary because the risk of fetal exposure can be minimized by patient behavior and laboratory testing, and (ii) initial determinations about whether that risk is adequately addressed are properly left to patients, physicians, local IRBs and sponsors with appropriate review and guidance by FDA, as are all other aspects of the safety of proposed investigations.” The policy of excluding women has been replaced by one that specifies that “the patients included in clinical trials should, in general, reflect the population that will receive the drug when it is marketed.” In fact, inclusion of women at the earliest possible stages is frequently mandated. This led to the current situation where requirements as to when developmental and reproductive testing must be performed are very different between ICH regions, with US FDA requirements generally not mandating any such studies until after phase I unless a potential risk/concern is indicated by drug mechanism or finding in other studies (most commonly the initial repeat-dose toxicity studies).

To comply with FDA policy, at least for the conduct of clinical trials in the United States, pharmaceutical companies have a few choices. They can conduct the standard battery of reproductive studies prior to enrolling women of childbearing potential in early clinical trials. The possible negative impact would be a delay in the initiation of clinical trials. Alternatively, pharmaceutical companies can enroll women of childbearing potential in early clinical trials without having conducted any reproductive toxicity studies and accept the additional risk resulting from exposure to untested drugs during inadvertent or undetected pregnancy. In either case, the incidence of pregnancy during clinical trials can be decreased by pregnancy testing and/or assurances of contraception.

15.3 METHODOLOGICAL ISSUES

15.3.1 Control of Bias

An important element to consider when designing developmental and reproductive toxicity studies is the control of bias. For example, animals should be assigned to groups randomly and preferably blocked by body weight. This can be accomplished by first ranking the animals in order of body weight and then, starting with the lightest or heaviest, assigning by rank to groups based on a list of sets of random permutations of numbers (e.g., 1, 2, 3, and 4 if there are four groups, where 1 represents the control group, 2 represents the low-dose group, etc.). Housing of treatment groups should also be unbiased. This can be done by “Latin square”

design where each block of four cages (if there are four groups) includes an animal from each group. It is often an acceptable compromise to have animals from different groups in alternating vertical columns with all the animals in a column from the same group. This provides equal vertical balancing for all groups. Historically, it has proven unwise to have groups segregated on separate racks.

The order of sacrifice on the day of cesarean sectioning should be balanced by group (again using random permutations) since fetuses continue to grow during the day and an unbalanced time of sacrifice would bias fetal weights, particularly for rodents. Alternatively, all animals can be killed at about the same time in the morning and the fetuses stored for examination later the same day. Fetal examinations should be conducted blind, that is, without knowledge of treatment group.

15.3.2 Diet

It is known that rodents require a diet relatively rich in protein and fats for successful reproduction (Zeman, 1967; Chow and Rider, 1973; Turner, 1973; Mulay et al., 1982). Consequently, rodents are fed high-protein, high-fat diets ad lib for reproductive toxicity studies and also generally as a maintenance diet for all toxicity studies. Female rats fed in this manner begin to show decreases in fertility, litter size, and the incidence of normal estrus cycling at the age of 6 months (Matt et al., 1986, 1987). The disadvantage of this feeding practice is that the animals more quickly acquire age-related diseases and sexual dysfunction and die sooner than if they are fed a restricted amount of calories (for review, see Weindruch and Walford, 1988). In relatively short-term studies (such as standard ICH studies), this rapid aging does not present a problem. However, for male breeding colonies or multigeneration studies with multiple litters per generation, it could be advantageous to restrict caloric intake, at least when the animals are not being bred. Restriction of food intake to achieve a 30% decrease in body weight gain compared to ad lib-fed controls has no adverse effect on male rat reproduction (Chapin et al., 1991), although it does affect reproduction in mice (Gulati et al., 1991) and female rats (Chapin et al., 1991).

Dietary restriction is even more important for rabbits. Rabbits fed ad lib fare very poorly. Some laboratories restrict New Zealand white rabbits to 150–180 g day⁻¹ of a high-fiber (at least 13.5%) diet. However, even this regimen results in some rabbits going off feed late in gestation. It has been observed that by restricting New Zealand white rabbits to only 125 g of food per day, nearly all control animals retain appetite throughout gestation and fewer of these animals abort (Clark et al., 1991). More uniform food consumption late in gestation is associated with greater uniformity in maternal body weight

change and fetal weight. This decreased variability makes these measures more sensitive indicators of maternal and developmental toxicity. Thus, 125 g is the preferred daily ration for New Zealand white rabbits.

15.3.3 Clinical Pathology

Regulatory guidelines require that there be maternal toxicity at the highest dosage level in embryo–fetal developmental toxicity studies. It is also important to avoid excessive toxicity in these studies since it is known that marked maternal toxicity can cause secondary developmental toxicity (see discussion in Section 15.5.3). This secondary developmental toxicity is irrelevant to the assessment of the developmental hazard of the test agent and thus simply confounds the interpretation of the data.

The traditional indicators of maternal toxicity in range-finding studies in pregnant animals (mortality, body weight, food consumption, and clinical signs) do not always provide a sensitive measure of toxicity. This insensitivity is a particular problem for rabbit studies since typically no other toxicity studies are conducted in rabbits and body weight change in rabbits is very variable (typically -100 to $+400$ g during gestation), making it a particularly insensitive indicator of toxicity.

Thus, it is desirable to improve the assessment of toxicity in range-finding studies in pregnant animals. Complete histopathologic examination is not practical. However, it is often feasible to perform hematologic and serum biochemical analyses that can significantly increase the changes of detecting significant toxicity and provide important information for selecting an appropriate highest dosage level for the embryo–fetal developmental toxicity study.

Based on more than 20 years of experience, body weight effects most often provided the basis for the selection of dosage levels in the segment II study. However, there have been cases where clinical pathology was or would have been useful to justify dosage selection. For example, the nonsteroidal anti-inflammatory drug diflunisal caused a decrease in erythrocyte count from 6.0 (million mm^{-3}) to 2.9 at a dosage level ($40 \text{ mg kg}^{-1} \text{ day}^{-1}$) that caused only a 1% decrease in body weight in pregnant rabbits. The severe hemolytic anemia caused by this excessively high dosage level in turn caused secondary axial skeletal malformations in the fetuses (Clark et al., 1984). Also, the angiotensin-converting enzyme (ACE) inhibitor enalapril caused an increase in serum urea nitrogen from 16 to 46 mg dL^{-1} (highest value = 117) at a dosage level ($10 \text{ mg kg}^{-1} \text{ day}^{-1}$) that had no apparent effect on body weight but caused a significant ($p < 0.05$) increase in resorptions (Minsker et al., 1990). Serum urea nitrogen concentration was used to select dosage levels for a subsequent ACE inhibitor, lisinopril. Likewise, the routine use of clinical pathology in range-finding studies has previously been proposed (Wise et al., 1988). The animals can be bled on the day after the last

dose or sooner to detect transient effects or to allow an evaluation of the data prior to cesarean section.

15.3.4 Gravid Uterine Weights

Effects of treatment on maternal body weight gain are commonly evaluated as indicators of maternal toxicity. However, maternal body weight gain is influenced by fetal parameters such as live fetuses per litter and fetal body weight. Thus, effects indicative of developmental toxicity could contribute to decreased maternal body weight gain and confound the interpretation of maternal toxicity. In addition, other maternal but pregnancy-related parameters, such as volume of intrauterine fluid, could be affected by treatment and contribute to effects on overall body weight gain.

In an attempt to correct this complication, some laboratories weigh the gravid uterus at cesarean section and then subtract the weight of the gravid uterus from the body weight gain to obtain an adjusted weight gain that is more purely maternal. This adjustment is imprecise, but not inappropriate for rats for which gravid uterine weight is correlated with and generally substantially less than maternal body weight change during gestation (e.g., see Figure 15.2 for which the correlation coefficient r was 0.63 and $p < 0.001$). However, the subtraction of gravid uterine weight from maternal weight gain is an overadjustment for rabbits. The maternal body weight gain of rabbits during gestation is generally less than the weight of the gravid uterus (see Figure 15.3). Moreover, gravid uterine weight is correlated with maternal body weight change in some but not all studies. For example, in the 53 untreated rabbits from the study shown in Figure 15.3, $r = 0.54$ and $p < 0.001$. However, in a study of 32 rabbits treated with a methylcellulose vehicle, $r = 0.21$ and $p = 0.25$. Thus, subtracting the gravid uterine weight from the maternal weight gain is not always appropriate. A preferred method for adjusting maternal body weight gain for possible developmental effects is to test and, if appropriate, use gravid uterine weight as a covariate (J. Antonello, personal communication, 1990). This method can be used for both rats and rabbits and for body weight change intervals in addition to those ending at study termination.

Alternatively, to avoid weighing the uterus (or if the analysis is being performed retrospectively and uterine weights are unavailable) or if a more purely fetal adjustment is desired, one can use the sum of the live fetal weights within the litter (total live fetal weight) as the covariate instead of gravid uterine weight. As expected, total live fetal weight is very highly correlated with gravid uterine weight in control animals ($r = 0.99$ in control rats and 0.95 in control rabbits; J. Antonello, personal communication, 1990). Thus, in general, using either gravid uterine weight or total live fetal weight as the covariate will yield similar results. However, if treatment were to have an effect on gravid uterine weight that was not reflected in total live fetal weight (e.g., if the volume of

FIGURE 15.2 Relationship of maternal body weight and gravid uterine weight in rats. Relationship between gravid uterine weight and maternal body weight change in control rats between days 0 and 20 of gestation. One hundred and twenty pregnant Sprague–Dawley (CrI: CD(SD)BR) rats were dosed orally with 0.5% aqueous methylcellulose on days 6–17 of gestation and cesarean sectioned on day 20 of gestation. The gravid uterus from each animal was removed and weighed.

FIGURE 15.3 Body weight changes versus gravid uterine weight changes in rabbits. Relationship between gravid uterine weight and maternal body weight change in untreated rabbits between days 0 and 28 of gestation. Fifty-three pregnant New Zealand white rabbits that had not been treated with control article or test agent were cesarean sectioned on day 28 of gestation. The gravid uterus from each animal was removed and weighed.

amniotic, extracelomic, or intrauterine fluid was affected), then total live fetal weight may not be highly correlated with gravid uterine weight and, hence, not interchangeable as a covariate. In that case, only weighing the gravid uterus would allow the detection of these effects not revealed by total live fetal weight.

15.3.5 Implant Counts and Determination of Pregnancy

Two observations suggest that the remnants of embryos that die soon after implantation are not apparent at gross examination of the uterus near term: First, embryos that were

observed to be resorbing at laparotomy early in gestation left no readily visible trace near term (Staples, 1971). Second, occult implantation sites can be revealed near term by staining the uterus with ammonium sulfide or sodium hydroxide (Salewski, 1964; Yamada et al., 1988). It is not known if the uterine staining techniques reveal all implantation sites. It is clear, though, that when uterine staining techniques are not used, very early resorptions may not be included in what is termed the “resorption rate” but instead may contribute to the apparent “preimplantation loss” or, if no implantation sites were detected, the rate of “nonpregnant” animals.

In normal circumstances, probably very few implantation sites are not detected without staining. However, cases have occurred in which probably treatment effects were detected only as a result of uterine staining. For example, in one rabbit study with drug treatment starting on day 6 of the gestation, a drug-treated group had four litters that had implantation sites that were seen only after staining with ammonium sulfide, indicating very early drug-induced resorption. For critical studies in rabbits designed to determine early effects on resorption and abortion rates, it would be advantageous to measure plasma levels of progesterone on day 6 of gestation since low levels indicate nonpregnant animals (Adams et al., 1989, 1990).

15.3.6 Fetal Examinations

Many fetal anomalies, such as cleft palate, exencephaly, ectrodactyly, and missing vertebra, are discrete and distinct and therefore easy to recognize objectively. Some anatomical structures, though, occur along a continuous gradation of size and shape and are only considered anomalous if the deviation from the typical exceeds a somewhat arbitrarily selected threshold. These anomalies are observed in all examination types and include micrognathia, reduced gallbladder, enlarged heart, distended ureter, wavy rib, and incomplete ossification at many sites. In many cases, it cannot be said with certainty whether a specific degree of variation from normal would have resulted in an adverse consequence to the animal and should therefore be considered abnormal. In the absence of certainty about outcome, the best approach is to uniformly apply a single criterion within a study (and preferably among studies) so that all treatment groups are examined consistently. The subjectivity (and hence fetus-to-fetus variability) of the examination can be minimized by having the criteria be as clear and objective as possible. For example, when examining for incompletely ossified thoracic centra or supraoccipitals, it can be required that the ossification pattern be absent (unossified), unilateral, or bipartite (which are objective observations) before recording as an observation. Subjective criteria such as being dumbbell or butterfly shaped would not be applied.

15.3.6.1 Examination of External Genitalia One aspect of external anatomy that is largely overlooked in the examination of offspring exposed *in utero* to test agents is the external genitalia, even though major malformations can occur in those structures. For example, hypospadias is a malformation in the male in which the urethra opens on the underside of the penis or in the perineum. Hypospadias can occur in the male rat following *in utero* exposure to antiandrogens (e.g., Neumann et al., 1970), testosterone synthesis inhibitors (e.g., Bloch et al., 1971), or finasteride, a 5 α -reductase inhibitor (Clark et al., 1990b). However, it is impractical to detect hypospadias in fetuses or young pups. Although the genital tubercle of the normal male rat fetus is grossly distinguishable from that of the normal female as early as day 21 of gestation (the female has a groove on the ventral side), the difference is very subtle, and partial feminization of the male genital tubercle would be very difficult to ascertain. Routine histological examination is obviously too labor intensive to be considered. Hypospadias can readily be determined, though, by expressing and examining the penis of the adult. Thus, it is recommended that adult F₁ males be examined for hypospadias. If the timing of the separation of the balanopreputial membrane is being included in the pre- and postnatal development study as a developmental sign (see Korenbrot et al., 1977), the examination of the penis for hypospadias can be conducted at the same time.

The critical period for the induction of hypospadias by finasteride in rats is days 16–17 of gestation (Clark et al., 1990a). It is unlikely that other agents would have a much earlier critical period since testosterone synthesis, which is required for the development of the penile urethra, begins in the rat on day 15 of gestation (Habert and Picon, 1984). Thus, if treatment in the embryo–fetal development study terminates on day 15 of gestation (as is done in some laboratories), it is doubtful that hypospadias could be induced. However, hypospadias could be induced in the pre- and postnatal development study. Since the formation of the penile urethra in the rat is not completed until day 21 of gestation (Anderson and Clark, 1990), it could be argued that “major organogenesis” continues until that time.

One parameter that is readily and commonly measured as an indicator of effects on differentiation of the external genitalia in rodent fetuses is the sexually dimorphic distance between the anus and the genital tubercle (anogenital distance). However, it should not be assumed that anogenital distance is synonymous with hypospadias, since effects on anogenital distance are not necessarily predictive of hypospadias. Finasteride caused both hypospadias and decreased anogenital distance in male offspring but with very different dose–response relationships and only a slight tendency for animals with hypospadias to have a shorter anogenital distance (Clark et al., 1990b). Also, the effects on anogenital distance were largely reversible, whereas hypospadias was not. Another

agent, triamcinolone acetonide, caused dramatic (reversible) decreases in anogenital distance in male rat fetuses on day 20 of gestation but did not affect the development of the genital tubercle and did not cause hypospadias (Wise et al., 1990b). Thus, decreased anogenital distance per se does not necessarily indicate a serious congenital anomaly.

When evaluating effects of treatment on fetal anogenital distance, it is obviously important to correct for effects on fetal weight. One approach is to calculate “relative” anogenital distance, the ratio between anogenital distance and another linear measure, for example, biparietal diameter (head width). The cube root of fetal weight simulates a linear measure (Wise et al., 1990b) and can also be used to normalize anogenital distance. Another approach is to compare the anogenital distance in a weight-reduced treatment group to that in a weight-matched control group at a younger age.

15.3.6.2 Visceral Fetal Examinations The examination of the abdominal and thoracic viscera of fetuses is performed either fresh without fixation (“Staples’ technique”) or after Bouin’s fixation by making freehand razor blade sections (“Wilson’s technique”; Wilson, 1965). Both techniques have advantages. The fresh examination technique, which may require less training to become thoroughly proficient, provides a more easily interpreted view of heart anomalies. The examination must be performed on the day the dam is terminated, though, so having a large number of litters to examine in one day requires that a large team of workers be committed to the task.

With both techniques, the heads of one-half of the fetuses can be fixed in Bouin’s fixative for subsequent freehand sectioning and examination. A common artifact induced by fixation in rabbit fetal heads is retinal folding.

Whether or not the kidneys are sliced transversely to examine the renal pelvis varies among laboratories. Hydronephrosis, delayed papillary development, and distended renal pelvis are most readily detected in this manner. However, it is not necessary to slice the kidneys to detect the urinary retention that can lead to distended renal pelvis and hydronephrosis. This point was demonstrated in a study in which $200000 \text{ IU kg}^{-1} \text{ day}^{-1}$ of vitamin A administered orally on days 8–10 of gestation induced hydronephrosis and/or distended renal pelvis in 29 fetuses (R. Clark, personal communication, 2004). In all of these 29 fetuses (and two others), distended ureter also occurred. Thus, distended ureter may be a more sensitive indicator of urinary retention than distended renal pelvis.

15.3.6.3 Skeletal Fetal Examination There is variability in the development of the fetal skeleton, including the number of vertebrae and ribs, patterns of sternebral ossification, alignment of ribs with sternebrae, and alignment of ilia with lumbar and sacral vertebrae. There is also extensive plasticity in the development of the skeleton beyond the fetal stage. For example, it is known that markedly wavy

ribs in fetuses can resolve so that the ribs in the adult are normal (Saegusa et al., 1980; Nishimura et al., 1982) and supernumerary ribs can be resorbed (Wickramaratne, 1988). This variability and plasticity complicate the classification of anomalies as true malformations as opposed to variations of normal. There is no unanimity on terminology, but, in general, a variation tends to be an alteration that occurs at relatively high spontaneous incidence ($>1\%$), is often reversible, and has little or no adverse consequence for the animal.

When tabulating and interpreting fetal skeleton data, a distinction is made between alterations in the pattern of development and simple delays in development that are considered to be less serious. A delay in skeletal development is usually apparent as a delay in ossification, as evidenced by an increased incidence of specific, incompletely ossified sites or decreases in counts of ossified bones in specific regions (e.g., sacrocaudal vertebrae). These delays are normally associated with decreases in fetal weight and commonly occur at dosage levels of the test agent that also cause decreased maternal body weight gain.

When determining the criteria for recording skeletal alterations, particularly sites of incomplete ossification, it is legitimate to consider the resulting incidences. For example, including an unossified fifth sternebra in the criteria for recording incomplete sternebral ossification may increase the control incidence to a very high proportion (over 95%) of fetuses affected, which would then reduce the sensitivity for detecting treatment effects. The additional effort expended in recording the extra observations due to fifth sternebra would be wasted. In addition, recording high incidences of incomplete ossification at many sites is not worth the effort involved. The ossification at various sites is highly correlated, so recording at multiple sites is redundant. In some cases, the incidences can be reduced to reasonable levels (1–20% of control fetuses) and the criteria simultaneously be made more objective by requiring that the bone be entirely unossified before recording.

15.3.7 Developmental Signs

The postnatal evaluation of F_1 pups includes the observation of developmental signs in two or more pups per sex per litter. In general, the acquisition of these developmental landmarks, including anatomical changes (e.g., ear pinna detachment, incisor eruption, hair growth, and eye opening) and reflexes (negative geotaxis, surface righting, and free-fall righting), is highly correlated with body weight, but as indicators of developmental toxicity, they are not as sensitive as body weight (Lochry et al., 1984; Lochry, 1987) and thus have minimal value. Possible exceptions to this generality are the ontogeny of the auditory startle reflex and the markers of sexual maturation (vaginal patency, testes descent, and balanopreputial separation in males).

The examinations for developmental signs should be performed daily starting before and continuing until the criterion is achieved. The separation of the balanopreputial membrane of the penis (occurring at postnatal week 6–7; Korenbrot et al., 1977) is becoming the preferred landmark of sexual maturation in males. The timing of the testes descent is more variable and very dependent on the achievement criteria used. Another advantage of determining the time of the balanopreputial separation is that anomalies of the penis may be observed at the same time (as noted in the preceding text).

15.3.8 Behavioral Tests

The trend within reproductive toxicology is to move from simple determinations of developmental landmarks and reflexes to more sophisticated and sensitive behavioral tests. This process was accelerated by the Environmental Protection Agency (EPA) of the United States, which issued guidelines requiring a “developmental neurotoxicity” study of compounds that meet any of several broad criteria (EPA, 1991). The behavioral tests to be performed in this study are extensive and rigidly defined. As laboratories become equipped and trained to meet these guidelines, they are adding such tests to their evaluations of pharmaceuticals. The suggestions for routine testing made in the succeeding text are considered reasonable for pre- and postnatal development studies intended as routine screens. It is suggested that testing be conducted on one or two adults per sex per litter, keeping the range of actual ages as tight as possible.

Measurement of motor activity is commonly performed in the dark in cages or plastic boxes (open field) or residential mazes in which movement is quantitated by infrared detectors or by recording the interruption of light beams as the test subject moves through a horizontal grid of light beams. Possible parameters to evaluate include horizontal activity (light beams interrupted), number of movements, and time spent in the middle of the cage. The test period is selected to be long enough (normally 30–50 min) to allow the activity of the animals to decrease to an approximately constant level (asymptote). Testing of young pups (e.g., 13 days of age) is not recommended as their activity level is fairly constant during the test period and young unweaned pups should not be separated from their mothers for extended periods of time.

Another test paradigm for detecting treatment effects on brain functioning in F_1 offspring measures auditory startle habituation. In this test, the animal is placed in a chamber with a floor that detects movement. The animal is exposed to a sequence of 50–60 auditory stimuli, each at 110–120 dB for 20–50 s and separated by 5–20 s. The gradual diminution of the animal’s movement response is indicative of normal habituation.

There is not a consensus about the procedures to use to test for effects on learning and memory. The two most commonly used techniques are the water-filled maze, which is preferred for measuring learning, and passive avoidance, which is preferred for measuring memory (see Buelke-Sam et al., 1985). Retention is tested in a repeat test conducted approximately 1 week later.

15.3.9 Detecting Effects on Male Reproduction

Male fertility studies with typical group sizes (15–30 males per group) are very insensitive for detecting effects on male fertility. If the control fertility rate is 80%, even a group size of 30 will only detect (at the 5% significance level) a 38% decrease in fertility 80% of the time and a 50% decrease 95% of the time (J. Antonello, personal communication, 1990). To detect slight effects on male fertility would require enormous group sizes. Mating each male with more than one female provides a more precise estimate of the reproductive capacity of each male, but does not greatly increase statistical power. If multiple matings are to be done, it is recommended that the cohabitations with multiple females be sequential rather than concurrent.

Not only is it difficult to detect effects on male fertility because of group-size considerations, effects on male fertility mediated by decreased sperm production are also difficult to detect because of the normally huge excess of sperm included in a rat ejaculate. Sperm production can be decreased by up to 90% without effect on fertility (either pregnancy rate or litter size) in the rat. This is not the case for men, so the sperm excess in the rat represents a serious flaw in the rat model (see Working, 1988). To address this deficiency and improve the sensitivity of the model, it is advisable to determine the effects of the test agent on testes weights, testicular spermatid counts, and histopathology of the testes (preferably plastic sections) in the male fertility study and/or the 14-week toxicity study. In some cases, these parameters may be more predictive of possible effects on male fertility in humans than the fertility rate in rats.

To improve sensitivity of the process, the FDA recently promulgated guidelines (FDA, 2015a) for assessing testicular toxicity in studies involving male test animals. Table 15.5 presents a summary of findings in such studies to be considered further.

15.4 DEVELOPMENTAL STUDIES IN PRIMATES

With the increasing development and use of highly humanized biological molecules as therapeutics in humans, it has become necessary to develop and validate an increasing range of study types which employ primates to evaluate risks to humans.

TABLE 15.5 General Nonclinical Findings to Consider in Male Fertility Risk Assessment**Nonclinical Findings That May Increase the Level of Concern for Infertility in Men**

- Finding is dose dependent
- Similar findings in multiple species
- Finding persists or increases in severity with increasing duration of exposure
- Finding persists after drug withdrawal, especially if withdrawal period is an entire spermatogenic cycle
- Finding occurs in bilateral tissues
- Finding is rare in healthy untreated animals
- Maximum dose without adverse effect occurs at exposures that are clinically relevant
- Reproductive organ weight change (increased or decreased weight) correlates with adverse histology
- Decreased male fertility and impaired mating behavior
- Sperm quality adversely affected (count, motility, or morphology)
- Adverse effects on reproductive tissues and function at multiple stages of life (repeat-dose study in adults, adult fertility assessment, effects in adulthood after exposure during pre/postnatal period, toxicity to the reproductive tissues during development)
- Antiandrogenic signs—reduced body weight, decreased weight and maturation of male sexual organs, clinical signs suggestive of reduced aggressiveness (e.g., lethargic or reduced mating behavior)
- Androgenic signs—masculinization of females (decreased fertility, female sexual organ pathology, or estrus cyclicity), decreased testes size, and impaired spermatogenesis

Confounding Issues

- Use of immature animals
- Pharmaceuticals that cause weight loss—in some cases, findings observed only in animals with weight loss may be difficult to ascribe to the drug exposure because weight loss alone may adversely affect male fertility independent of drug exposure. Also, weight loss may be secondary to overt toxicity and may not be clinically relevant
- Pharmaceuticals that impair mating behavior or neuromuscular function
- Inappropriate animal model—pharmaceutical is not active in the species or has different metabolite profile, tissue distribution, or extent of elimination

One of these needs is to be able to evaluate developmental toxicity in a model responsive to primate-specific pharmacodynamics.

Figure 15.4 presents a line chart for the study design for an embryo–fetal developmental toxicity study (segment II in old parlance) to be conducted in nonhuman primates (NHPs); the studies present a number of difficulties and need for compromise, starting with the facts that the animals are limited in supply and have small litters (1 or 2 is common).

15.5 DATA INTERPRETATION**15.5.1 Use of Statistical Analyses**

Statistical analysis is a very useful tool for evaluating the effects of treatment on many developmental and reproductive toxicity parameters. For some parameters, such as maternal body weight changes, fetal weight, and horizontal activity in an open field, the comparison to the concurrent control is the primary consideration, and, assuming adequate group size, the investigator relies heavily on the results of appropriate statistical analyses to interpret differences from control.

For other parameters, though, statistical analysis is just one of several considerations that include historical control data and other relevant information about the test agent and related test agents. For example, statistical analysis of a low incidence of an uncommon fetal malformation will usually not be significant ($p > 0.05$) even if treatment related, due to the low power for detecting such effects with typical group sizes. In such cases, examination of the historical control data becomes paramount. If two fetuses with a particular malformation occur in separate litters only in a high-dose group, the finding is of much more concern if it is a very rare malformation than if recent historical control groups have had a few fetuses with that malformation.

Other known effects of the test agent or related agents also sometimes contribute to data interpretation. For example, a low incidence of a malformation may be considered treatment related if it is at the low end of a typical dose–response curve or if it is in a high-dose group and that malformation is an expected effect of the test agent. In general, though, a single occurrence of a fetal malformation in a treatment group (with none in control) is not cause for alarm, since this occurs in almost every study (together with occurrences of some malformations only in the control group).

Statistical methods exist to appropriately analyze most developmental and reproductive toxicity parameters. Exceptions to this are the “ r/m ” litter parameters in which, for each litter, there is a number affected divided by the number in the litter. These parameters include preimplantation loss (r = corpora lutea–implants, m = corpora lutea), resorption rate (r = resorptions, m = implants), and the family of alteration rates (r = affected fetuses, m = fetuses). There are two factors complicating the statistical analysis of these data that have heretofore been inadequately handled (Clark et al., 1989). One is that almost all of these parameters have a strong dependence on m . For example, both preimplantation loss (Figure 15.5) and resorption rate (Figure 15.6) are normally higher at both the low and high extremes of M . In contrast, supernumerary rib tends to occur at higher incidences in average-size litters (Figure 15.7). The second factor that complicates the statistical analysis of r/m data is that affected

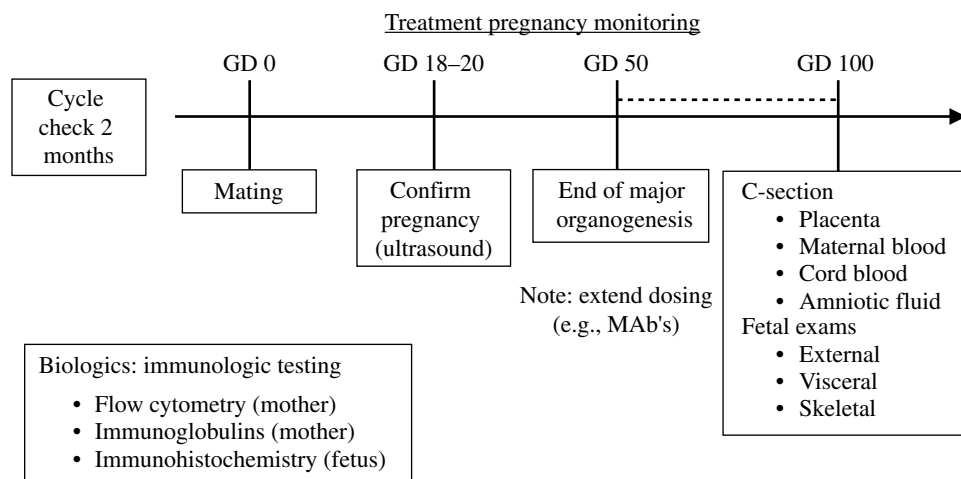

FIGURE 15.4 Embryo–fetal development (EFD) study in nonhuman primates.

FIGURE 15.5 Percentage preimplantation losses versus corpora lutea in rats. Effect of litter size on mean percentage preimplantation loss in 1035 control rat litters. Between 1970 and 1988, 1035 control rats were cesarean sectioned on day 20 of gestation, and the numbers of resorptions and implants were counted. Numbers within the bars indicate the number of litters.

implants tend to occur in clusters within litters (“litter effects”); that is, the intralitter correlation is greater than the interlitter correlation. For example, the total number of litters affected with anasarca, missing vertebra, and supernumerary rib is much less than would be expected by change based on the number of affected fetuses (Table 15.6 and Figure 15.8).

These problems have been resolved for analysis of resorption rate (and preimplantation loss) in Sprague–Dawley rats using a three-step process (Soper and Clark, 1990). First, based on an analysis of data from 1379 control rat litters examined since 1978, a likelihood score was derived for each (r, m) couplet based on the incidence of that couplet given that value of m . These scores were approximately equal to r . Second, an analysis of 136 litters from groups

with slight effects on resorption rate revealed that, at low-effect doses of embryocidal test agents, the increases in resorptions tended to occur as an increased number of resorptions within affected litters rather than as an increased proportion of affected litters. To maximize the difference in scores between control and affected litters, the scores for control-like litters ($r = 1, 2, \text{ or } 3$) were downgraded from r (1, 2, and 3) to 0.4, 1, and 2.4, respectively. Third, to arrive at the final score for each litter, the modified r score for each litter was divided by the expected control value for that value of m . This last step makes the litter score immune to spontaneous or treatment-related effects on m . The final “robust” scores have more power for detecting effects than various other measures (raw r/m , affected litters/litters, r ,

FIGURE 15.6 Resorption rate versus number of implants in rats. Effect of litter size on mean percentage resorption rate in 2258 control rat litters. Between 1970 and 1988, 2258 control rats were cesarean sectioned on day 20 of gestation and the numbers of resorptions and implants were counted. Numbers within the bars indicate the number of litters.

FIGURE 15.7 Effect of litter size (live fetuses per litter) on incidence of supernumerary rib in 1379 control rat litters. Between 1978 and 1988, fetal skeletons from 1379 litters of control rats were stained with alizarin red and examined for supernumerary rib.

$\Sigma r/\Sigma n$, and the likelihood score) and have a lower false-positive rate with fluctuations in m .

Covariance analysis (Snedecor and Cochran, 1989) can be used to reduce variability in a parameter and thereby increase sensitivity. For example, much of the variability in fetal weight data is due to variable litter size and, for rats, litters being sacrificed at different times during the workday. The variability due to these sources can be reduced by using litter size and time of sacrifice as potential covariates. Similarly, litter size and length of gestation can be used as covariates for

neonatal pup weights, and body weight at the beginning of treatment can be used as a covariate for maternal body weight changes during the treatment period of an embryo–fetal development study.

15.5.2 Potential Hazard Categories of Developmental Toxins

It is generally agreed that an agent that causes developmental toxicity in laboratory animals at dosage levels that cause no

TABLE 15.6 Examples of Litter Effects in Control Litters

Effect	Affected Fetuses	Affected Litters	Litters Examined
Anasarca	22	12	2203
Missing vertebra	53	13	1951
Supernumerary rib	1817	621	1579

FIGURE 15.8 Litter effect with supernumerary rib in 1379 control litters. Between 1978 and 1988, fetal skeletons from 1379 litters of control rats were stained with alizarin red and examined for supernumerary rib in addition to other anomalies. The calculation of the expected number of fetuses with supernumerary rib in each litter was based on the assumption that each fetus had an equally likely chance of having supernumerary rib independent of the incidence among littermates (K. Soper, personal communication, 1990). *Source:* Soper and Clark (1990).

maternal toxicity (i.e., “selective” developmental toxins) is potentially more hazardous to humans than agents that cause developmental toxicity only at maternotoxic dosages (“non-selective” developmental toxins; e.g., see Johnson, 1981, 1984; Schwetz, 1981; Fabro et al., 1982; Johnson and Christian, 1984). This position is based on the supposition that pregnant women will avoid being exposed to toxic dosages of pharmaceuticals (which is usually but not always true). Developmental toxins can also be categorized as acting directly on the embryo or indirectly via an effect on the mother. All selective developmental toxins are presumably direct acting. Nonselective developmental toxins can either act directly or indirectly.

Direct-acting developmental toxins may be potentially more hazardous to humans than indirectly acting ones even if the direct developmental toxicity occurred only at maternotoxic dosages in the species of laboratory animals tested. When the developmental toxicity of an agent is secondary to maternal toxicity in all species tested, the dose–response curves for developmental and maternal toxicity in various species may be invariably linked, and developmental toxicity would never occur at nonmaternotoxic dosages. However, when an agent acts directly on the embryo to cause develop-

mental toxicity, the dose–response curves may not be linked and, although they may be superimposed in the species of laboratory animals tested, they may not be superimposed in other species including humans. Thus, a direct-acting developmental toxin that is nonselective in one species may be selective in another species.

The ranking of potential developmental hazard in terms of selective, direct/nonselective, and indirect is more meaningful than the use of the terminology of specific/nonspecific and malformation/variation. However, when it cannot be determined if observed developmental toxicity is a direct or indirect effect, the alternative terminology becomes useful. A nonspecific effect (including in some cases decreased fetal weight, supernumerary rib, cleft palate in mice, and abortion in rabbits) is one that occurs commonly in response to high toxic dosages of a test agent. What makes a nonspecific effect generally less important than a specific effect is that nonspecific effects commonly occur only at maternally toxic dosages (“coeffective”) and may be secondary to maternal toxicity—that is, indirect. However, when an apparently nonspecific adverse developmental effect is selective (direct), that is, it occurs at nonmaternotoxic dosages, it may nevertheless be indicative of a potential developmental hazard.

In general, an agent that induces a malformation (i.e., a teratogen) is considered to be more of a potential hazard than one that induces only a minor variation. Also, there has traditionally been more of a stigma associated with an agent that induces malformations than one that causes resorptions, even though embryo death is obviously a seriously adverse outcome. The point that makes the distinction among malformations, variations, or resorptions less important is that an agent that perturbs development to cause one effect in one species may cause a different effect in another species. Thus, any developmental toxic effect at nonmaternotoxic dosages should be considered carefully.

15.5.3 Associations Between Developmental and Maternal Toxicity

The developmental toxicity of many pharmaceuticals occurs only at maternally toxic dosages (Khera, 1984, 1985; Schardein, 1987, 2000). Also, there are several compounds for which there is evidence that their developmental toxicity is secondary to their maternal toxicity. The decreased uterine blood flow associated with hydroxyurea treatment of pregnant rabbits may account for the embryotoxicity observed (Millicovsky et al., 1981). The teratogenicity of diphenylhydantoin in mice may be secondary to decreased maternal heart rate (Watkinson and Millicovsky, 1983) as supported by the amelioration of the teratogenicity by hyperoxia (Millicovsky and Johnston, 1981) and the dependence on maternal genotype in genetic crosses between sensitive and resistant strains (Johnston et al., 1979; Hansen and Hodes, 1983). The hemolytic anemia caused in pregnant rabbits by diflunisal was severe enough to explain the concomitant axial skeletal malformations (Clark et al., 1984). Acetazolamide induced fetal malformations in mice are apparently related to maternal hypercapnia (Weaver and Scott, 1984a, b) and hypokalemia (Ellison and Maren, 1972). The increased resorption rate induced in rabbits by the antibiotic norfloxacin depends on exposure of the maternal gastrointestinal tract (Clark et al., 1991).

In addition, various treatments that simulate effects that can result from pharmaceutical treatment have been shown to cause developmental toxicity. Food deprivation can cause embryo–fetal toxicity and teratogenicity in mice (Szabo and Brent, 1975; Hemm et al., 1977) and rats (Ellington, 1980) and fetal death, decreased fetal weight, and abortions in rabbits (Matsuzawa et al., 1981; Clark et al., 1991). Treatments that result in maternal hypoxia, such as hypobaric exposure (Degenhardt and Kladetzky, 1955) and blood loss (Grote, 1969), have been shown to be teratogenic. Also, the results from testing with numerous agents suggest that supernumerary rib in mice is caused by maternal stress (Kavlock et al., 1985; Beyer and Chernoff, 1986).

Thus, in any case where developmental toxicity occurs at dosage levels with only moderate to severe maternal toxicity,

the possibility of the developmental toxicity being secondary to the maternal toxicity can be considered. That is not to say, however, that it can be concluded that the developmental toxicity is secondary any time there is coincident maternal toxicity. On the contrary, it is usually very difficult to establish a causal relationship. Superficially similar types of maternal toxicity do not always cause the same pattern of developmental toxicity (Chernoff et al., 1990). This may be because the developmental toxicity is secondary to maternal toxicity, but, since typical developmental toxicity studies include only a very cursory evaluation of maternal toxicity, the developmental toxicity may be secondary to an aspect of maternal toxicity that is not even being measured.

To demonstrate that a developmental effect is secondary to a particular parameter of maternal toxicity, it is necessary but not sufficient to show that all mothers with developmental toxicity also had maternal toxicity and that the severity of the developmental effect was correlated with the maternal effect. An example of such a correlation is shown in Figure 15.9, in which a drug-induced effect on maternal body weight change in rabbits is correlated ($r = 0.45$; $p < 0.05$) with a drug-induced decrease in fetal weight. Other examples where this approach has been used to evaluate the relationship between maternal and developmental toxicity include (i) the negative correlation between resorption rate and maternal body weight change in norfloxacin-treated rabbits (Clark et al., 1991), supporting the contention that the developmental toxicity was secondary, and (ii) the lack of correlation between embryotoxicity and maternal body weight change in pregnant mice treated with caffeine and L-phenylisopropyladenosine (Clark et al., 1987), suggesting no causal relationship between developmental and maternal toxicity may be required.

15.5.4 Assessment of Human Risk

Most test agents can be demonstrated to be developmentally toxic if tested under extreme conditions. This fact has been popularized as Karnofsky's law: "Any drug administered at the proper dosage, at the proper stage of development, to embryos of the proper species . . . will be effective in causing disturbances in embryonic development" (Karnofsky, 1965, p. 185). In practice, about 37% of 3301 chemicals tested have been found to be teratogenic according to one tabulation (Schardein, 2000, p. viii; see also Shepard and Lemire, 2010). Contributing to this high rate is the practice of testing maternotoxic doses (to satisfy regulatory guidelines) that in some cases result in developmental toxicity secondary to maternal toxicity. Despite the high rate of positives in animal tests, very few xenobiotics are known to cause developmental toxicity in humans as commonly used. Thus, simply the induction of developmental toxicity by a test agent in animals does not necessarily indicate that test agent will be a developmental hazard to human conceptuses under normal exposure conditions.

FIGURE 15.9 Maternal weight change versus fetal weight changes. Correlation between drug-induced effects on maternal body weight change and fetal weight in rabbits. The data were collected from the high-dosage group of a developmental toxicity study of a prospective drug candidate. The rabbits were dosed orally with the test agent from days 6 to 18 of gestation. On day 28 of gestation, the rabbits were cesarean sectioned and the live fetuses weighed.

When a prospective drug under development for use in women of childbearing potential is determined to cause developmental toxicity in laboratory animals, the first question to be considered is whether that agent would cause developmental toxicity in humans at the anticipated therapeutic dosage level. This assessment and the related decision of whether to continue development of the drug candidate are currently based on the following:

1. The ratio between the estimated systemic exposure at the lowest effect level (or highest no-observed-effect level [NOEL]) and the estimated systemic exposure at the anticipated therapeutic dosage level (the “safety factor”)
2. Whether the effect is selective, direct, and/or specific
3. The potential benefit to the patient population (compared to other available therapies)

The most common finding is that minor, nonselective, non-specific developmental toxicity (e.g., decreased fetal weight) is observed at dosages at least 10-fold above the anticipated therapeutic dosage level. In this situation, development of the agent would normally proceed even if the “safety factor” were only 3–5. This is the case since (i) many pharmaceuticals cause maternal toxicity in laboratory animals at low multiple (e.g., 10) of the clinical exposure, (ii) nonspecific developmental toxicity commonly accompanies maternal toxicity, and (iii) pharmaceuticals fitting this pattern do not usually cause developmental effects as used clinically (which often includes the practice of not prescribing for women known to be pregnant).

In contrast, a drug candidate that selectively causes major malformations at a dosage threefold higher than the clinical dosage would likely not be developed to treat a nonlife-threatening disease. However, it might be developed if the disease to be treated was particularly debilitating, no other effective therapy was available, and it was felt that the exposure of pregnant women could be largely avoided.

Once a new pharmaceutical is approved by the FDA, it is placed in one of five pregnancy categories (A, B, C, D, or X) based on the results of animal developmental toxicity studies and, when available (usually not), information from human usage experience (see Table 15.7 and Frankos, 1985). Note that the categorization does not depend on the safety factor for a developmental effect or whether the effect is major, selective, direct, or specific (although these factors may be considered

TABLE 15.7 Pregnancy Categories^a

Outcome of Human Studies	Outcome of Animal Studies		
	+	–	Not Available
+	X or D	X or D	X or D
–	B	A	A or B
Not available	C ₁	B	C ₂

^aA, B, C₂: use during pregnancy only if clearly needed.
 C₁: use during pregnancy only if the potential benefit justifies the potential risk to the fetus.
 D: if used during pregnancy, the patient should be apprised of the potential hazard to the fetus.
 X: contraindicated in women who are or may become pregnant.

when determining if a drug is to be approved). Most often, there are positive findings in animals and no experience in pregnant women, and the drug is placed in pregnancy category C, indicating that it is to be used in pregnancy only if the potential benefit justifies the risk to the conceptus. Thus, it is left to the prescribing physician to regulate the exposure of pregnant women to the drug. If animal studies were negative and there is no information on effects on pregnant women, the agent is placed in pregnancy category B, indicating that the agent is to be used in pregnancy only if clearly needed. If developmental toxicity has been established in women (or, in some cases, if only strongly suspected), the agent is placed in category D or X. With category D, women may be prescribed the drug if the benefit outweighs the risk and the patient is informed of the potential hazard to the conceptus. Category X drugs are contraindicated in women who are or may become pregnant. Table 15.8 summarizes these categories and the proportions of drugs in each in 2000 (according to the PDR). It should be noted that the FDA proposed a change to these in May of 2008.

It should be noted that the FDA proposed a change to these in May of 2008. This new FDA Pregnancy Labeling Guidance was proposed for labeling of drugs for reproductive and pregnancy risks. The proposed rule would remove the letter categories from the pregnancy section. The new format would have three sections:

1. *Fetal risk summary*: This section would begin with a one-sentence risk conclusion that characterizes the likelihood that the drug increases the risk of four types of developmental abnormalities: structural anomalies, fetal and infant mortality, impaired physiologic function, and alterations to growth. An example of a risk conclusion based on human data is that “human data do not indicate that Drug X increases the overall risk of structural anomalies.” Many of the risk conclu-

sions in the proposed rule are standardized statements that must be used. This would be followed by a summary of significant effects.

2. *Clinical considerations*: This component would address three main topics important when counseling with, and prescribing for, women who are pregnant, lactating, or of childbearing age.
3. *Data*: This section would have a more detailed discussion of available data. Human data would appear before animal.

The pregnancy section would also include information about whether there is a pregnancy registry for the drug. Pregnancy exposure registries collect and maintain data on the effects of approved drugs that are prescribed to and used by pregnant women.

The lactation section of prescription drug labeling would provide information on use of the drug while breastfeeding and would use the same format as the pregnancy section.

Using the highest NOEL for determining a safety factor has the following flaws:

1. The determination of a true no-effect level (should one actually exist, which is debatable in some cases) is impossible given the statistical power associated with the group sizes typically used; thus, the reported NOEL is very dependent on the selected group size.
2. The NOEL depends greatly on the selection of dosage levels; unless the selected dosage is just below the threshold for detectable effects, the reported NOEL is an underestimate; thus, tightly spaced dosage levels favor the determination of a higher NOEL.

Accordingly, the FDA has developed a sequential method of evaluating and dealing with reproductive and developmental analysis. This is called wedge analysis and is demonstrated in Figures 15.10–15.12.

TABLE 15.8 Pregnancy Categories

A: adequately tested in humans, no risk (0.7% of approved drugs)
 B/C/D: increasing levels of concern (92.3% of approved drugs— 66% in C)
 X: contraindicated for use in pregnancy (7.0% of approved drugs)

Use-in-pregnancy ratings, FDA (1979).

- A: animal studies and well-controlled studies in pregnant women failed to demonstrate a risk to the fetus.
 B: animal studies have failed to demonstrate risk to fetus; no adequate and well-controlled studies in pregnant women.
 C: animal studies showed adverse effect on fetus; no well-controlled human studies.
 D: positive evidence of human fetal risk based upon human data, but potential drug benefit outweighs risk.
 X: studies show fetal abnormalities in animals and humans; drug is contraindicated in pregnant women.

15.6 JUVENILE AND PEDIATRIC TOXICOLOGY

Safety of drug products to developing children has been a concern for more than a decade. Historically, healthcare providers rarely had explicit guidance on either dose levels to administer for drugs or of unusual risks that might be expected in these patients when drugs were given. The usual approach for adjusting dose was to scale approximately based on body weight.

Unfortunately, the differences between an adult and a developing child (usually considered as ranging from neonatal to 16 years of age) may be much more complex (Hoberman and Lewis, 2011):

TABLE 15.9 Cross-Species Postnatal Maturation

Organ System	Maturation
Neurologic	Adolescent/adult
Reproductive	Adolescent/puberty
Pulmonary (alveoli)	Infant (1–2 years)
Renal function	Infant (1 year)
Skeletal	Adolescent/adult
Immune (IgG, IgA)	Infant/child (5 and 12 years)

- Developmental differences and sensitivity differences may result in altered PF/PD in juveniles and require consideration of:
 - Development (structure/function), which is continuous
 - Role of developmental versus chronologic age-matched animal/kids
 - Cross-species postnatal maturation (Table 15.9)

In 2005, 2006, and 2014 both the European Medicines Agency (EMA) and the FDA provided guidance as to study requirements (CHMP, 2005, 2008; FDA, 2006; FDA, 2014).

While helpful, these guidances also introduced a number of points of uncertainty (Which species? What ages in test species equate to human developmental situation at different human ages?) and to the need to develop proficiency in areas of technique not previously commonly available (such as how does one go about dosing preweaning animals in toxicology studies—see Zoetis and Walls, 2003).

Tables 15.10–15.18, originally provided in the FDA 2006 guidance, provide organ system-specific guidances for equivalent developmental ages between the principal test species and humans. Figure 15.13 provides a chronological comparison of timing of key developmental stages for five primary species.

15.7 IN VITRO TESTS FOR DEVELOPMENTAL TOXICITY

Many *in vitro* systems have been proposed as tests for developmental toxicity (for review, see Brown and Freeman, 1984; Lin, 1987; *In vitro* Teratology Task Force, 1987; Gad, 2000). Various uses have been suggested for these *in vitro* tests including the following:

1. A general prescreen to select likely developmental toxins for subsequent whole-animal studies
2. A prescreen to select among possible backups to a lead drug candidate that had been found to be developmentally toxic
3. To study mechanisms of developmental toxicity
4. To provide supplementary information about developmental toxicity in addition to that provided by whole-animal studies
5. To replace whole animals for evaluating developmental toxicity

Uses one and five in the preceding text are very unlikely to be applicable to the pharmaceutical industry. One problem with *in vitro* systems for these purposes is that the percentages of the agents that are positive are very high, for example, 69% of agents tested in the mouse ovarian tumor (MOT) cell attachment test and 72% of agents tested in the mouse limb bud (MLB) assay. High correlations between *in vivo* and *in vitro* results have been reported based on the limited number of validation work completed. But these correlations have compared an *in vitro* end point to teratogenicity in laboratory animals without regard to maternal toxicity. Thus, the question that these screens seem to be answering is: Can this agent be teratogenic or developmentally toxic in laboratory animals at any dosage level? However, as discussed in the preceding text, it is not important for the purpose of safety assessment if an agent can be developmentally toxic in laboratory animals at high, maternotoxic dosages. The important question for prospective screens to answer is this: Is the agent a selective or direct developmental toxin? For these reasons, a promising drug candidate would not be dropped from development due to a positive result in a current *in vitro* test, and a negative result would not preclude the need for whole-animal studies.

To relate a positive finding in an *in vitro* test to the *in vivo* situation, one must either compare the concentration that caused the positive developmental effect *in vitro* to the exposure level of the embryo *in vivo* or compare the *in vitro* concentration for a developmental effect to the maternal toxicity that would be associated with exposure at that concentration *in vivo*. To do the necessary pharmacokinetic studies *in vivo* would defeat the purpose of using an *in vitro* test. It would be very desirable and may be possible, though, to have an end point in an *in vitro* test that would correlate with maternal toxicity.

Currently, only the *Hydra* system incorporates a measurement of “toxicity” to the adult to provide a comparison of the sensitivity of the “embryo” with that of the adult (Johnson et al., 1988). However, the *Hydra* screen has not been fully validated as being predictive of results in mammals and has fallen from favor. Thus, a major goal of research directed toward developing an *in vitro* teratogen screen should be to find a simple yet appropriate measure of toxicity unre-

lated to development. This would allow the comparison of the dose for a 50% effect (ED_{50}) of “developmental toxicity” as measured *in vitro* to an ED_{50} for “adult” toxicity *in vitro*. The validation of such a dual *in vitro* system would involve comparing the developmental selectivity *in vitro* to that *in vivo* for a large number of compounds. In a preliminary effort in this regard, effects on cell division in the rat limb bud micromass assay were considered as a possible correlate of maternal toxicity (Wise et al., 1990a).

Another possible use of *in vitro* developmental toxicity tests would be to select the least developmentally toxic backup from among a group of structurally related compounds with similar pharmacological activity (use 2 from the preceding text), for example, when a lead compound causes malformations *in vivo* and is also positive in a screen that is related to the type of malformation induced. However, even for this limited role for a developmental toxicity screen, it would probably also be desirable to have a measure of the comparative maternal toxicity of the various agents and/or information on the pharmacokinetics and distribution of the agents *in vivo*.

In vitro developmental toxicity systems have clearly been useful for studies of mechanisms of developmental effects (e.g., Daston et al., 1989)—use 3 from the preceding text. It is unclear, though, whether *in vitro* developmental toxicity tests will provide useful information about developmental toxicity that is not derived from whole-animal studies (use 4). As is true for a possible use as a prescreen, the interpretation of a positive finding in an *in vitro* test will depend on knowing the exposure level *in vivo*. When this is known, the *in vitro* information could be helpful. The results of *in vivo* studies, though, would still likely be considered definitive for that species.

15.8 APPRAISAL OF CURRENT APPROACHES FOR DETERMINING DEVELOPMENTAL AND REPRODUCTIVE HAZARDS

The current system for testing new pharmaceuticals for developmental and reproductive toxicity has been largely intact since 1966. In that time, no thalidomide-like disasters have occurred. It cannot be proven, but there is a good chance that these two statements are linked, that is, that the testing system has prevented potent, selective, human teratogens from being marketed. Indeed, the development of many compounds has been terminated because of positive findings in standard developmental toxicity studies. We do not know for certain if any of these agents would have been developmental hazards in humans, but it seems very likely. Due to the limited information on developmental toxicity of chemical agents in humans and the obvious inability to conduct controlled human studies, the correlation between animal studies and human findings is uncertain, and it is difficult to extrapolate precisely from animals to humans (see Frankos, 1985).

However, the worst hazards—the few dozen selective developmental toxins that are known to be teratogens in humans—are generally also selective teratogens in animals. Thus, although the current battery of animal studies is not perfect, it appears to have been adequate and effective in performing the important task of preventing the widespread exposure of pregnant women to dangerous developmental toxins. In the few cases where new pharmaceuticals have been shown to cause malformations in humans, animal studies had been positive and provided an early warning to the potential problem. Concern with the risk of potential male-mediated developmental toxicity not being adequately assessed has led to the issuance of a new guidance (FDA, 2015b) and to suggesting steps such as monitoring drug in male test animal ejaculate, with concentration on *in vitro* genotoxicity as means of addressing the issue.

16

CARCINOGENICITY STUDIES

16.1 INTRODUCTION

Cancer is a group of diseases characterized by the uncontrolled growth and spread of abnormal cells. If the spread is not controlled, it can result in death by a variety of mechanisms. Cancer is induced/caused by both external factors (physical effects, infectious organisms, chemicals, radiation) and internal factors (inherited mutations, hormones, suppressed immune function, and mutations that can occur due to metabolism). These causes, as will be discussed later, can be genotoxic or non-genotoxic effect (i.e., do not result from damage to DNA); the differences in these are discussed in Table 16.1.

Table 16.2 summarizes the potential mechanisms of action for non-genotoxic carcinogens and presents some exemplary compounds associated with these mechanisms. Note that non-genotoxic carcinogens have clear thresholds of action and dose response surfaces. ICH S6(2021) provides guidances for the current selection of models and interpretation of results.

TABLE 16.1 Features of Genotoxic and Non-genotoxic Carcinogens

Genotoxic carcinogens

- Mutagenic
- Can be complete carcinogens
- Tumorigenicity is dose responsive
- No theoretical threshold

Non-genotoxic carcinogens

- Nonmutagenic
- Threshold, reversible
- Tumorigenicity is dose responsive
- May function at tumor promotion stage
- No direct DNA damage
- Species, strain, tissue specificity

These causal factors may also act together or in sequence to initiate or promote the development of cancer (Klaunig and Wang, 2019). Usually, but not always, decades pass between external causes and the appearance of detectable cancer. Note that some agents may cause cancer by a combination of genetic and nongenetic mechanism.

While the causes of all cancers (also called malignant neoplasia or malignant oncogenicity) are not known, more than half a million deaths a year are attributed directly to the presence of cancer in the United States. It is estimated that there will be 1.9 million new cancer cases in the United States in 2021 (American Cancer Society, 2021) and a sizable portion of these are believed to be due to a wide range of environmental factors or behavioral factors that should be avoidable or preventable. In 1775, Percivall Pott first described the association between exposure to a xenobiotic (chimney soot) and an increase in the incidence of cancers (scrotal and nasal). Since Pott’s early observations and particularly since World War II, the understanding of the associations and mechanisms underlying chemically and physically induced cancer has grown due to epidemiological observations and from the results of experimental studies performed in mammalian and *in vitro* studies (Crum Brown and Fraser, 1869; Diamandopoulos, 1996; Creech, 2000).

We do know that specific factors (intrinsic and external) associated with the development of cancer are correlated with specific forms of neoplasia (not with generalized multiple organ effects). For external factor-associated cancers, we can identify causes and their relative risks using well-established experimental models. At the same time, as will be explored later in this chapter, there are predictive tests (short-term *in vitro* and computational or QSAR) which are quite effective in identifying potential risks of carcinogenicity.

TABLE 16.2 Proposed Modes of Action for Selected Non-genotoxic Chemical Carcinogens

Mode of Action	Example
Cytotoxicity	Chloroform Melamine
A2u-Globulin binding	D-Limonene 1,4-Dichlorobenzene
Receptor-mediated	
CAR	Phenobarbital Toxaphene
PPARα	Trichloroethylene Perchloroethylene Diethylhexylphthalate
AhR	Fibrates (e.g., clofibrate) 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD) Polychlorinated biphenyls (PCBs) Polybrominated biphenyls (PBBs)
Hormonal	Biogenic amines Steroid and peptide hormones Diethylstilbestrol (DES) Phytoestrogens (Bisphenol-A) Tamoxifen
Altered methylation	Phenobarbital Phenobarbital Choline deficiency Diethanolamine
Immunosuppression	Atrazine Bisphenol A Phthalates
Oxidative stress inducers	Ethanol TCDD Lindane Dieldrin Acrylonitrile

The multistep, multifactorial process by which normal cells are thought to be transformed into neoplastic cells involves the loss of genomic stability and the sequential acquisition of genetic alterations (Loeb and Loeb, 2000; Eyfjord and Bodvarsdottir, 2005). Driver mutations in cells are those which are causally involved in the neoplastic process and are selected for during the process of tumorigenesis. Passenger mutations are neutral and nonlethal; therefore, they are retained by chance during cell population expansion. Proto-oncogenes and tumor suppressor genes have been identified as the main mutational targets (Bishop, 1991), and carcinogen-specific mutational patterns have been observed in these genes in tumors of laboratory animals (Balmain and Brown, 1988) as well as in human cancers (Semenza and Weasel, 1997). This association suggests a multistep mechanistic link between carcinogen exposure, genetic alterations, and cancer (Hussain and Harris, 1999). The highly increased tumor incidence in subjects with defects in nucleotide excision repair (NER)

supports the key role of DNA alterations in the process of cancer development (Stary and Sarasin, 2002). Moreover, organ- and cell-type-specific differences in DNA repair capacity have been demonstrated to correlate with site of tumor formation under a variety of experimental situations. Animal models used to detect carcinogenetic potential are presented in Table 16.3. The traditional approach is of course the chronic 2-year bioassay in two rodent species.

In the hands of skilled practitioners, the results of *in vitro* studies, QSAR evaluations, and shorter-term (3–6 months) animal studies can serve to identify those substances that have a low probability of being carcinogenic (Sistare et al., 2011).

2005	Schiffman	Human papillomavirus

Pierce and Damjanov, 2006; Gad et al., 2015; Klaunig and Wang, 2019). Carcinogens can be chemical or physical, the latter including UV light and ionizing radiation. The general feeling among cancer researchers is that carcinogenesis is a multistage genetic and epigenetic process, requiring on the average a minimum of two up to approximately six to eight mutations. These changes produce a shift in the homeostatic state of a cell or cells from that which is a highly regulated population of cells, which would normally differentiate and at some time point become apoptotic to a new population of cells which exhibit unregulated control, proliferate freely, demonstrate autonomous growth, exhibit reduced levels of apoptosis, sustain angiogenic activity, become invasive, and show metastatic behavior. So, succinctly put, a mutated or initiated cell divides or proliferates to eventually form a neoplasm. A neoplasm or tumor can be benign or malignant.

While chemicals or agents that cause cancer can be effective at a variety of levels, they can be categorized into two broad groups, those chemicals or agents that are genotoxic and those that are epigenetic. Epigenetic carcinogens are not genotoxic, but do involve interactions with genomic DNA. Genetic carcinogens react with DNA.

16.3 GENOTOXIC CARCINOGENS

A genotoxic carcinogen is an agent or chemical that reacts with DNA, causing some sort of damage to the DNA (McKinnell, 2006; Perantoni, 2006; Klaunig and Kamendulis, 2008; Bhandari et al., 2012; Klaunig and Wang, 2019; Preston and Hoffmann, 2013). This damage can include a chemical reaction in which chemical reacts with and binds via a covalent bond to the DNA, forming a DNA adduct. In either case, whether the DNA is just damaged or structurally modified by the formation of an addition product (DNA adduct), a mutation can eventually be produced, and the process of carcinogenesis begun.

In addition to genotoxic chemicals being mutagenic, they can also function as complete carcinogens (see following text), do not exhibit any threshold level of activity, and show a dose response-like tumorigenic effect. It is important to note that a not insignificant number of carcinogens do not cause the development of cancer in and of themselves. A variety of genotoxic carcinogens exist and include such chemicals as polyaromatic hydrocarbons, alkylating agents, aromatic amines, and amides. Damage to DNA or DNA-adduct formation can result in the development of transversions or transitions:

- Transitions are a substitution of a purine with a different purine base or a pyrimidine with another pyrimidine base.

- Transversions are the substitution of a purine base with a pyrimidine base and vice versa.

Such simple substitution changes can lead to a misreading of the genetic code. Any misread copy (daughter strand of originally mutated DNA) can have the mutation fixed in place, when DNA replicates and become impervious to further repair processes of DNA.

Alternatively, misreading can result in what is known as a frameshift mutation. This type of mutation most commonly occurs in a situation where a DNA adduct has formed. What happens here is that the reading frame is shifted, either upstream or downstream, essentially garbling the genetic message. Finally, the DNA strands can actually break as a result of DNA-adduct formation. This is seen in situations where the formation of DNA adducts involves either the phosphodiester backbone or a DNA base. A single-strand break can lead to the formation of double-strand breaks, recombination, or other alterations in DNA structure and function.

As a complete class, genotoxic carcinogens can be subclassified as to whether or not they require metabolic activation to react with DNA. Chemicals that require metabolic activation to react with DNA are termed indirect-acting carcinogens and include, but are not limited to, such chemicals as aflatoxin, mycotoxins, azo dyes, and *N*-nitrosamines (Miller and Miller, 1981b; Conney, 1982; Miller et al., 1983; Pegg, 1984; Swenberg et al., 1984, 1985; Ames and Shigenaga, 1993; Klaunig and Kamendulis, 2004; Perantoni, 2006; Klaunig and Kamendulis, 2008; Groopman and Wogan, 2011; Penning, 2011; Bhandari et al., 2012; Klaunig and Wang, 2019). These chemicals require some sort of metabolic activation. Commonly these unactivated chemicals are referred to as procarcinogens, and the intermediate metabolites and final metabolites are referred to as proximate carcinogens and ultimate carcinogens, respectively. It is these proximate and ultimate forms that react with DNA to cause mutation and start the process of carcinogenesis. Depending upon the metabolic processes and pathways involved, there can be more than one proximate and more than one ultimate carcinogen for each procarcinogen, and in many cases the actual chemical species reacting with DNA is not known.

Keep in mind that while metabolic activation pathways are actively working, detoxification pathways are also functioning and both competing against each other for the same procarcinogen substrate. Some of these detoxification pathways may even result in inactivation of the carcinogen. Indirect-acting carcinogens do not generally manifest their carcinogenic effects at the original site of exposure, but rather manifest their toxicity at the site or sites of their metabolism and transformation into moieties, which can react with DNA and form DNA adducts.

Direct-acting carcinogens do not need any sort of metabolic change in their structure in order to react with DNA. Hence for these types of compounds, the unmetabolized form

of the chemical represents the ultimate carcinogen. Direct-acting carcinogens include, but are not limited to, such agents as dimethyl sulfate, methyl methanesulfonate, nitrogen mustard, and bis(chloromethyl) ether (Sontag, 1981; Pollard and Luckert, 1985; Marselos and Vainio, 1991; Kiaris, 2006; Perantoni, 2006; Klaunig and Kamendulis, 2008; Bhandari et al., 2012; Klaunig and Wang, 2019). Direct-acting carcinogens cause the formation of tumors at the site of their initial exposure and can also be carcinogenic at multiple sites. These chemical agents are ultimate carcinogens in their native forms and also in their native and unmetabolized forms possess electrophilic centers, which seek out and bind to nucleophilic centers (DNA and macromolecules).

A characteristic held in common by both indirect- and direct-acting carcinogens is that they all have strongly electrophilic centers. As electrophiles, they are highly reactive, stable, long lived, and capable of forming strong covalent bonds with other molecules possessing nucleophilic centers and seeking out the nucleophilic centers of other molecules, especially DNA. Molecules possessing oxygen, sulfur, and nitrogen atoms are ideal targets for an electrophile, because of the unpaired electrons on these particular atoms. This means that good sources for nucleophilic targets are DNA bases and the phosphodiester backbone of DNA. The strength of a given electrophile is important. Strong electrophiles can readily react with both weak and strong nucleophiles. But weak electrophiles are capable of only reacting with strong nucleophiles. Examples of electrophiles include carbonium ions, diazonium ions, epoxides, strained lactones, and various free radicals. The ability of an electrophile to form an adduct with DNA is in part limited by the structure of DNA itself, the size and spatial configuration of the electrophile itself, and the metabolic environment in the immediate environment of the DNA. While adducts of DNA can form at any site on DNA, the most common sites of alkylation are generally considered to be O⁶, N³, and/or N⁷ of guanine bases and N¹ and/or N³ of adenine bases. The most common adduct reaction with the phosphodiester backbone of DNA is ethylation.

There is some debate as to the effective carcinogenic potency of the various types of DNA adducts formed, but this has not been demonstrated unequivocally. The effectiveness of either direct-acting or indirect-acting genotoxic carcinogens depends highly upon the strength of attraction between the electrophile and DNA, stability of the electrophile, membrane permeability transport, as well as successful competition with detoxification pathways and the presence of, and opportunity for reaction with, other cellular nucleophiles.

Undoubtedly DNA adducts are formed each and every day, but the mechanisms for the repair of DNA in the cell keep the frequencies of these mutations at a low level. The interval between the time of the DNA insult and the time of its repair is critical. Lack of timeliness in repair can fix the mutation in

place forever. However, just because DNA damage exists does not necessarily mean that the process of carcinogenesis has started. Indeed, the pathway to carcinogenesis depends strongly upon such factors as the frequencies of DNA replication and repair within a given tissue or organ. In actuality, the development of cancer following an exposure to a carcinogen is relatively rare.

While the whole process of carcinogenesis is very complex, with the involvement of many different factors, the repair of DNA is a very potent defense against the development of genotoxicity and the development of cancer (Rupp and Howard-Flanders, 1968; Lehmann, 1972; di Caprio and Cox, 1981; Prakash, 1981; Neumann, 1983; Becker and Shank, 1985; Morrison et al., 1989; Perera et al., 1991; Hsieh and Hsieh, 1993; Volkert, 1998; Masutani et al., 1999; Sancar, 2003; Watson et al., 2004; Zhang and Lawrence, 2005; Kiaris, 2006; Lopes et al., 2006; Perantoni, 2006; Callegari and Kelly, 2007; Klaunig and Kamendulis, 2008; Asagoshi and Wilson, 2011; Basu, 2011; Peng et al., 2011; Bhandari et al., 2012; Klaunig, 2013). During the repair of DNA, the region of DNA that is damaged or has been modified through the formation of a DNA adduct, the repair systems detect, recognize, remove, and repair the DNA with a patch, so to speak, using the intact opposite strand as a building template. The DNA patch or segment is then spliced into the DNA molecule, replacing the defective segment.

It cannot be strongly enough emphasized that any repair of DNA needs to occur before mitosis occurs. If repair has not taken place before mitosis occurs, the damaged areas of DNA become fixed, and this in turn can lead to the incorrect pairing of bases, rearrangements, translocations, and other mutagenic sequelae or clastogenic events, which can start the cell down the path of carcinogenesis. While the carcinogen itself is an important parameter in the process of neoplastic transformation, the rate of mitosis for a given cell is another extremely important factor that needs to be considered. A variety of mechanisms are available to a cell to repair DNA, and there is some redundancy of activity between processes. While these processes are highly effective, they are not 100% efficient and flawless in the conduct of their function. Lack of accuracy in the repair process can leave residual DNA damage, which can ultimately lead to transcription and translation errors from the mutated genetic templates. This in turn can lead to the formation of proteins and other molecules with altered structure and function. These altered proteins and enzymes can impact the carcinogenesis process. Mutations of oncogenes, tumor suppressor genes, and other genes controlling the cell cycle or cell communication can lead to the development of a group of cells with a distinct advantage for survival as compared to other cells. Common forms of DNA damage include, but are not limited to, adduct formation, DNA cross-linking, hydroxylation of bases, single-strand DNA breaks, double-strand DNA breaks, and the loss of bases. DNA repair processes include excision repair systems, postreplication

repair, direct reversal of DNA damage, and nonhomologous end joining.

Regions of DNA that contain bases that are chemically modified or possess adducts are generally repaired by excision repair processes. Excision repair systems include mismatch repair, NER, and base excision repair activities:

- In base excision repair, a single base, whose structure has been altered by oxidation, alkylation, hydrolysis, or deamination, is removed and replaced.
- In NER, bulky helix distorting lesions are recognized and removed.
- In mismatch repair, errors of DNA replication and recombination that have resulted in mispaired but undamaged nucleotides are corrected. Spontaneous mutations occur frequently and are known as point mutations. That is a change in a single base in a base pair unit.

However, the challenge here for the repair system is determining which strand is the damaged or nontrue strand of DNA. Depurination is an activity that occurs fairly frequently and produces a site where the purine base is missing. If not repaired, mechanisms for the synthesis and repair of DNA are unable to determine what the appropriate base should be at the replication fork for proper pairing and a mutation can be the end result. Endonucleases cut DNA near apurinic sites and then extend that cut via the action of exonucleases. The resulting gap is then repaired by the actions of DNA polymerases and ligases. The end-joining repair of nonhomologous DNA involves the joining of pieces of free DNA. Pieces of free DNA typically result from the formation of double-stranded breaks in DNA as a result of exposure to ionizing radiation or some antineoplastic drugs.

The problem with this type of repair is that many times these pieces of DNA are translocated from one chromosome to another chromosome. This leads to the potential of placement of, for example, a proto-oncogene next to, for example, a gene controlling some aspect of cell growth. So the cell growth gene is now under the control of a different gene promoter. So even though the DNA is rejoined and not lost, it is in the incorrect place in the DNA for normal function. Double-stranded breaks in DNA are only correctly repaired when the free ends are rejoined exactly as they were before. Also, when this rejoining of DNA takes place, base pairs are not infrequently lost at the juncture point, which can lead to miscoding and misreading of DNA and a subsequent mutational change.

Postreplication repair (PRR) is repair that takes place after DNA has replicated. Several polymerases have been implicated in this process. The elucidation of postreplication error processes is currently an active area of research in molecular biology and still very much in flux in terms of the details. However, the activity of PRR enzymes may be controlled by

the postreplication checkpoint response that has been observed in eukaryotic cells. Cells are also known to eliminate some types of damage to their DNA by chemically reversing it. These processes do not require a template, because this type of damage can occur in only one of the four bases. Direct reversal does not involve the breakage of the phosphodiester backbone. An example is the formation of pyrimidine dimers, two pyrimidines directly connected by a covalent bond. This dimerization occurs as a result of exposure to UV light. An enzyme, photolyase, which is activated by a very specific wavelength range of UV light (300–500 nm), directly reverses this change. In another example of this direct reversal of damage, the methylation of guanine bases can be directly reversed by the action of guanine methyltransferase (MGMT).

16.4 EPIGENETIC CARCINOGENS

Any carcinogen that is not genotoxic can contribute to the process of carcinogenesis in what is termed an epigenetic manner (Trosko et al., 1998; Powell and Berry, 2000; Moggs et al., 2004; Kiaris, 2006; Klaunig and Kamendulis, 2008; Darwanto et al., 2011; Bhandari et al., 2012; Klaunig, 2013). The key difference from genotoxic carcinogens is that agents or metabolites of agents of this category do not *directly* damage, bind to, or interact with DNA. These agents are typically active only above a certain threshold level, and the process by which they work may be species specific. A number of different subcategories exist within this group, and they and their mechanisms of action are outlined in the following text.

The methylation of DNA is a normal ongoing cellular process, and this activity can profoundly affect the level of gene expression and the process of carcinogenesis (Holliday, 1990; Baylin, 1997; Klaunig and Kamendulis, 2004; Klaunig and Kamendulis, 2008; Klaunig, 2013). If there is a copious amount of methylation within a gene, it is usually silenced. Alternatively, if there is little methylation within a gene, it is highly active. DNA methylation takes place as a result of the activity of DNA methylases, which obtain their methyl groups for transfer to the cytosine bases in DNA from *S*-adenosylmethionine or choline. Lower than normal levels of DNA methylation have been associated with increases in the rates of mutation. Chemical agents such as phenobarbital and diethanolamine are associated with methyltransferase activity, the alteration of DNA methylation patterns, and resultant changes in chromosomal structure. Deviations from the norm in methylation patterns have been associated with the activity of tumor suppressor genes, bladder cancer, retinoblastoma, and metastatic tumors.

Reactive oxygen species (ROS) can contribute to the process of carcinogenesis and are produced by the reduction of molecular oxygen (Rao and Reddy, 1991; Clarkson and Thompson, 2000; Ding et al., 2000; Simeonova and

Luster, 2000; Abuja and Albertini, 2001; Martindale and Holbrook, 2002; Klaunig and Kamendulis, 2008; Klaunig, 2013). Two chemicals that have been associated with the production of ROS are ethanol and acrylonitrile. Many different ROS exist and include such moieties as hydrogen peroxide, the superoxide anion, and the hydroperoxyl radical. Both endogenous (e.g., macrophages, oxidative phosphorylation, P450 metabolism, peroxisomes) and exogenous (e.g., metals, radiation, redox-cycling compounds) sources can cause the formation of oxygen radicals. These oxygen radicals can be neutralized by antioxidants, which can be endogenous or exogenous and can be enzymatic (e.g., catalase, superoxide dismutase) or nonenzymatic (e.g., vitamin C, vitamin E).

As an example, peroxisome proliferators (e.g., clofibrate) increase the production of peroxisomes by interacting as an agonist with a peroxisome proliferator-activated receptor (PPAR) by increasing the formation of peroxisomes (Rao and Reddy, 1991; Peters et al., 1998; Pugh et al., 2000; Burkhardt et al., 2001; Klaunig et al., 2003; Klaunig and Kamendulis, 2008; Klaunig, 2013). These receptors exist in different forms (α , β , δ , γ) and stimulate the formation of hydrogen peroxide, which can cause oxidative stress in the cell. ROS of this oxidative stress can cause damage to cellular macromolecules, biomembranes, and DNA. The damage to DNA can include but is not limited to strand breaks, cross-linking, and base modifications. This DNA damage can result in a lack of or faulty induction, replication errors, faulty or lack of signal transduction, and a generalized instability of the genome. Damage to biomembranes can result in the production of highly reactive electrophilic compounds such as epoxides, which can inflict damage to DNA as mentioned earlier. ROS can also influence various signal transduction pathways altering genetic expression in a positive or negative fashion. Such alteration can lead to the development of apoptosis, altered differentiation, or changes in the rates of cellular proliferation.

A number of chemicals have been shown to be capable of causing the formation of neoplasms through receptor-mediated pathways as well as via the disturbance of hormonal homeostasis (Noller et al., 1972; Tavani et al., 1993; Capen et al., 1995; Li et al., 1997; Hood et al., 1999; Klaunig and Kamendulis, 2008; Klaunig, 2013). Some of these chemicals include but are not limited to tamoxifen, diethylstilbestrol (DES), and phenobarbital. Some hormones are also known to cause cell proliferation in their target organ. A loss of hormonal control can lead to the development of persistently elevated levels of a given hormone and rampant cellular proliferation and resultant neoplasm formation. Epidemiologic data on patients afflicted with breast or ovarian cancer has revealed that individuals with high levels of estrogen as well as those individuals exposed to DES were at an increased risk to develop cancer. Indeed, a classic example involves the compound DES. Exposed females gave birth to daughters, who had significantly higher incidences of cancers of the

vagina and cervix. The mechanism here is ostensibly the ability of DES to cause aneuploidy. Synthetic estrogens and anabolic steroids have been implicated in the development of hepatic adenomas in both laboratory animals and human females. These adenomas shrink or disappear with removal to hormone (oral contraceptive) stimulation. Yet, interestingly enough, estrogens are protective in males with prostate cancer. Thyroid-stimulating hormone (TSH) drives proliferative activity in the thyroid gland, and agents (e.g., phenobarbital) that increase the levels of TSH lead to the development in the thyroid of hypertrophy, hyperplasia, and neoplasia.

The repeated exposure of cells to chemicals or agents that produce cell death cause a cycle of persistent cell growth or hyperplasia in an attempt to regenerate lost organ function (Andersen et al., 1998; Klaunig and Kamendulis, 2008; Klaunig, 2013). Such constant stimulation and resultant replicative activity increase the potential and probability for the development of the spontaneous mutation of DNA. As numbers of mutated cells increase in number and proliferate, preneoplastic lesions develop, and these can eventually lead to the formation of neoplasms. An important point to note here is that many carcinogens, whether they are genotoxic or not, at sufficiently high enough doses can cause cell death and an associated regenerative response, which may contribute ultimately to the carcinogenicity profile of some chemicals. A classic carcinogen of this subcategory is chloroform.

Some epigenetic agents work through receptors. The classic example of this subcategory is the aryl hydrocarbon receptor (AhR) (Whysner et al., 1996; Nebert et al., 2000; Ueda et al., 2002; Kodama et al., 2004; Moennikes et al., 2004; Klaunig and Kamendulis, 2008; Klaunig, 2013). Chemical agents that have been associated with the development of tumors are polybrominated biphenyls, polychlorinated biphenyls, and 2,3,7,8-tetrachlorodibenzodioxin (TCDD). The mechanism of action here is that chemical agents bind to the AhR and then this ligand–AhR complex moves into the nucleus, where it dimerizes with the Ah receptor nuclear translocator (ARNT). AhR/ARNT in turn now binds to aryl hydrocarbon response elements (ARE) (also known as xenobiotic response elements (XRE) or dioxin response elements [DRE]). There are AhR/ARNT-dependent genes that are associated with various P450 enzymes and other phase I and phase II enzymes that are involved in metabolic activation and detoxification. It is thought that TCDD works chiefly as a cancer promoter, promoting the carcinogenicity initiated by other compounds. Other proposed mechanisms for TCDD-induced carcinogenesis include, but are not limited to, the generation of ROS, altered signal transduction, or the disruption of endocrine homeostasis. Another receptor proposed to be involved in the process of carcinogenesis is the constitutive androstane receptor (CAR). CAR is a member of the nuclear receptor family, and the most commonly studied chemical agent here is phenobarbital. It is widely known that phenobarbital induces the activity of P450 enzymes, especially CYP2B.

While phenobarbital has many other actions that support the development of cancer, it is argued that the mechanism of action through CAR may well be the causation of oxidative stress.

The protein $\alpha_2\mu$ -globulin is synthesized in the liver of the male rat and filtered through the glomerulus and only partly excreted in the urine (Melnick et al., 1996; Klaunig and Kamendulis, 2008; Klaunig, 2013). Reabsorption of the protein occurs in the P2 segment of the proximal tubule, where it is hydrolyzed into constituent amino acids. Some chemicals, such as d-limonene, have the ability to bind to $\alpha_2\mu$ -globulin and prevent its catabolism. Accordingly, $\alpha_2\mu$ -globulin accumulates in renal lysosomes. This accumulation results in the dysfunction of the organelle with the release of destructive enzymes and the development of cell necrosis. As tubular cells are wiped out, regeneration tries to take place in order to regain lost organ function. Ultimately the mechanism of carcinogenesis here might well be that of cytotoxicity.

Cell-to-cell communication, although not typically classified as an epigenetic contributor to the process of carcinogenesis, is still nonetheless an important contributor to the development of cancer (Pitts, 1994; Colombo et al., 1995; White and Paul, 1999; Kelsell et al., 2001; Willecke et al., 2002; Leithe et al., 2006; Klaunig and Kamendulis, 2008; Klaunig, 2013). While there are a variety of ways by which cells can communicate with each other, for purposes of this discussion we will focus on gap junctions. Gap junctions are intercellular plasma membrane structures that allow the direct exchange of ions and small molecules through channels between adjacent cells. Gap junction channels are composed of connexin. Connexins play very important roles in the regulation of cell growth and differentiation. It has been shown that cancer cells usually have a downregulated expression of gap junctions, and evidence supports the claim that loss of gap junctional intercellular communication is an important step in the process of carcinogenesis.

Supporting this hypothesis is the observation that the renewed expression of connexins in cancer cells causes a reduction in the rate of tumor growth and a return to a pattern of normal cell growth control. Various mechanisms are involved in the loss of gap junctions in neoplastic cells, ranging from the loss of connexin gene transcription to the loss or alteration of function of connexin proteins. The details of actual mechanisms involved in the downregulation of connexins in carcinogenesis remain to be elucidated, and an understanding of their actions will aid a deeper understanding of the role of gap junctions in the process of carcinogenesis.

In the experimental evaluation of substances for carcinogenesis based on experimental results of studies in a non-human species at some relatively high dose or exposure level, an attempt is made to predict the occurrence and level of tumorigenesis in humans at much lower levels. In this chapter, we will examine the assumptions involved in this undertaking and review the aspects of design and interpretation of

traditional long-term (lifetime) animal carcinogenicity studies as well as some alternative short-term models. It should be noted that these are required of the majority of marketed drugs but are only performed on the minority of drugs which reach a stage of development where a marketing application is likely and to occur within three or so years.

At least in a general way, we now understand what appear to be most of the mechanisms underlying chemical- and radiation-induced carcinogenesis. The most recent regulatory summary on identified carcinogens (NIH, 2021) lists 48 agents classified as “known to be human carcinogens.” Several hundred other compounds are also described as having lesser degrees of proof. A review of these mechanisms is not germane to this chapter (readers are referred to Miller and Miller (1981a) for a good short review), but it is now clear that cancer as seen in humans is the result of a multifocal set of causes.

The mechanisms and theories of chemical carcinogenesis are as follows:

1. Genetic (all due to some genotoxic event)
2. Epigenetic (no mutagenic event)
3. Oncogene activation
4. Two-step (induction/promotion)
5. Multistep (combination of above)

Looked at another way, the four major carcinogenic mechanisms are DNA damage, cell toxicity, cell proliferation, and oncogene activation. Any effective program to identify those drugs which have the potential to cause or increase the incidence of neoplasia in humans must effectively screen for these mechanisms (Kitchin, 1998; Williams and Iatropoulos, 2001; McGregor, 2009).

The single most important statistical consideration in the design of bioassays in the past was based on the point of view that what was being observed and evaluated was a simple quantal response (cancer occurred or it didn't) and that a sufficient number of animals needed to be used to have reasonable expectations of detecting such an effect. Though the single fact of whether or not the simple incidence of neoplastic tumors is increased due to an agent of concern is of interest, a much more complex model must now be considered. The time to tumor, patterns of tumor incidence, effects on survival rate, and age of first tumor all must now be captured in a bioassay and included in an evaluation of the relevant risk to humans.

The task of interpreting the results of any of the animal-based bioassays must be considered from three different potential perspectives as to organ responsiveness:

- I Those organs with high animal and low human neoplasia rates
- II Those organs with high neoplasia rates in both animals and humans
- III Those organs with low animal but high human neoplasia rates

Note that not considered is the potential other case—where the neoplasia rates are low for both animals and humans. This is a very rare case and one for which our current bioassay designs probably lack sufficient power to be effective.

In group I, the use of animal cancer data obtained in the liver, kidney, forestomach, and thyroid gland is perceived by some as being hyperresponsive, too sensitive, and of limited value and utility in the animal cancer data obtained in group I organs. The liver is such a responsive and important organ in the interpretation of carcinogenesis data that the discussion of this subject area has been broken up into three chapters for human, rat, and mouse data. Peroxisome proliferation in the liver, particularly in mice, is an area of interpretive battle as in many cases the metabolism and mechanisms involved are not relevant to man.

Group II organs (mammary gland, hematopoietic, urinary bladder, oral cavity, and skin) are less of an interpretive battleground than group I organs. For group II organs, all four major mechanisms of carcinogenesis (electrophile generation, oxidation of DNA, receptor–protein interactions, and cell proliferation) are known to be important. The high cancer rates for group II organs in both experimental animals and humans may at first give us a false sense of security about how well the experimental animal models are working. As we are better able to understand the probable carcinogenic mechanism(s) in the same organ in the three species, we may find that the important differences between the three species are more numerous than we suspect. This is particularly true for receptor-based and cell-proliferation-based carcinogenic mechanism.

Animal cancer data of group III organs are the opposite of group I organs. Group III organs have low animal cancer rates and high human cancer rates. In contrast to the continuing clamor and interpretive battleground associated with group I organs, there is little debate over group III organs. Few voices have questioned the adequacy of the present-day animal bioassay to protect the public health from possible cancer risks in these group III organs. Improved efforts must be made toward the development of cancer predictive systems or short-term tests for cancer of the prostate gland, pancreas, colon/rectum, and cervix/uterus.

Carcinogenicity bioassays are the longest and most expensive of the extensive battery of toxicology studies required for the registration of pharmaceutical products in the United States and in other major countries. In addition, they are often the most controversial with respect to interpretation of their results. These studies are important because, as noted by the International Agency for Research on Cancer (IARC) (1987), “in the absence of adequate data on humans, it is biologically plausible and prudent to regard agents for which there is sufficient evidence of carcinogenicity in experimental animals as if they presented a carcinogenic risk to humans.”

In this chapter, we consider the major factors involved in the design, conduct, analysis, and interpretation of carcinogenicity studies as they are performed in the pharmaceutical industry.

16.5 REGULATORY REQUIREMENTS AND TIMING

The need for carcinogenicity testing of pharmaceuticals is a dual criterion: that such studies were required to support registration of a drug that was to be administered for a period of 3 months or more for FDA (in Japan and Europe this was stated to be 6 months or more) and such testing had to be completed before filing for registration in such cases. ICH guidelines (ICH, 1995, 2021) now fix this human exposure triggering period at 6 months, excluding agents given infrequently through a lifetime or for shorter periods of exposure unless there is reason for concern (such as positive findings in genotoxicity studies, structure–activity relationships suggesting carcinogenic risk, evidence of occurrence of preneoplastic lesions in repeat-dose studies, or previous demonstration of carcinogenic potential in the product class that is considered relevant to humans). Such studies are still only required to be completed before filing for registration unless there is “reason for concern.” Reason for concern would be that the drug in question is structurally related to a known carcinogen, or findings in earlier nonclinical studies indicate that the drug is potentially a carcinogen. In such cases, it may be required that a study be performed before initiation of Phase 3 clinical studies. On the other hand, there now exists the possibility of requesting a waiver of testing if genotoxicity is negative, if there are no signs of preneoplastic changes in earlier nonclinical studies, and if there are no structurally alerting features. To request a waiver, the supporting documentation and a request letter is submitted with form 1571 as an amendment to the IND (via the responsible division). The request is then forwarded to the Carcinogenicity Advisory Committee (CAC) for review where it is either approved or rejected. Most developers conduct carcinogenicity studies in parallel with phase III clinical studies.

Endogenous peptides and protein substances and their analogs are generally not required to be evaluated for carcinogenicity. There are three conditions which call the need into question however:

1. Products where there are significant differences in biological effects to the natural counterparts
2. Products where modifications lead to significant changes in structure compared to the natural substance
3. Products resulting in humans having a significant increase over the existing local or systemic concentration

ICH has also given guidance on the design, dose selection, statistical analysis, and interpretation for such studies (ICH, 1995, 1997, 2008, 2012). The FDA has also offered guidance, the most recent from (FDA, 2001) a 44-page document available online.

There has been extensive debate and consideration on the relevance and value of the traditional long-term rodent bioassays. The FDA has looked at rat and mouse studies for 282 human pharmaceuticals, resulting in the conclusion that “sufficient evidence is now available for some alternative *in vivo* carcinogenicity models to support their application as complimentary studies in combination with a single 2-year carcinogenicity study to identify trans-species tumorigens (Contrera et al., 1997).” FDA is considering a range of changes to the S1 guidance governing the conduct of rodent carcinogen studies (FDA, 2012, 2013).

The Europeans, meanwhile, have focused on the need for better care in study design, conduct, and interpretation (Spindler et al., 2000), aiming to incorporate these in the revision of the Center for Proprietary Medicinal Products (CPMP) carcinogenicity guidelines (Weaver and Brunden, 1998).

The conduct of bioassays in compliance with regulatory expectations requires that an adequate 90-day range finder study be conducted in the intended test species to set doses. Additionally, it is strongly suggested that the planned study protocols (and data supporting species/models and intended doses) be reviewed and approved by the Carcinogenicity Advisory Committee (CAC).

16.5.1 Waivers of Required Testing

Datasets evaluated by the ICH S1 expert working group (S1 EWG) suggest that knowledge of pharmacologic targets and pathways together with toxicological and other data can, in certain cases, provide sufficient information to anticipate the outcome of 2-year rat carcinogenicity studies and their potential value in predicting the risk of human carcinogenicity of a given pharmaceutical. Consideration of this information is hypothesized to provide sufficient information to conclude that a given pharmaceutical in certain cases presents a negligible risk or, conversely, a likely risk of human carcinogenicity without conducting a 2-year rat carcinogenicity study. It is envisioned that sponsors of such pharmaceuticals would provide Drug Regulatory Agencies (DRAs) a Carcinogenicity Assessment Document (CAD) which could justify a “waiver request” that seeks to omit the conduct of 2-year rat carcinogenicity studies. The CAD would address the overall carcinogenic risk of the investigational drug as predicted by the endpoints discussed in this document and a rationale for why the conduct of 2-year rat carcinogenicity studies would or would not add value to that assessment. (ICH, 2021)

16.6 SPECIES AND STRAIN

Two rodent species are routinely used for carcinogenicity testing in the pharmaceutical industry—the mouse and the rat. Sprague–Dawley-derived rats are most commonly used in American pharmaceutical toxicology laboratories. However, the Hans Wistar and Fischer 344 (F344) strains are favored by some companies, while the Long Evans and CFE (Carworth) strains are rarely used (Pharmaceutical Manufacturers Association (PMA), 1988).

With respect to mice, the CD-1 is by far the most commonly used strain in the pharmaceutical industry. Other strains used less frequently are the B6C3F1, CF-1, NMRI, C57B1, Balb/c, and Swiss (Pharmaceutical Manufacturers Association (PMA), 1988; Rao et al., 1988). “Swiss” is the generic term since most currently used inbred and outbred strains were originally derived from the “Swiss” mouse.

If either the mouse or the rat is considered to be an inappropriate species for a carcinogenicity study, the hamster is usually chosen as the second species.

The use of two species in carcinogenicity studies is based on the traditional wisdom that no single species can be considered an adequate predictor of carcinogenic effects in humans. Absence of carcinogenic activity in two different species is thought to provide a greater level of confidence that a compound is “safe” for humans than data derived from a single species.

One may question this reasoning on the basis that data from two “poor predictors” may not be significantly better than data from a single species. It is also reasonable to expect that the ability of one rodent species to predict a carcinogenic effect in a second rodent species should be at least equal to, if not better than, its ability to predict carcinogenicity in humans. The concordance between mouse and rat carcinogenicity data has been investigated, and a summary of the results is presented in the next paragraph.

A review of data from 250 chemicals found 82% concordance between results of carcinogenicity testing in the mouse and the rat (Purchase, 1980). Haseman et al. (1984a) reported a concordance of 73% for 60 compounds studies in both species. However, 30–40% of 186 National Cancer Institute (NCI) chemicals were found to be positive in one species and negative in the other (Gold et al., 1984). It is reasonable to conclude that neither rodent species will always predict the results in the other rodent species or in humans and that the use of two species will continue until we have a much better understanding of the mechanisms of carcinogenesis.

The choice of species and strain to be used in a carcinogenicity study is based on various criteria including susceptibility to tumor induction, incidence of spontaneous tumors, survival, existence of an adequate historical database, and availability.

Susceptibility to tumor induction is an important criterion. There would be little justification for doing carcinogenicity

studies in an animal model that did not respond when treated with a “true” carcinogen. Ideally, the perfect species/strain would have the same susceptibility to tumor induction as the human. Unfortunately, this information is usually unavailable, and the tendency has been to choose animal models that are highly sensitive to tumor induction to minimize the probability of false negatives.

The incidence of spontaneous tumors is also an important issue. Rodent species and strains differ greatly in the incidence of various types of spontaneous tumors. The Sprague–Dawley stock, although preferred by most pharmaceutical companies, has a very high incidence of mammary tumors in aging females, which results in substantial morbidity during the second year of a carcinogenicity study. If one chooses the F344 strain, the female mammary tumor incidence will be lower, but the incidence of testicular tumors will be higher (close to 100%), than that in Sprague–Dawley rats.

A high spontaneous tumor incidence can compromise the results of a carcinogenicity study in two ways. If a compound induces tumors at a site that already has a high spontaneous tumor incidence, it may be impossible to detect an increase above the high background “noise.” Conversely, if a significant increase above control levels is demonstrated, one may question the relevance of this finding to humans on the basis that the species is “highly susceptible” to tumors of this type.

The ability of a species/strain to survive for an adequate period is essential for a valid assessment of carcinogenicity. Poor survival has caused regulatory problems for pharmaceutical companies and is, therefore, an important issue (Pharmaceutical Manufacturers Association (PMA), 1988). The underlying concept is that animals should be exposed to the drug for the greater part of their normal life span to make a valid assessment of carcinogenicity. If animals on study die from causes other than drug-induced tumors, they may not have been at risk long enough for tumors to have developed. The sensitivity of the bioassay would be reduced and the probability of a false-negative result would be increased.

The availability of an adequate historical database is often cited as an important criterion for species/strain selection. Historical control data can sometimes be useful in evaluating the results of a study. Although such data are not considered equal in value to concurrent control data, they can be helpful if there is reason to believe that the concurrent control data are “atypical” for the species/strain.

Although outbred stocks (e.g., Sprague–Dawley rats and CD-1 mice) are generally favored in the pharmaceutical industry, inbred strains are also used (e.g., F344 rats and B6C3F1 mice). Inbred strains may offer greater uniformity of response, more predictable tumor incidence, and better reproducibility than outbred strains. However, their genetic homogeneity may also result in a narrower range of sensitivity to potential carcinogens than exists in random-bred animals. In addition, extrapolation of animal data to humans is the ultimate

goal of carcinogenicity studies, and the human population is anything but genetically homogeneous.

The ideal species for carcinogenicity bioassays should absorb, metabolize, and excrete the compound under study exactly as humans do. Unfortunately, because of the small number of species that meet the other criteria for selection, there is limited practical utility to this important scientific concept, as applied to carcinogenicity studies.

Before concluding this discussion of species/strain selection, it may be worthwhile to take a closer look at the animals preferred by pharmaceutical companies to determine to what extent they meet the conditions described earlier. Advantages of the CD-1 mouse are (i) a good historical database including various routes of exposure, (ii) demonstrated susceptibility to induction of tumors, and (iii) relatively low spontaneous incidence of certain tumors to which other strains are highly susceptible, especially mammary and hepatic tumors. Disadvantages are (i) lack of homogeneity, (ii) relatively low survival, (iii) moderate to high incidence of spontaneous pulmonary tumors and leukemias, and (iv) high incidence of amyloidosis in important organs, including the liver, kidney, spleen, thyroid, and adrenals (Sher et al., 1982).

There has recently been a reduction in survival of Sprague–Dawley rats and rats of other strains (Food and Drug Administration (FDA), 1993). This reduction may be the result of ad libitum feeding, as preliminary results suggest that caloric restriction may improve survival. Leukemia appears to be the major cause of decreasing survival in the F344 rat. The problem of reduced survival may necessitate a reevaluation of the survival requirements for carcinogenicity studies by regulatory agencies.

16.7 ANIMAL HUSBANDRY

Because of the long duration and expense of carcinogenicity studies, the care of animals used in these studies is of paramount importance. Various physical and biological factors can affect the outcome of these studies. Some important physical factors include light, temperature, relative humidity, ventilation, atmospheric conditions, noise, diet, housing, and bedding (Rao and Huff, 1990). Biological factors include bacteria and viruses that may cause infections and diseases.

The duration, intensity, and quality of light can influence many physiological responses, including tumor incidence (Greenman et al., 1984; Wiskemann et al., 1986). High light intensity may cause eye lesions, including retinal atrophy and opacities (Bellhorn, 1980; Greenman et al., 1982). Rats housed in the top row and the side columns of a rack may be the most severely affected.

The influence of light on the health of animals may be managed in several ways. The animals may be randomly assigned to their cages on a rack such that each column contains animals of a single-dose group. The location of the col-

umns on the rack may also be randomized so that the effect of light is approximately equal for all dose groups. In addition, the cages of each column of the rack may be rotated from top to bottom when the racks are changed.

Room temperature has been shown to influence the incidence of skin tumors in mice (Weisbrode and Weiss, 1981). Changes in relative humidity may alter food and water intake (Fox, 1977). Low humidity may cause “ringtail,” especially if animals are housed in wire mesh cages (Flynn, 1960).

Diets for rodents in carcinogenesis studies should ideally be nutritionally adequate while avoiding excesses of nutrients that may have adverse effects.

Types of caging and bedding have been shown to affect the incidence and latency of skin tumors in mice. In a study by DePass et al. (1986), benzo[*a*]pyrene-treated mice were housed either in stainless steel cages or polycarbonate shoe-box cages with hardwood bedding. The mice housed in shoe-box cages developed tumors earlier and with higher frequency than those housed in steel cages.

Housing of rats in stainless steel cages with wire mesh floors may result in decubitus ulcers on the plantar surfaces. This condition may be a significant clinical problem associated with high morbidity and may affect survival of the animals if euthanasia is performed for humane reasons. Ulcers are particularly frequent and severe in older male Sprague–Dawley rats, perhaps because of their large size and weight compared with females and rats of other strains.

Common viral infections may affect the outcome of carcinogenicity studies by altering survival or tumor incidence. Nevertheless, viral infections did not cause consistent adverse effects on survival or tumor prevalence in control F344 rats from 28 NCI–National Toxicology Program (NTP) studies, though body weights were reduced by Sendai and pneumonia viruses of mice (Rao et al., 1989). The probability of such infections can be minimized by using viral-antibody-free animals, which are readily available.

16.8 DOSE SELECTION

16.8.1 Number of Dose Levels

In the pharmaceutical industry, most carcinogenicity studies have employed at least three dose levels in addition to the controls, but four levels have occasionally been used (Pharmaceutical Manufacturers Association (PMA), 1988). The use of three or four dose levels satisfies regulatory requirements (Speid et al., 1990) as well as scientific and practical considerations. If a carcinogenic response is observed, information on the nature of the dose–response relationship will be available. If excessive mortality occurs at the highest dose level, a valid assessment of carcinogenicity is still possible when there is adequate survival at the lower dose levels.

16.8.2 Number of Control Groups

Pharmaceutical companies have most frequently favored the use of two control groups of equal size (Pharmaceutical Manufacturers Association (PMA), 1988). A single control group of the same size as the treated groups is also used, and, less frequently, one double-sized control group may be used. The diversity of study designs reflects the breadth of opinion among toxicologists and statisticians on this issue.

Use of two control groups has the advantage of providing an estimate of the variation in tumor incidence between two groups of animals in the absence of a drug effect. If there are no significant differences between the control groups, the data can be pooled, and the analysis is identical to that using a single, double-sized group. When significant differences occur between the control groups, one must compare the data from the drug-treated groups separately with each control group.

There will be situations in which the incidence of a tumor in one or more drug-treated groups is significantly higher than that of one control group but similar to that of the other control group. In such a situation, it is often helpful to compare the tumor incidences in the control groups to appropriate historical control data. One may often conclude that, for this tumor, one of the control groups is more “typical” than the other and should, therefore, be given more weight in interpreting the differences in tumor incidence.

In spite of its current popularity in the pharmaceutical industry, the use of two control groups is opposed by some statisticians on the grounds that a significant difference between the two groups may indicate that the study was compromised by excessive, uncontrolled variation. Haseman et al. (1986), however, analyzed tumor incidence data from 18 color additives tested in rats and mice and found that the frequency of significant pairwise differences between the two concurrent control groups did not exceed that which would be expected by chance alone.

The use of one double-sized group is sometimes preferred because it may provide a better estimate of the true control tumor incidence than that provided by a smaller group. Nevertheless, more statistical power would be obtained by assigning the additional animals equally to all dose groups rather than to the control group only, if power is a primary consideration.

16.8.3 Criteria for Dose Selection

Dose selection is one of the most important activities in the design of a toxicology study. It is especially critical in carcinogenicity studies because of their long duration. Whereas faulty dose selection in an acute or subchronic toxicity study can easily be corrected by repeating the study, this situation is much less desirable in a carcinogenicity study, especially since such problems may not become evident until the last stages of the study.

The information used for dose selection usually comes from subchronic toxicity studies, but other information about the pharmacological effects of a drug and its metabolism and pharmacokinetics may also be considered. The maximum recommended human dose (MRHD) of the drug may be an additional criterion, if this is known when the carcinogenicity studies are being designed.

For most pharmaceutical companies, the doses selected are as follows. The highest dose is selected to be the estimated maximum tolerated dose (MTD). The lowest dose is usually a small multiple (1–5 times) of the MRHD, and the middose approximates the geometric mean of the other two doses (Pharmaceutical Manufacturers Association (PMA), 1988; McGregor, 2009).

The MTD is commonly estimated to be the maximum dose that can be administered for the duration of the study that will not compromise the survival of the animals by causes other than carcinogenicity. It should be defined separately for males and females. ICH (1995) states that the MTD is “that dose which is predicted to produce a minimum toxic effect over the course of the carcinogenicity study, usually predicted from the results of a 90-day study.” Factors used to define minimum toxicity include no more than a 10% decrease in body weight gain relative to controls, target organ toxicity, and/or significant alterations in clinical pathology parameters. If the MTD has been chosen appropriately, there should be no adverse effect on survival, only a modest decrement in body weight gain and minimal overt signs of toxicity. The procedures for dose selection described earlier are generally consistent with major regulatory guidelines for carcinogenicity studies (Speid et al., 1990; Food and Drug Administration (FDA), 2007¹). There are, however, exceptions to the general approach described previously. For example, for nontoxic drugs, the difference between the high and the low doses may be many orders of magnitude, if the high dose is set at the estimated MTD and the low dose is a small multiple of the clinical dose. Some guidelines request that the low dose be no less than 10% of the high dose (Speid et al., 1990). In this situation, it may be acceptable to set the high dose at 100 times the MRHD, even if the MTD is not achieved (Speid et al., 1990). Similarly, when a drug is administered in the diet, the highest concentration should not exceed 5% of the total diet, whether or not the MTD is achieved (Japanese Ministry of Health and Welfare (MHW), 1989).

Metabolism and/or pharmacokinetic data, when available, should also be considered in the dose selection process. It is desirable that a drug not be administered at such a high dose that it is excreted in a different manner than at lower doses,

¹Note that the *FDA Redbook* applies, strictly speaking, only to food additives. It is cited here because it is a well-known toxicology guideline routinely applied to animal pharmaceuticals to which humans may be exposed. The *Redbook* has recently been updated by the FDA (Food and Drug Administration, 2007).

such as the MRHD. Similarly, the high dose should not lead to the formation of metabolites other than those formed at lower (clinical) doses. If data show that a given dosage produces maximum plasma levels, administration of higher doses should be unnecessary. These considerations may be very useful when interpreting the results of the study or attempting to extrapolate the results to humans.

16.9 GROUP SIZE

The minimum number of animals assigned to each dose group in pharmaceutical carcinogenicity studies is 50 of each sex (Pharmaceutical Manufacturers Association (PMA), 1988). Most companies, however, use more than the minimum number, and some use up to 80 animals per sex per group. The most important factor in determining group size is the need to have an adequate number of animals for a valid assessment of carcinogenic activity at the end of the study. For this reason, larger group sizes are used when the drug is administered by daily gavage because this procedure may result in accidental deaths by perforation of the esophagus or aspiration into the lungs. Larger group sizes are also used when the carcinogenicity study is combined with a chronic toxicity study in the rat. In this case, serial sacrifices are performed at 6 and 12 months to evaluate potential toxic effects of the drug.

In the final analysis, the sensitivity of the bioassay for detecting carcinogens is directly related to the sample size. Use of the MTD has often been justified based on the small number of animals at risk compared to the potential human population, in spite of the difficulties inherent in extrapolating effects at high doses to those expected at much lower clinical doses. A reasonable compromise may be the use of doses lower than the MTD combined with a larger group size than the 50 per sex minimum accepted by regulatory agencies.

16.10 ROUTE OF ADMINISTRATION

In the pharmaceutical industry, the two most common routes of administration are via diet and gavage (Pharmaceutical Manufacturers Association (PMA), 1988). Some compounds are given by drinking water, topical (dermal) application, or injection, depending on the expected clinical exposure route, which is the primary criterion for determining the route of administration in carcinogenicity studies. When more than one clinical route is anticipated for a drug, the dietary route is often chosen for practical reasons.

Dietary administration is often preferred over gavage because it is far less labor intensive. Another advantage is that the MTD has rarely been overestimated in dietary studies, whereas it has often been overestimated in gavage studies, according to data from the NTP (Haseman, 1985). The dietary route is unsuitable for drugs that are unstable in rodent chow

or unpalatable. The dietary route is also disadvantaged by the fact that dosage can only be estimated based on body weight and food intake data, in contrast with gavage by which an exact dose can be given. Disadvantages of gavage testing are the likelihood of gavage-related trauma, such as puncture of the trachea or esophagus, and possible vehicle (e.g., corn oil) effects.

When doing studies by the dietary route, the drug may be administered as a constant concentration at each dose level, or the concentration may be increased as body weight increases to maintain a constant dose on a milligram per kilogram basis. The later method allows greater control of the administered dose and avoids age- and sex-related variations in the dose received, which occur with the former method. Both methods are acceptable to regulatory agencies.

16.11 STUDY DURATION

The duration of carcinogenicity studies for both rats and mice is 2 years in most pharmaceutical laboratories (Pharmaceutical Manufacturers Association (PMA), 1988). Occasionally, rat studies are extended to 30 months, while some companies terminate mouse studies at 18 months. The difference in duration between mouse and rat studies is based on the belief that rats have a longer natural life span than mice. Recent data indicate, however, that this is not the case. The most commonly used strains, the Sprague–Dawley rat and the CD-1 mouse, have approximately equal survival at 2 years, based on industry data (Pharmaceutical Manufacturers Association (PMA), 1988). The same is true for the most popular inbred strains, the F344 rat and the B6C3F1 mouse (Pharmaceutical Manufacturers Association (PMA), 1988). Data from NCI studies confirm that the 2-year survival of the B6C3F1 mouse is at least equal to, if not greater than, that of the F344 rat (Cameron et al., 1985).

16.12 SURVIVAL

As stated earlier, adequate survival is of primary importance in carcinogenicity studies because animals must be exposed to a drug for the greater part of their life span to increase the probability that late-occurring tumors can be detected. Early mortality, resulting from causes other than tumors, can jeopardize the validity of a study because dead animals cannot get tumors.

In general, the sensitivity of a carcinogenicity bioassay is increased when animals survive to the end of their natural life span, because weak carcinogens may induce late-occurring tumors. The potency of a carcinogen is often inversely related to the time-to-tumor development. By analogy, as the dose of a carcinogen is reduced, the time-to-tumor occurrence is increased (Littlefield et al., 1979; DePass et al., 1986).

Why do we not allow all animals on a carcinogenicity study to live until they die a natural death if by so doing, we could identify more drugs as carcinogens? In fact, the sensitivity of a bioassay may not be improved by allowing the animals to live out their natural life span because the incidence of spontaneous tumors tends to increase with age. Thus, depending on the tumor type, the ability of the bioassay to detect a drug-related increase in tumor incidence may actually decrease, rather than increase, with time. Therefore, the optimum duration of a carcinogenicity study is that which allows late-occurring tumors to be detected but does not allow the incidence of spontaneous tumors to become excessive.

Reduced survival in a carcinogenicity study may or may not be drug related. Sometimes, the MTD is exceeded, and increased mortality occurs at the highest dose level and occasionally at the middose level as well. This situation may not necessarily invalidate a study; in fact, the protocol may be amended to minimize the impact of the drug-induced mortality. For example, cessation of drug treatment may enhance the survival of the animals in the affected groups and allow previously initiated tumors to develop. As shown by Littlefield et al. (1979) in the CNTR ED01 study, liver tumors induced by 2-AAF, which appeared very late in the study, were shown to have been induced much earlier and not to require the continuous presence of the carcinogen to develop. By contrast, bladder tumors that occurred in the same study were dependent on the continued presence of the carcinogen.

Whether drug treatment is terminated or not, drug-related toxicity may also be managed by performing complete histopathology on animals in the lower-dose groups rather than on high-dose and control animals only. If there is no increase in tumor incidence at a lower dose level that is not compromised by reduced survival, the study may still be considered valid as an assessment of carcinogenicity.

When reduced survival is related to factors other than excessive toxicity, the number of animals at risk for tumor development may be inadequate, and the validity of the study may be compromised even in the absence of a drug effect on survival. Obviously, the adjustments described earlier for excessive drug-related toxicity are not relevant to this situation.

There is no unanimity of opinion among regulatory agencies as to the minimum survival required to produce a valid carcinogenicity study or as to the best approach for dealing with survival problems. Even within a single agency such as the FDA, different opinions exist on these issues. For example, the recently issued *FDA Redbook II Draft Guideline* requires that rats, mice, or hamsters be treated for 24 months. Early termination due to decreased survival is not recommended. The EEC guidelines differ in that they suggest termination of the study when survival in the control group reaches 20%, while Japanese guideline suggest termination at 25% survival in the control or low-dose groups (Speid et al., 1990).

These provisions make good sense in that they do not request termination of the study when drug-related mortality may be present only at the highest dose.

16.13 END POINTS MEASURED

A carcinogenicity study is more focused than a chronic toxicity study—fewer end points are evaluated, and as such it is a simpler study. The key end points are actually few:

Pathology (limited to neoplastic and preneoplastic tissue transformations)

Body weight (to ensure that toxicity is not so great as to invalidate the assays and also that it is just sufficient to validate the assay)

Survival (key to determining when to terminate the study)

Clinical pathology (limited to evaluating the morphology of white blood cells, and usually this is actually deferred until there are indications that such data is needed)

Food consumption (actually measured to ensure that dietary administration doses are accurate)

Only pathology will be considered in detail.

The primary information for carcinogenicity evaluation is generated by pathologists. Table 16.5 lists the tissues normally collected, processed, and evaluated. These professionals, like any other group of professionals, vary in their training and experience, and these are characteristics which may influence the evaluation in a number of ways. Some of these are listed as follows:

1. Differences in terminology may be important when considering controversial lesions.
2. Lack of consistency throughout a study is likely when a pathologist has only recently become involved with

TABLE 16.5 Standard Tissue List

Kidney	Urinary bladder	Aorta
Heart	Trachea	Lungs
Liver	Gallbladder	Pancreas
Fat	Salivary gland	Spleen
Cervical lymph node	Mesenteric lymph node	Thymus
Tongue	Esophagus	Stomach
Duodenum	Jejunum	Ileum
Cecum	Colon	Mammary gland
Skin	Skeletal muscle	Sciatic nerve
Parathyroid	Thyroid	Adrenal
Pituitary	Prostate	Seminal vesicles
Testes	Epididymides	Ovaries

rodent carcinogenicity. Training is often in a clinical situation (especially in Europe), where each animal or person is unique and there is in a rodent carcinogenicity study consisting of 500 animals.

3. Unfamiliarity with the observed lesion in a particular species may cause problems in interpretation.

Possible bias introduced by knowledge of treatment can be corrected in several ways, but the use of a two-stage process would seem to be most efficient:

1. An initial evaluation is performed with full knowledge of the animal's history, including treatment.
2. A second evaluation of specific lesions is then carried out. This should be done blind, either by the same pathologist or, preferably, by the same and a second pathologist.

Differences in evaluation between pathologists should always be discussed by them to resolve the differences; they may be due to subtle differences in diagnosis and do not indicate incompetence in one of the pathologists. It is unacceptable for study sponsors to shop around until they find a pathologist who gives—for whatever reason—the result the pathologist is looking for without giving an opportunity for interaction with all of the other evaluators. Sometimes these diagnoses are given years apart, during which time understanding of the pathogenesis of lesions may change, and even the first pathologist may not arrive at the same conclusion as the pathologist did some years ago.

Evaluation of the data is not purely a statistical exercise. A number of important factors should be considered: (i) dose-effect relationship, (ii) a shift toward more anaplastic tumors in organs where tumors are common, (iii) earlier appearance of tumors, and (iv) presence of preneoplastic lesions.

The language used to describe the carcinogenic response has masked its complexity and presents a stumbling block to its understanding among nonhistopathologists. Benign or malignant neoplasms do not arise without some precursor change within normal tissue. An important concept in carcinogenicity evaluation is that of neoplastic progression, which was derived from studies on skin tumors (Berenblum and Shubik, 1947) and expanded to a number of other tissues (Foulds, 1969, 1975). There is, on many occasions, a far from clear distinction between hyperplastic and “benign” neoplasias and between benign and malignant neoplasias.

Hyperplasia and benign and malignant neoplasias are convenient medical terms with prognostic significance. Hyperplasia can occur either as a regenerative response to injury, with no neoplastic connotations, or as a sustained response to a carcinogenic agent. It is an increase in the number of normal cells retaining normal intercellular relationships within a tissue. This normally may break down, resulting in altered growth patterns and altered cellular

differentiation—a condition which may be described as atypical hyperplasia or presumptively as preneoplastic lesions. Possible sequelae to hyperplasia are (i) persistence without qualitative change in either structure or behavior; (ii) permanent regression; (iii) regression, with later reappearance; and (iv) progression to develop new characteristics indicating increased probability of malignancy. The last of these is the least likely to occur in experimental multistage models, such as in mouse skin or rat liver, where large numbers of hyperplastic lesions may occur, but notably fewer carcinomas develop from them.

Benign neoplasms in most rodent tissues apparently arise in hyperplastic foci, for example, squamous cell papillomas of the skin and forestomach. Furthermore, these papillomas seldom demonstrate autonomous growth and even fewer progress to squamous cell carcinomas (Burns et al., 1976; Colburn, 1980). This decisive progression to carcinoma, when it occurs, provides powerful evidence for the multistage theory of carcinogenesis: the new, malignant cells arising as a focus within the papilloma or even in an area of hyperplasia, since the papilloma is not a necessary intermediate stage. In other organs, benign neoplasia is usually characterized by well-differentiated cell morphology, a fairly uniform growth pattern, clear demarcation from surrounding tissues, and no evidence of invasion. The progression toward malignancy involves anaplasia (loss of differentiation) and pleomorphism (variety of phenotypic characteristics within the neoplasm). These changes may be focal in an otherwise benign neoplasm and may vary in degree and extent. Evidence of invasion of the surrounding tissues or of metastasis is not an essential characteristic of malignancy, although their presence strengthens the diagnosis.

The grouping together of certain tumor types can aid statistical analysis, but it must be done carefully, with full appreciation of the biology and whatever is known of the pathogenesis of the lesions. Grouping for analysis of all animals showing neoplasia, irrespective of the tumor type, is inappropriate because the incidence in most treatment control groups can be very high and, in US NTP studies, approaches 100% in rats and 50–70% in mice (Table 16.6).

There may be similar incidences of tumors in aging people, but the real prevalence of tumors in human populations is uncertain. In the United States, where autopsies are uncommon, over one-third reveal previously undiagnosed cancers when they are conducted (Silverberg, 1984). A single type of neoplasm, renal adenoma, is present in 15–20% of all adult kidneys (Holm-Nielsen and Olson, 1988), although it is unclear whether these 2–6 mm foci of proliferating tubular and papillary epithelium represent small carcinomas or benign precursors of renal cell carcinomas. Irrespective of the significance of these lesions in human pathology, the presence of similar foci in a rodent carcinogenicity experiment would trigger the recording of renal tumor-bearing animals and, hence, their consideration in the statistical and pathological

TABLE 16.6 Tumor-Bearing Animals in Control Groups from Rodent Studies

Control Animals for 2-Year NTP Bioassay	Number of Animals	% with Tumors

evaluation processes. Evaluation is further complicated by the increased background incidences of tumors as animals get older.

The independent analysis of every different diagnosis in rodent studies would also mask significant effects in many cases while enhancing them in others. Benign and malignant neoplasms of a particular histogenesis are often grouped because the one is seen as a progression from the other. However, this grouping may result in a nonsignificant difference from the controls because there has been an acceleration of progression toward malignancy, the incidence of benign neoplasms decreasing while the malignant neoplasms increasing. Guidelines are available for “lumping” or “splitting” tumor types, but in using them, the basis for the classification of neoplastic lesions should be clarified, especially when data generated over several or many years are coupled, since diagnostic criteria and ideas regarding tumor histogenesis may have changed. Reliance on tabulated results alone can lead to serious misinterpretation by those not closely connected with a particular study. For this very important reason, the pathology and toxicology narrative should be full and clear. If it is not, then there will always be doubts about future interpretations, even if these doubts are not, in reality, justified.

16.14 TRANSGENIC MOUSE MODELS

Since the early 1970s, the standard for adequate evaluation of the carcinogenic potential of a candidate pharmaceutical has been the conduct of lifetime, high-dose assays in two species—almost always the rat and the mouse.

The relevance (and return on investment) for the bioassays performed in mice have been questioned for some time. In

1997, ICH opened the possibility for the substitution of some form of short- or medium-term mouse test as an alternative for the traditional lifetime mouse bioassay. FDA has subsequently stated that it would accept “validated” forms of a set of medium-term mouse studies based on transgenic models, and significant effort has since gone into such validation.

The huge advances made in molecular biology since the late 1980s have provided the possibility of approaches to evaluating chemicals and potential drugs for carcinogenic potential in approaches which are different and less expensive, and which take a shorter period of time than traditional long-term bioassays. This work has also been stimulated by dissatisfaction with the performance of traditional test systems.

The traditional long-term bioassays use highly inbred animals, developed with the goal of reducing the variability in background tumor incidences as a means of increasing the statistical sensitivity of the bioassays. This inbreeding has led to narrowing of the allelic pool in the strains of animals that are currently used for testing, as opposed to the wildtype populations (of humans) that the tests are intended to protect (Festing, 1979). Transgenic models should serve to improve the identification of carcinogens by providing the gene-specific mechanistic data, minimizing the influence of spontaneous tumors and strain-specific effects, and reducing time required, as well as cost and animal usage (Eastin et al., 1998).

As it has become possible to transfer new or engineered genes to the germlines of mammals, the results have been transgenic mice that can be used in shorter-term *in vivo* assays for carcinogenicity and that are also useful for research into the characterization of genotoxic events and mechanisms in carcinogenesis. By coupling reporter phenotypes (such as papillomas in the Tg.AC mouse), the task of “reading” results in test animals is made much less complex.

There are four transgenic mouse models that have been broadly evaluated—the TSPp53^{+/−}, the Tg.AC, the Hras2, and the XPA^{−/−}. Each of these has its own characteristics. Each of these merits some consideration. They are each made by either zygote injection or specific gene targeting in embryonic cells (French et al., 1999; McAnulty, 2000).

16.14.1 The Tg.AC Mouse Model

This was the earliest of the models to be developed, and its use in mouse skin carcinogenicity studies was first reported in 1990. The mice have four copies of the v-H-ras oncogene in tandem on chromosome 11, and the transgene is fused with a fetal ζ-globin gene which acts as a promoter. The transgene codes for a switch protein which is permanently “on,” and this results in the mice having genetically initiated skin. The application of tumor promoters to the surface of the skin causes the rapid induction of pedunculate papillomas

that arise from the follicular epithelium. This is despite the fact that the transgene is not expressed in the skin, although it is present in the papillomas that form, and also in the focal follicular hyperplastic areas that are the precursors to the papillomas. In about 40% of the mice, the papillomas become malignant skin tumors—mainly squamous cell carcinomas and sarcomas.

The first assessments of this model as an alternative to traditional carcinogenicity studies were performed by the US NIEHS and NTP, and the results with over 40 chemicals have been published. The majority of studies were performed by skin painting, regardless of whether the product was a dermal or systemic carcinogen. However, a good correlation was found with the known carcinogenicity of the test compounds, and both mutagenic and nonmutagenic were identified. It was found that great care had to be taken with the skin, because damage could also induce papillomas, which means that these animals cannot be identified using transponder chips. This sensitivity may also explain some of the false-positive results that have occurred with resorcinol and rotenone. Of more concern is that there have been false negatives with known carcinogens, namely, ethyl acrylate and *N*-methyl-*o*-acrylamide. The model was designed for use in the context of the two-stage model of carcinogenesis with the underlying mechanistic pathway involving specific transcription factors, hypomethylation, and cell-specific expression of the results; along with the p53, this model has seen the widest use and evaluation (in terms of number of agents evaluated) so far. The carrier mouse strain employed, the FVB/N, is not commonly employed in toxicology and is prone to sound-induced seizures. It may be that the dermal route is not suitable for all systemic carcinogens, and this is the reason that in the ILSI program, both the dermal and systemic routes are being investigated in this model.

Another problem with this model was the occurrence of a nonresponder genotype to positive control agents. This was found to be attributable to a rearrangement of the ζ -globin promoter region, but it is claimed that this problem has been resolved. However, this has considerably delayed the ILSI studies with this model, but all data should be available in time for the November meeting. It is already clear that the model gives a robust response to the positive control agent, 12-*o*-tetradecanoylphorbol-13-acetate (TPA).

16.14.2 The Tg.rasH2 Mouse Model

This model was developed at CIEA in Japan, and the first information about the mouse was published in 1990. The mice have five or six copies of the human H-ras protooncogene inserted in tandem into their genome surrounded by their own promoter and enhancer regions. This transgene has been very stable, with no loss of responsiveness since the model was developed. The transgene codes for a molecular

switch protein in the same way as the previous model, but the transgene is expressed in all organs and tissues. Thus, the response end point is not primarily dermal.

The initial studies with this model revealed a rapid appearance of forestomach papillomas with *N*-methyl-*N*-nitrosourea (MNU), and this compound has already been used as the positive control agent in subsequent studies with this strain. A study duration of 6 months is sufficient to obtain a positive response, and longer periods should be avoided because the mice start to develop various spontaneous tumors, such as splenic hemangiosarcomas, forestomach and skin papillomas, lung and Harderian gland adenocarcinomas, and lymphomas. It has a high level of constitutive expression and some spontaneous tumors even when the animals are younger. It is, however, very responsive to carcinogens—one gets a rapid onset after exposure and a higher response incidence than with the other models. The underlying mechanism is still not certain.

A large number of studies have been run in this strain in Japan in advance of the ILSI program. The model is sensitive to both mutagenic and nonmutagenic carcinogens, although cyclophosphamide and furfural have given equivocal results in each category, respectively. The majority of noncarcinogens have also been identified correctly, although again, there are a small number of compounds that have given equivocal results. In the ILSI program, all of the studies were completed by the end of 2001. This is the favored transgenic model currently.

16.14.3 The P53^{+/-} Mouse Model

The TSP p53^{+/-} (hereafter referred to as the p53—the designation of the tumor suppressor gene involved) is a heterozygous knockout with (up to seven or so months of age) a low spontaneous tumor incidence. It is responsive to the genotoxic carcinogens by a mechanism based on the fact that many (but not all) tumors show a loss of the wild-type allele. The p53 has been extensively worked on by Tennant's group at NIEHS (Tennant et al., 1995, 1999). This model was developed in the United States and carries a hemizygous knockout of the p53 gene which was developed by integrating a mutated copy of the gene into the genome of mice. The p53 gene is known as a tumor suppressor gene, and it is the most commonly mutated gene in human malignancies. It searches for a protein transcription factor which activates multiple genes when damage to DNA strands occurs, and this in turn leads to either the arrest of the cell cycle while DNA repair occurs or to apoptosis (programmed cell death), which removes the damaged cell. The heterozygote is used because homozygotes show a very high incidence of spontaneous tumors within a few months of birth. The heterozygotes have a low background incidence of tumors up to 12 months, but during this time there is a high chance of

a second mutagenic event occurring—following exposure to a carcinogen, for example—and this would result in a loss of suppressor function or an increase in transforming activity.

The initial studies with this model as an alternative in traditional carcinogenicity testing were performed at the US NIEHS, and these suggested that it was sensitive to mutagenic carcinogens such as benzene and *p*-cresidine within 6 months. Nonmutagenic carcinogens were negative in the assay, as were mutagenic noncarcinogens. However, subsequent studies and some parts of the ILSI program have shown clear indications that a 6-month duration may be insufficient. In particular, benzene has given negative or equivocal results within 6 months, although positive results have been obtained by extending the study to 9 months. It will be very important to assess the results of the ILSI program when deciding the best study duration for this model. This is the most popular model in the United States.

16.14.4 The XPA^{-/-} Mouse Model

This was the last of the models to be developed and was created using a knockout technique after the XPA gene had been cloned. The first data were published by RIVM in the Netherlands in 1995. Both alleles of the XPA gene have been inactivated by a homologous recombination in ES cells, resulting in a homozygous deletion of the gene spanning exons three and four. The protein coded by this gene is essential for the detection and repair of DNA damage, using the NER pathway. This model only has between 2% and 5% of residual NER activity.

The initial studies at RIVM demonstrated that exposure of these mice to IV-B radiation or 7,12-dimethylbenz[*a*] anthracene resulted in the rapid induction of skin tumors. It was also shown that various internal tumors could be induced following oral administration of mutagenic carcinogens such as benzo[*a*]pyrene (B[*a*]P) and 2-acetylaminofluorene (2-AAF). The early studies suggested that this response could occur within six months, but further experience has indicated that a 9-month treatment period is essential in order to obtain a response with positive control agents such as B[*a*]P, 2-AAF, and *p*-cresidine.

All of the 13 studies that have been undertaken with this model were available for review at the November 2000 meeting. The model is sensitive to both UV and genotoxic carcinogens and the same nonmutagenic carcinogens, such as DES, Wy-16643 and cyclosporin A. There have been no false positives with noncarcinogens. Some laboratories have also investigated a double transgenic XPA^{-/-} p53^{+/-} model, and this seems to increase the sensitivity of the assay. For example, in a DES study, seven animals with metastasizing osteosarcomas were found in the double transgenic group, compared with one in the XPA group and none among the wild-type animals.

There remains concern (as with any new model) that these models may be overly sensitive or (put another way) that the relevance of positive findings to risk in humans may not be clear. The results of the ILSI/HESI workshop seem to minimize these concerns.

It is generally proposed that while such models can improve the identification of carcinogens in three ways (providing gene-specific mechanistic data, minimizing the influence of spontaneous tumors and strain-specific effects, and reducing the time, cost, and animal usage involved), they have two potential uses in pharmaceutical development. These are either in lieu of the mouse 2-year cancer bio-assay or in sub-chronic toxicity assessments prior to making a decision to commit to a pair of 2-year carcinogenicity bioassays.

As performance data has become available on these strains, ICH (1997) has incorporated their use into pharmaceutical testing guidelines in lieu of the second rodent species tests (i.e., to replace the long-term mouse bioassay when the traditional rat study has been performed). The FDA has stated that they would accept such studies when “performed in a validated code.” In fact, CBER has accepted such studies as a sole carcinogenicity bioassay in some cases where there were negative traditional genotoxicity data and strong evidence of a lack of a mechanistic basis for concern.

A joint ILSI and HESI validation program has been completed, looking at the results of the four prime candidate models in identifying carcinogens as compared to the results of traditional long-term rodent bioassays. This validation program involved 51 different laboratories and imposed protocol standards to allow comparison of results. Three dose levels were studied per chemical, with 15 males and 15 females being used for each dose group. A vehicle and high-dose control in wild-type animals was also included, with information from NTP bioassays and 4-week range-finding assays being used to help set doses. Animals were dosed for 26 weeks. The issues in and coming out of these validation programs bear consideration (Tennant et al., 1999):

- Is the proper comparator data for evaluating performance human or rodent bioassay data? It should be kept in mind that there are sets of rodent bioassay data (particularly those involving liver tumors in mice) that are widely accepted as irrelevant in the prediction of human risk.
- How will the data from these assays be incorporated into any weight-of-evidence (WOE) approach to assessing human health risk?
- What additional mechanistic research needs to be undertaken to improve our understanding of the proper incorporation and best use of the data from these assays?
- How can the results of current validation efforts be best utilized in the timely evaluation of the next generation of assays?

- Given that, at least under some conditions, assays using these models tend to “blow up” (have high spontaneous tumor rates) once the animals are more than 8 or 9 months of age, how critical are age and other not currently apprehended factors to optimizing both sensitivity and specificity?
- How wide and unconditional will FDA (and other regulatory bodies) acceptance be of these models in lieu of the traditional 2-year mouse bioassay?

16.15 INTERPRETATION OF RESULTS: CRITERIA FOR A POSITIVE RESULT

There are three generally accepted criteria for a positive result in a carcinogenicity study. The first two are derived directly from the results of the statistical analysis: (i) a statistically significant increase in the incidence of a common tumor and (ii) a statistically significant reduction in the time-to-tumor development. The third criterion is the occurrence of very rare tumors, that is, those not normally seen in control animals, even if the incidence is not statistically significant. Table 16.7 presents an evaluation matrix for these factors.

16.16 STATISTICAL ANALYSIS

Irrespective of the specific protocols used, all carcinogenicity studies end with a statistical comparison of tumor proportions between treated and control groups. This analysis is

necessary because the control incidence of most tumor types is rarely zero. In the unlikely case that a type of tumor is found in treated animals but not in concurrent or appropriate historical controls, it is reasonable to conclude that the tumor is drug related without statistical analysis.

Most pharmaceutical companies analyze tumor data using mortality-adjusted methods (Pharmaceutical Manufacturers Association (PMA), 1988). Peto/IARC methodology is most commonly used, perhaps because this method is currently favored by the FDA (Peto et al., 1980). The use of life-table methods is most appropriate for “lethal” tumors, that is, those that cause the death of the animals. Various statistical methods are available for analyzing the incidence of the lethal and nonlethal tumors (e.g., Gart et al., 1979, 1986; Chu et al., 1981; Dinse and Lagakos, 1983; McKnight, 1988; Portier and Bailer, 1989; Gaylor and Kodell, 2001). These methods are especially useful when there are drug-related differences in mortality rates. When there is no drug effect on survival, unadjusted methods will generally give the same results.

As a general approach, most pharmaceutical statisticians begin by testing for the presence of a dose-related trend in tumor proportions. If the trend test is significant, that is, the *p* value is less than or equal to 0.05, pairwise comparisons are performed between the treated and control groups. Trend and pairwise analyses may be adjusted for mortality as stated earlier or performed without mortality adjustment using such simple methods as chi-square or Fisher’s exact tests.

Although in most cases the use of trend tests is appropriate since most biological responses are dose related, there are

TABLE 16.7 Interpretation of the Analysis of Tumor Incidence and Survival Analysis (Life Table)

Outcome Type	Tumor Association with Treatment	Mortality Association with Treatment	Interpretation
A	–	+	Unadjusted test ^a may underestimate tumorigenicity of treatment
B	+	+	Unadjusted test gives valid picture of tumorigenicity of treatment
C	+	–	Tumors found in treated groups may reflect longer survival of treated groups. Time-adjusted analysis is indicated
D	–	+	Apparent negative findings on tumors may be due to the shorter survival in treated groups. Time-adjusted analysis and/or a retest at lower doses is indicated
E	–	0	Unadjusted test gives a valid picture of the possible tumor-preventive capacity of the treatment
F	–	–	Unadjusted test may underestimate the possible tumor-preventive capacity of the treatment
G	0	+	High mortality in treated groups may lead to unadjusted test missing a possible tumorigen. Adjusted analysis and/or retest at lower doses is indicated
H	0	0	Unadjusted test gives a valid picture of lack of association with treatment
I	0	–	Longer survival in treated groups may mask tumor-preventive capacity of treatment

+ = Yes, – = no, and 0 = no bearing on discussion.

^aThe unadjusted test referred to here is a contingency table type of analysis of incidence, such as Fisher’s exact test.

exceptions to this rule. Certain drugs, especially those with hormonal activity, may not produce classical dose responses and may even induce inverse dose–response phenomena. In these cases, a pairwise comparison may be appropriate in the absence of a significant positive trend.

Most (70%) pharmaceutical companies use one-tailed comparisons, and a substantial number use two-tailed methods (Pharmaceutical Manufacturers Association (PMA), 1988). Since regulatory agencies are primarily interested in identifying carcinogenic drugs, as opposed to those that inhibit carcinogenesis, the use of one-tailed tests is generally considered more appropriate. Some companies prefer two-tailed comparisons because, in the absence of a true carcinogenic effect, there is an equal probability of seeing significant decreases as well as significant increases by chance alone.

One of the most important statistical issues in the analysis of carcinogenicity data is the frequency of “false positives,” or type I errors. Because of the multiplicity of tumor sites examined and the number of tests employed, there is concern that noncarcinogenic drugs may be erroneously declared carcinogens. If a $p < 0.05$ increase in tumor incidence is automatically regarded as a biologically meaningful result, then the false-positive rate may be as high as 47–50% (Haseman et al., 1986).

Several statistical procedures designed to correct for the multiplicity of significance tests have been published (and reviewed by Haseman (1990)). One approach to the problem of multiple tumor site/type testing is a procedure attributed to Tukey by Mantel (1980). This method is used to adjust a calculated p value based on the number of tumor types/sites for which there are a minimum number of tumors in the particular study. The reasoning here is that, for tumor sites, the number of tumors found is so small that it is impossible to obtain a significant result for that tumor site no matter how the tumors might have been distributed among the dose groups. Only those sites for which a minimum number of tumors are present can contribute to the false-positive rate for a particular study.

A method proposed by Schweder and Spjotvoll (1982) is based on a plot of the cumulative distribution of observed p values. Farrar and Crump (1988) have published a statistical procedure designed not only to control the probability of false-positive findings but also to combine the probabilities of a carcinogenic effect across tumor sites, sexes, and species.

Another approach to controlling the false-positive rate in carcinogenicity studies was proposed by Haseman (1983). Under this “rule,” a compound would be declared a carcinogen if it produced an increase significant at the 1% level in a common tumor or an increase significant at the 5% level in a rear tumor. A rare neoplasm was defined as a neoplasm that occurred with a frequency of less than 1% in control animals.

The overall false-positive rate associated with this decision rule was found to be not more than 7–8%, based on control tumor incidences from NTP studies in rats and mice. This false-positive rate compares favorably with the expected rate of 5%, which is the probability at which one would erroneously conclude that a compound was a carcinogen. The method is notable for its simplicity and deserves serious consideration by pharmaceutical statisticians and toxicologists. Without resorting to sophisticated mathematics, this method recognizes the fact that tumors differ in their spontaneous frequencies and, therefore, in their contribution to the overall false-positive rates in the carcinogenicity studies. False-positive results are much less likely to occur at tissue sites with low spontaneous tumor incidences than at those with high frequencies.

As a final point that has special relevance to pharmaceutical carcinogenicity studies, one may question whether the corrections for multiple comparisons and their effect on the overall false-positive rate are appropriate for all tumor types. For example, if a compound is known to bind to receptors and produce pharmacological effects in a certain organ, is it justified to arbitrarily correct the calculated p value for the incidence of tumors in that organ, using the methods described previously? It is difficult to justify such a correction considering that the basis for correcting the calculated p value is that the true probability of observing an increased incidence of tumors at any site by chance alone may be much higher than the nominal alpha level (usually 0.05). It is reasonable to expect that when a drug has known pharmacological effects on a given organ, the probability of observing an increased tumor incidence in that organ by chance alone is unlikely to be higher than the nominal 5% alpha level.

Although most pharmaceutical statisticians and toxicologists agree on the need to control the probability of false-positive results, there is no consensus as to which method is most appropriate or most acceptable to regulatory agencies. The FDA and other such agencies will accept a variety of statistical procedures but will often reanalyze the data and draw their own conclusions based on their analyses.

The actual statistical techniques used to evaluate the results of carcinogenicity bioassays basically utilize four sets of techniques, three of which have been presented earlier in this book. These methods are as follows:

1. Exact tests
2. Trend tests
3. Life tables (such as log-rank techniques)
4. Peto analysis

These are then integrated into the decision-making schemes discussed earlier in this chapter. The methods themselves and alternatives are discussed elsewhere in detail (Chow and Liu, 1998; Gad, 2005).

16.16.1 Exact Tests

The basic forms of these (the Fisher exact test and chisquare) have previously been presented, and the reader should review these. Carcinogenicity assays are, of course, conducted at doses that are at least near those that will compromise mortality. As a consequence, one generally encounters competing toxicity producing differential mortality during such a study. Also, often, particularly with certain agricultural chemicals, latency of spontaneous tumors in rodents may shorten as a confounded effect of treatment with toxicity. Because of such happenings, simple tests on proportions, such as χ^2 and Fisher–Irwin exact tests on contingency tables, may not produce optimal evaluation of the incidence data. In many cases however, statisticians still use some of these tests as methods of preliminary evaluation. These are unadjusted methods without regard for the mortality patterns in a study. Failure to take into account mortality patterns in a study sometimes causes serious flaws in interpretation of the results. The numbers at risk are generally the numbers of animals histopathologically examined for specific tissues.

Some gross adjustments on the numbers at risk can be made by eliminating early deaths or sacrifices by justifying that those animals were not at risk to have developed the particular tumor in question. Unless there is dramatic change in tumor prevalence distribution over time, the gross adjusted method provides fairly reliable evidence of treatment effect, at least for nonpalpable tissue masses.

16.16.2 Trend Tests

Basic forms of the trend tests (such as that of Tarone) have previously been presented in this text.

Group comparison tests for proportions notoriously lack power. Trend tests, because of their use of prior information (dose levels), are much more powerful. Also, it is generally believed that the nature of true carcinogenicity (or toxicity for that matter) manifests itself as dose–response. Because of the previous facts, evaluation of trend takes precedence over group comparisons. In order to achieve optimal test statistics, many people use ordinal dose levels (0, 1, 2, . . .) instead of the true arithmetic dose levels to test for trend. However, such a decision should be made a priori. The example in Table 16.8 demonstrates the weakness of homogeneity tests.

As is evident from this example, often group comparison tests will fail to identify significant treatment while trend test will. Same arguments apply to survival-adjusted tests on proportions as well. In an experiment with more than one dose group ($K > 1$), the most convincing evidence for carcinogenicity is given by tumor incidence rates that increase with increasing dose. A test designed specifically to detect such dose-related trends is Tarone’s (1975) trend test.

TABLE 16.8 Trend versus Heterogeneity

Number at Risk	Number with Tumor	Dose Level
50	2	0
50	4	1
50	6	2
50	7	3

Cochran–Armitage Test for Trend

	Calculated Chi-Square Subgroup	DF	Alpha	2-Tail p
Trend	3.3446	1	0.0500	0.0674
Departure	0.0694	2	0.0500	0.9659
Homogeneity	3.4161	3	0.0500	0.3321

One-Tail Tests for Trend

Type	Probability
Uncorrected	0.0337 ^a
Continuity corrected	0.0426 ^a
Exact	0.0423 ^a

Multiple Pairwise Group Comparisons by Fisher–Irwin Exact Test

Groups Compared	Alpha	One-Tail Probability
1 versus 2	0.0500	0.33887
2 versus 3	0.0500	0.13433
1 versus 4	0.0500	0.07975

^a Direction = +.

Letting $\mathbf{d} = (O, d_1, d_2, \dots, d_k)^T$ be the vector of dose levels in all $K + 1$ groups and letting $(\mathbf{O} - \mathbf{E}) = (O_0 - E_0, \dots, O_k - E_k)^T$

and $\mathbf{V} = \begin{pmatrix} V_{00} & \dots & V_{0K} \\ \vdots & & \vdots \\ V_{K0} & \dots & V_{KK} \end{pmatrix}$ contain elements as described in the

previous section but for all $K + 1$ groups, the trend statistic is

$$\text{given by } \chi^2_T = \frac{[d^T (\mathbf{O} - \mathbf{E})]^2}{d^T \mathbf{V} d}.$$

The statistic χ^2_T will be large when there is evidence of a dose-related increase or decrease in the tumor incidence rates and small when there is little difference in the tumor incidence between groups or when group differences are not dose related. Under the null hypothesis of no differences between

groups, χ^2_T has approximately a chi-squared distribution with one degree of freedom.

Tarone's trend test is most powerful at detecting dose-related trends when tumor onset hazard functions are proportional to each other. For more power against other dose-related group differences, weighted versions of the statistic are also available; see Breslow (1984) or Crowley and Breslow (1984) for details.

These tests are based on the generalized logistic function (Cox, 1972). Specifically, one can use Cochran–Armitage test (or its parallel, Mantel–Haenszel version) for monotonic trend as heterogeneity test.

16.16.3 Life Table and Survival Analysis

These methods are essential when there is any significant degree of mortality in a bioassay. They seek to adjust for the differences in periods of risk individual animals undergo. Life-table techniques can be used for those data where there are observable or palpable tumors. Specifically, one should use Kaplan–Meier product limit estimates from censored data graphically, Cox–Tarone binary regression (log-rank test), and Gehan–Breslow modification of Kruskal–Wallis tests (Thomas et al., 1977) on censored data.

The Kaplan–Meier estimates produce a step function for each group and are plotted over the lifetime of the animals. Planned, accidentally killed, and lost animals are censored. Moribund deaths are considered to be treatment related. A graphical representation of Kaplan–Meier estimates provides an excellent interpretation of survival-adjusted data except in the cases where the curves cross between two or more groups. When the curves cross and change direction, no meaningful interpretation of the data can be made by any statistical method because proportional odds characteristic is totally lost over time. This would be a rare case where treatment initially produces more tumor or death and then, due to repair or other mechanisms, becomes beneficial.

In Cox–Tarone binary regression (Tarone, 1975; Thomas et al., 1977), censored survival and tumor incidence data are expressed in a logistic model in dose over time. The log-rank test (Peto, 1974), tests based on the Weibull distribution, and Mantel–Haenszel (Mantel and Haenszel, 1952) test are very similar to this test when there are no covariates or stratifying variables in the design. The logistic regression-based Cox–Tarone test is preferable because one can easily incorporate covariates and stratifying variables which one cannot in the IARC methods.

The Gehan–Breslow modification of the Kruskal–Wallis test is a nonparametric test on censored observations. It assigns more weight to early incidences compared to the Cox–Tarone test.

For survival-adjusted tests on proportions, as mentioned earlier, in the case of survival-adjusted analyses, instead of having a single $2 \times k$ table, one has a series of such $2 \times k$ tables across the entire lifetime of the study. The numbers at risk for

such analyses will depend on the type of tumor one is dealing with. These are shown as follows:

1. Palpable or lethal tumors: Number at risk at time t = number of animals surviving at the end of time $t - 1$.
2. Incidental tumors: The number at risk at time t = number of animals that either died or sacrificed whose particular tissue was examined histopathologically.

The methods of analyzing the incidences, once the appropriate numbers at risk are assigned for these tumors, are rather similar, either binary regression based or by pooling evidence from individual tables (Gart et al., 1986).

16.16.4 Peto Analysis

The Peto method of analysis of bioassay tumor data is based on careful classification of tumors into five different categories, as defined by IARC:

1. Definitely incidental
2. Probably incidental
3. Probably lethal
4. Definitely lethal

Comment Combine (1) and (2)

Comment These categories may be combined into one (otherwise it requires a careful cause of death determination).

5. Mortality independent (such as mammary, skin, and other observable or superficial tumors)

16.16.4.1 Interval Selection for Occult (Internal Organ) Tumors

1. FDA: 0–50, 51–80, 81–104 weeks, interim sacrifice, terminal sacrifice
2. NTP: 0–52, 53–78, 79–92, 93–104 weeks, interim sacrifice, terminal sacrifice
3. IARC: *Ad hoc* selection method (Peto et al., 1980)

Comment Any of the above may be used. Problems with IARC selection method include two sexes and two or more strains will have different intervals for the same compound. Different interval selection methods will produce different statistical significance levels. This may produce bias and requires an isotonic tumor prevalence for ready analysis.

16.16.4.2 Logistic Regression Method for Occult (Internal Organ) Tumors (Dinse, 1985) Tumor prevalence is modeled as logistic function of dose and polynomial in age.

Comment Logistic tumor prevalence method is unbiased. It requires maximum likelihood estimation and allows for covariates and stratifying variables. It may be time-consuming and have convergence problem with sparse tables (low tumor incidences) and clustering of tumors.

16.16.5 Methods to Be Avoided

The following methods and practices should be avoided in evaluation of carcinogenicity:

1. Use of only the animals surviving after 1 year in the study.
2. Use of a two-strata approach: Separate analyses for animals killed during the first year of the study and the ones thereafter.
3. Exclusion of all animals in the study that died on test and analyze only the animals that are sacrificed at the end of the study.
4. Exclusion of interim sacrifice animals from statistical analyses.
5. Evaluation of number of tumors of all sites as opposed to the number of animals with tumors for specific sites of specific organs.

Another issue is subjectivity in slide reading by most pathologists who do not want to read them in a coded fashion whereby they will not know the dose group an animal is coming from. This is not under statisticians' control, but they should be aware of that in any case.

Often a chemical being tested is both toxic and potentially carcinogenic. When competing toxicity causes extreme differences in mortality or there is clustering effect in tumor prevalence in a very short interval of time, none of the adjusted methods works. One then must use biological intuition to evaluate the tumor data.

Use of historical control incidence data for statistical evaluation is controversial. There are too many sources of variation in these data. For example, different pathologists use different criteria for categorizing tumors (in fact, the same pathologist may change opinion over time); there is laboratory-to-laboratory variation; there may be genetic drift over time; location of suppliers may make a difference; and finally, these data are not part of the randomized concurrent control. Regulatory agencies and pathologists generally use these data for qualitative evaluation. My personal view is that is where they belong.

16.16.6 Use of Historical Controls

When the study is over, the data analyzed, and the *p* values corrected, as appropriate, one may find that one or more tumor types increased in drug-treated groups relative to

concurrent controls. Although the FDA and other regulatory agencies play down the importance of historical control data, it is common practice in the pharmaceutical industry to use historical data in the interpretation of tumor findings. The first and most appropriate comparison of a treated group is with concurrent control group(s), but it is of interest to see how tumor incidences in the treated groups compare with the historical incidence, and such a comparison is an accepted practice in toxicology and biostatistics (Gart et al., 1979; Hajian, 1983; Haseman et al., 1984b). A treated group may have a tumor incidence significantly higher than that of the concurrent control group(s), but comparable to or lower than the historical incidence. Occasionally, a small number of tumors may be found in a treated group, and the incidence may be significant because of the absence of this tumor in the concurrent controls. Review of appropriate historical control data may reveal that the low tumor incidence in the treated group is within the "expected" range for this tumor.

The role of historical control data in interpreting carcinogenicity findings depends on the "quality" of the historical data. Ideally, the data should be derived from animals of the same age, sex, strain, and supplier and housed in the same facility, and the pathology examinations should have been performed by the same pathologist or using the same pathological criteria for diagnosis. Since genetic drift occurs even in animals of a given strain and supplier, recent data are more useful than older data. The value of historical control data is directly proportional to the extent to which these conditions are fulfilled.

Although methods are available for including historical control data in the formal statistical analysis (Tarone, 1982; Dempster et al., 1983), this is usually not done and for good reason. The heterogeneity of historical data requires that they be used qualitatively and selectively to aid in the final interpretation of the data, after completion of the formal statistical analysis. Table 16.9 presents a summary of background tumor incidences for the most commonly employed rodent strains.

16.16.7 Relevance to Humans

After statistical analyses have been performed and historical data consulted, the final interpretation may be that a drug appears to cause tumors at one or more tissue sites in the mouse or the rat. But what does this mean for the species to which the drug will be administered, namely, the human? Extrapolation of rodent carcinogenicity data to humans remains one of the greatest challenges of modern toxicology. There is no simple formula, and each case must be evaluated on its own merits. Very generally speaking, the FDA and other major regulatory agencies consider compounds that are tumorigenic in one or more animal species to be "suspect" tumorigens in humans. The actual impact of this conclusion on the approval of a drug depends on the target population and the indication. For example, even a suspicion

TABLE 16.9 Comparative Percent Incidence of Pertinent Neoplasia in Different Strains of Rats and Mice (104 Weeks Old)

of carcinogenic activity may be fatal for a potential contraceptive drug intended for use in a very large population of healthy people. By contrast, clear evidence of carcinogenic activity may be overlooked in a drug being considered for use in a restricted population with a life-threatening disease.

Regardless of the target population and indication, the FDA and other agencies have, in recent years, attempted to consider the mechanism of tumor induction in rodents and its relevance for humans. If a drug is known to cause tumors in a rodent via a mechanism that does not exist in humans, the importance of the tumor findings may be markedly reduced. For example, drugs that cause tumors by a secondary hormonal mechanism shown to be inapplicable to humans may

be given special consideration. It is the sponsor’s responsibility to provide pertinent data on the mechanism of tumor induction and its relevance, or irrelevance, for humans. If the sponsor can show that an apparently drug-related tumor is species specific, the importance of the tumor in the overall evaluation of the drug will be greatly minimized. Table 16.10 presents a list of neoplastic/tumorigenic responses seen in rodents which have limited relevance to human safety. Part of the consideration must also be recognition of the main characteristics of nongenotoxic carcinogens. These are recognized to be dose-dependent responses with operative thresholds. The major characteristics are (Spindler et al., 2000) as follows:

TABLE 16.10 Examples of Neoplastic Effects in Rodents with Limited Significance for Human Safety

Neoplastic Effect	Pathogenesis (Agents)
Renal tubular neoplasia in male rats	$\alpha_2\mu$ -Globulin nephropathy/hydrocarbons (<i>d</i> -limonene, <i>p</i> -dichlorobenzene)
Hepatocellular neoplasia in rats and mice	Peroxisome proliferation (clofibrate, phthalate esters, phenoxy agents) Phenobarbital-like promotion
Urinary bladder neoplasia in rats	Crystalluria, carbonic anhydrase inhibition, urine pH extremes, melamine, saccharine, carbonic anhydrase inhibitors, dietary phosphates
Hepatocellular neoplasia in mice	Enzymatic-metabolic activation (in part unknown)/phenobarbital-like promotion
Thyroid follicular cell neoplasia in rats	Hepatic enzyme induction, thyroid enzyme inhibition/oxazepam, amobarbital, sulfonamides, thioureas
Gastric neuroendocrine cell neoplasia mainly in rats	Gastric secretory suppression, gastric atrophy induction (cimetidine, omeprazole, butachlor)
Adenohypophysis neoplasia in rats	Feedback interference/neuroleptics (dopamine inhibitors)
Mammary gland neoplasia in female rats	Feedback interference/neuroleptics, antiemetics, antihypertensives (calcium channel blockers), serotonin agonists, anticholinergics, exogenous estrogens
Pancreatic islet cell neoplasia in rats	Feedback interference/neuroleptics
Harderian gland neoplasia in mice	Feedback interference/misoprostol (PGE ₁), nalidixic acid, aniline dyes
Adrenal medullary neoplasia in rats	Feedback interference (lactose, sugar alcohols)
Forestomach neoplasia in rats and mice	Stimulation of proliferation/butylated hydroxyanisole, phthalate esters, propionic acid
Lymphomas in mice	Immunosuppression/cyclosporin
Mononuclear cell leukemia in rats (mainly F344)	Immunosuppression (in part unknown)/furan, iodinated glycerol
Splenic sarcomas in rats	Methemoglobinemia (in part unknown)/dapson
Osteomas in mice	Feedback interference/lactose, sugar alcohols, H ₂ antagonists, carbamazepine, vidarabine, isradipine, dopaminergics, finasteride
Leydig cell testicular neoplasia in mice	Feedback interference (proestrogens, finasteride, methoxychlor, cadmium)
Endometrial neoplasia in rats	Feedback interference (proestrogens, dopamine agonists)
Uterine leiomyoma in mice	Feedback interference (β -antagonists)
Mesovarial leiomyoma in rats (occasionally in mice)	Feedback interference (β_2 -agonists)
Ovarian tubulostromal neoplasia in mice	Feedback interference (cytotoxic agents, nitrofurantoin)

- Specificity (of species, sex, and organ).
- A threshold is operative and must be exceeded for cell proliferation and tumor development to occur.
- There is a stepwise dose–response curve/relationship between exposure, cell proliferation, and tumor development.
- The response is reversible with a cessation of dosing unless a point of no return has been passed.

Regulatory agencies are very aware of these challenges and deserve credit for attempting to respond to changes in the state of knowledge while still discharging their responsibility to protect the public health. For example, the latest version of the Japanese guidelines (Speid et al., 1990) acknowledges that the highest dose in a carcinogenicity study may be set at 100 times the clinical dose, instead of requiring that the MTD be achieved. It is also noteworthy that the FDA Center for Drug Evaluation established the Carcinogenicity Assessment Committee (CAC) representing all drug review divisions. This group advises all the divisions on issues related to carcinogenicity and reviews and advises on proposed drug carcinogenicity testing programs, protocols, and test doses.

16.17 WEIGHT-OF-EVIDENCE FACTORS FOR CONSIDERATION IN A CARCINOGENICITY ASSESSMENT DOCUMENT (CAD)

Each of the factors listed in the following should be considered in formulating a prediction in the outcome and value of conducting a 2-year rat carcinogenicity study and an overall integrated assessment of the carcinogenic risk for humans. Some factors can be appropriate for both, other more appropriate for one or the other purpose. This guidance can be used as a guide by sponsors for writing a CAD:

- Knowledge of intended drug target and pathway pharmacology, secondary pharmacology, and drug target distribution in rats and humans Target- and pathway-related mechanistic/pharmacologic and understood secondary pharmacologic characteristics can contribute to the prediction of outcomes of carcinogenicity studies and can improve prediction of potential human carcinogens. The CAD is expected to convey a thorough and critical assessment of the sponsor’s knowledge of all such characteristics including a comprehensive literature review specifically addressing carcinogenicity

risk. Examples of such data sources include the following:

- Prior experience with other molecules in the drug class
- Experience with human genetic polymorphisms in the target or pathway
- Clinical trial data
- Genetically engineered rodent models
- Animal disease models
- Unintended pharmacology
- Hormonal perturbation
- Targeted tissue genomic biomarker measurements
- Genetic toxicology study results

The criteria in ICH S2(R1) will be used to evaluate genetic toxicology data using a WOE approach.

- *Histopathologic evaluation of repeat-dose rat toxicology studies*

Histopathologic risk factors of neoplasia should be evaluated in the 6-month chronic rat study. Findings seen only in shorter-term repeat-dose rat toxicity studies are generally considered of less value for 2-year rat study outcome prediction but should be addressed. Histopathologic findings of particular interest include cellular hypertrophy, diffuse and/or focal cellular hyperplasia, persistent tissue injury and/or chronic inflammation, preneoplastic changes, and tumors. It is important to address the human relevance of such findings. For example, liver tumors are observed at relatively high frequency in the rat, sometimes with Leydig cell and thyroid follicular cell tumors. Hepatocellular hypertrophy associated with increased liver weight often results from hepatic enzyme induction, the latter being a well-understood mechanism of rodent specific tumorigenesis at these sites with little relevance to humans (McClain, 1989; Cook et al., 1999). The CAD should review the data supporting such mechanisms in assessing the risk for humans.

- *Exposure margins in chronic rat toxicology studies*

A high exposure margin in a chronic rat toxicology study absent of any carcinogenic risk factors can provide additional support for a carcinogenicity study waiver. Additionally, risk factors for neoplasia occurring only at high multiples of anticipated human exposure may provide additional support for considering a carcinogenicity study waiver. The inability to achieve high exposure margins in a chronic rat toxicology study due to limitations of tolerability, pharmacology, or absorption would not preclude a rat carcinogenicity study waiver.

- *Metabolic profile*

As per ICH S1C(R2), a comparison of the metabolic profile between rats and humans should also be taken into account when assessing the potential carcinogenicity of small molecules. Therefore, the adequacy of

the metabolic profile in rats and exposure to human metabolites should also be discussed in the CAD.

- *Evidence of hormonal perturbation*

Evidence of hormonal perturbation should be considered from both repeat-dose and reproductive toxicology studies. Such evidence can come from weight, gross, and/or microscopic changes in endocrine organs or parameters from reproductive toxicology studies. Serum hormone levels can be useful to address findings but are not always essential.

- *Immunosuppression*

Immunosuppression can be a causative factor for tumorigenesis in humans. Effects on the immune system can alter tumor surveillance or result in tumors secondary to recrudescence of oncogenic viruses. As such, an assessment of potential impact to the immune system should be evaluated according to the ICH S8 guideline and factored into the CAD.

- *Special studies and end points*

Data from special stains, new biomarkers, emerging technologies, and alternative test systems can be submitted with scientific rationale to help explain or predict animal and/or human carcinogenic pathways and mechanisms when they would contribute meaningfully.

- *Results of nonrodent chronic study*

Assessment of carcinogenic risk factors in the nonrodent toxicology studies should be considered for human risk assessment regardless of results in the chronic rat study.

- *Transgenic mouse study*

A transgenic mouse carcinogenicity study (usually raH2 or p53^{+/-} mouse) is not required for the WOE argument. However, if conducted on a case-by-case basis, a transgenic mouse carcinogenicity study can contribute to the WOE.

- ICH S1B(R1) has changed the potential pathway to either a waived program or reduced program. Currently FDA's response is more common to make carcinogenicity studies (rat traditional and a transgenic mouse) a post approval requirement.

16.18 CONCLUSIONS

The design, conduct, and interpretation of carcinogenicity studies are the major challenges for the pharmaceutical toxicologist, pathologist, biostatistician, and regulator. This is a rapidly changing field generating more questions than answers. The largest question continues to be the extrapolation of rodent data to humans, especially when data on mechanisms of tumor induction are unavailable or controversial. Much has been written on the difficulties inherent in extrapolating results from rodents treated with MTDs of a

compound to humans who will be exposed to much lower doses and often for shorter periods. A discussion of these and other aspects of carcinogenic risk assessment is beyond the scope of this chapter.

17

HISTOPATHOLOGY AND CLINICAL PATHOLOGY IN NONCLINICAL PHARMACEUTICAL SAFETY ASSESSMENT

17.1 INTRODUCTION

Toxicologic pathology in its broadest sense is the study of the molecular, cellular, tissue, biochemical, and/or organ responses of a living organism when exposed to injurious chemical or physical agents. These responses represent a spectrum of cellular changes ranging from cell death to malignant transformations, tissue and organ responses (including regeneration inflammation), and organization and overall response as identified by clinical changes and alterations in body fluids (Arnold et al., 1990; MHLW, 1990; EEC, 1992; EMEA, 2000; ICH, 2000, 2005; Haschek et al., 2021; McCance and Huether, 2015; Steinbach et al., 2019). It starts from recognition of the fact that the cell constitutes the basic unit of life. Accordingly, morphologic changes in organs and tissues that arise as a result of injury begin with the responses of underlying cells to the toxic insult. A proper evaluation and understanding of related pathology must start at the cellular level. Some cellular components whose alterations have been reported to be critically associated with cell injury include the plasma membrane, site of osmotic, electrolyte, and water regulation, as well as signal transduction; the mitochondrion, site of energy storage and aerobic respiration; the endoplasmic reticulum, site of much protein synthesis; and the nucleus, which contains the genetic information and where transcription of the genetic code takes place (Ham, 1974; Wallig, 2002; Maronpot et al., 2018). As more sensitive and relevant tools (such as image analysis biomarkers) flow cytometry and means of detecting, identifying, and quantitating such changes are developed and validated, they are being incorporated into the pathological tool list (Yoshikawa et al., 2020).

Biochemical changes such as enzyme induction and gene expression occur at the earlier stages of the exposure-disease

continuum. The degrees of cellular injury in different target tissue depend on the metabolic rate. Cells with high metabolic rates such as neurons, myocardial cells, and renal proximal convoluted tubule epithelial cells frequently suffer from injury more quickly than low-metabolizing ones. These high-metabolism cells depend on a continuous flow of oxygen to conduct the aerobic metabolism necessary to provide required energy in the form of ATP for the maintenance of membrane polarity and membrane integrity (neurons), for the continual muscular contraction/relaxation and calcium transport (myocardium), and for the transport of fluids, electrolytes, and metabolites (renal peritubular capillaries [PTCs]). Hence, any depletion in oxygen supply is likely to have a significant impact on their survival.

In contrast, cells with low metabolic activity such as fibroblasts and adenocytes are less affected by the low supply of oxygen, and they have a prominent role in regeneration and scarring. Homeostasis is one of the most remarkable and most typical properties of highly complex biologic systems. It defines the ultimate environment under which cells maintain the physiochemical conditions (intracellular pH, cytosolic osmolarity, ion gradients) necessary to perform their biologic functions. In biologic systems, homeostasis is maintained by means of a multiplicity of dynamic equilibriums rigorously controlled by interdependent regulation mechanisms. Hence, the homeostatic system reacts to changes or disturbances in response to various insults by exerting a series of modifications or adjustments to maintain the internal balances and conditions within tolerable limits.

Pathology (including all the aspects of anatomic, aka histopathology, clinical chemistry and clinical pathology, aka hematology) is generally considered the single most significant portion of data to come out of systemic toxicity studies (particularly the repeat dose with exposure duration going from

14 days to 2 years) (Roy and Andrews, 2004; Perez and Barthold, 2007; Tehouwan and Centeno, 2008; Frame et al., 2014). Anatomic pathology evaluations actually consist of three related sets of data (gross pathology observations, organ weights, and microscopic pathology) that are collected during termination of the study animals. At the end of the study, a number of tissues are collected during termination of all surviving animals (test and control). Organ weights and terminal body weights are recorded at study termination so that absolute and relative (to body weight) values can be statistically evaluated. Michael et al. (2007) have provided a review of practices of how such organ weight information is evaluated and utilized in the overall evaluation of pathology and adverse effects. In general with the exception of brain weights relative to body weight, changes are considered more relevant to identifying target organ toxicities.

These “standard list” tissues, along with the organs for which weights are determined, are listed in Table 17.1 (OECD, n.d.). All tissues collected are typically processed for microscopic observation, but only those from the high-dose and control groups are necessarily evaluated microscopically. If a target organ is discovered in the high-dose group, then the effect is “followed” in successively lower-dose groups until a NOEL (devoid of effect) is determined.

In theory, all microscopic evaluations should be performed in a blind manner (without the pathologist knowing from which dose group a particular animal came), but this is difficult to do in practice, and such an approach frequently actually limits and degrades the quality of the evaluation. Like all the other portions of data in the study, proper evaluation benefits from having access to all data that addresses the rele-

vance, severity, timing, and potential mechanisms of a specific toxicity. Blind examination is best applied in peer review or consultations on specific findings after a primary evaluation.

In addition to the “standard” set of tissues specified in Table 17.1, observations during the course of the study or in other or previous studies may dictate that special examination or tissue preparation procedures (such as polarized light or electron microscopy, immunocytochemistry, or quantitative morphometry) be undertaken to evaluate the relevance of such findings and help or understand the mechanisms underlying certain observations (Bradley and Jacobsen, 2019).

The evaluation of the pathological alterations induced in laboratory animals by new drugs represents the cornerstone of their safety assessment before they can be first tried in patients. This preliminary assessment, which is based largely on conventional histopathological techniques, represents a major contribution to the development of new treatments for both human and animal diseases.

Although there have been many changes over the past few decades in the details of study design and conduct, the principles of drug testing prior to trial in humans are the same as those expounded by Geiling and Cannon after they studied the pathological effects and causes of death of patients treated with toxic elixir of sulfanilamide over 60 years ago (Geiling and Cannon, 1938; Table 17.2). The basic paradigm of dosing laboratory animals with various doses of new drug for increasing periods of time accompanied by careful clinical observations and biochemical and hematological monitoring followed by histopathological examination of the tissue remains essentially unaltered. The pathologist is required to not only evaluate alterations to organs and tissues and any relationship that they might have to drug treatment but also to assess the likely relevance any treatment-related findings might have for patients (see Table 17.3).

TABLE 17.1 Tissues for Histopathology

Adrenals ^a	Mainstream Bronchi
Body and cervix	Major salivary gland
Brain, all three levels ^a	Mesenteric lymph nodes
Cervical lymph nodes	Ovaries and tubes
Cervical spinal cord	Pancreas
Duodenum	Pituitary
Esophagogastric junction	Prostate
Esophagus	Skeletal muscle from proximal hind limb
Eyes with optic nerves	Spleen ^a
Femur with marrow	Sternebrae with marrow
Heart ^a	Stomach
Ileum	Testes with epididymides ^a
Kidneys ^a	Thymus and mediastinal contents ^a
Large bowel	Thyroid with parathyroid ^a
Larynx with thyroid and parathyroid	Trachea
Liver ^a	Urinary bladder
Lungs ^a	Uterus including horns

^aOrgans to be weighed.

TABLE 17.2 Principles of Drug Testing Before Trials in Humans as Defined in 1938 by Geiling and Cannon

1. Exact composition of drug should be known; if not, method of preparation
2. Acute toxicity studies in animals of different species
3. Chronic toxicity experiments at varying doses in different species for cumulative effects
4. Careful and frequent observations of animals to develop a composite picture of clinical effects
5. Careful pathological examination of tissues with appropriate stains
6. Effects of drugs on excretory or detoxifying organs, especially kidney and liver
7. Rate of absorption and elimination, path and manner of excretion, and concentration in blood and tissues at varying times
8. Possible influence of other drugs and foodstuffs
9. Careful examination for any synergies or untoward reactions

TABLE 17.3 Discriminating Factors for Assessing Cause–Effect Relationships and Adversity of Pathology Findings*Discriminating Factors for Assessing Cause–Effect Relationship*

- There is no obvious dose–response
- The group change is due to an outlier in one or more animals
- The measurement of the end point is inherently imprecise
- The change is within normal biological variation (historical control or reference values)
- There is a lack of biological plausibility (e.g., the difference is inconsistent with class effects, mode of action, or what is known or expected of the test material)

Discriminating Factors for Assessing Adversity

- The effect causes no alteration in the general function of the test organism or the organs/tissues affected
- The effect is adaptive
- The effect is transient (i.e., resolves in the course of treatment versus reversibility, which refers to resolution with cessation of treatment)
- The severity of the effect is limited (below threshold of concern)
- The effect is not a precursor (i.e., not part of a continuum of changes known to progress with time to an established adverse effect)
- The effect is secondary to other adverse effects
- The effect is a consequence of the experimental model (e.g., stress associated with restraint or reactions to physical properties of the test substance, such as taste or odor).

Source: Adapted from Lewis et al. (2002, pp. 66–74).

Statistical analysis can also be helpful in assessing whether findings are chance or not, and the causality and relevance of such changes (Gad and Rousseaux, 2021), but care must be taken in their application.

The use of animals to study the pathological effects of chemicals and therapeutic agents has a long history. In the eighteenth century, Morgagni reported his attempts to compare pathological changes produced by accidental ingestion by people of chemicals such as arsenic. A thorough and systematic review of pathology induced by toxins in humans and animals was published by Orfila as long ago as 1815 (Orfila, 1815). Although in the modern era drug safety evaluation has been practiced in rodent and nonrodent species widely since before World War II, there have been very few critical comparisons of the effects of drugs in man and those seen in laboratory animals. Much potentially useful information still awaits data mining in the archives of pharmaceutical companies and government agencies. Nevertheless, the available data suggest that the traditional approach using experimental pharmacology alongside conventional toxicology studies with pathology is usually sufficient to predict important adverse effects and to support the safe conduct of the first clinical studies in humans (Turton and Hoasen, 1998; Greaves et al., 2004). Such a degree of concordance varies between different organs and tissues. Therefore, each observed drug-induced pathological finding needs to be assessed on a

case-by-case basis for its likely clinical relevance. For some systems, histopathology remains critical for some organ systems but of lesser importance for others. Traditional animal studies are poor predictors of subjective neurological symptoms, but histopathological examination of the nervous system in laboratory animals treated with cancer drugs does well at potential serious clinical neurotoxic effects. Results from non-clinical studies frequently fail to predict renal and hepatic toxicity (largely because of a “formula” approach to evaluation), but there is generally a good correlation for gastrointestinal effects, and histopathology still seems to represent one of the most sensitive techniques to detect effects on the reproductive system; though the relevance of such findings can be confounded by general systemic toxicity, the pathologist also needs to be aware that some minor inflammatory alterations in certain organs, such as the liver, may have greater significance for the use of a drug in humans than other types of severe damage such as subendocardial necrosis in the myocardium mediated by exaggerated hemodynamic effects.

Treatment-induced findings in conventional toxicity studies found in different laboratory animal species also seem to possess different degrees of relevance for humans. Although the data are fragmentary, findings in beagle dog studies are not often better predictors of human adverse effects than data from rodents or, surprisingly, from primates (Greaves et al., 2004). Dog gastrointestinal and cardiovascular physiology appears to model particularly well for humans, though the pig is generally better yet.

Another long-standing issue most recently recognized again due to findings with the cyclooxygenase 2 (COX-2) inhibitors is the importance of evaluating the adverse effects of some therapies with specific human diseases. COX-2 inhibitors were used for inflammatory disorders because of their perceived lower adverse effect profile on the gastrointestinal tract compared with conventional drugs, but this benefit is outweighed by an increased incidence of cardiovascular disease in some patients. Such effects are difficult if not impossible to predict from nonclinical safety studies in “normal” healthy animals. Unfortunately, the detection of an increased incidence of a common event such as heart attack or stroke is difficult in patients, for it requires careful collection and analysis of data, even though it may have a big impact on public health (Dragen, 2005). Such interactions usually require randomized controlled trials specifically designed to look for such risks. It has to be remembered that aspirin was in use for over 100 years before it became generally acknowledged about 30 years ago to be associated with Reye’s syndrome, a devastating toxicity in children (Monto, 1999). While the actual mechanism involved in Reye’s syndrome is still unknown, it is often preceded by a viral infection and displays a strong correlation with the subsequent ingestion of aspirin.

Histopathology testing is a terminal procedure, and, therefore, sampling of any single animal is a one-time event

(except in the case of a tissue collected by biopsy). Because it is a regulatory requirement that the tissues from a specific minimum number of animals be examined at the stated end of the study, any evaluation of effects in tissues at another time course (most commonly, to investigate recovery from an effect at study termination) requires that additional numbers of animals be incorporated into that study at start-up. Such animals are randomly assigned at the beginning of the study and otherwise treated the same as the rest of their group/cohort animals.

Anatomic pathology evaluation occurs only after the in-life portion of a study is complete and is typically the rate-limiting step in producing a report on the study. At the end of the study the animals are euthanized, final blood and urine samples are taken, and tissues are collected, with a prespecified set being weighed while still wet, and evaluated grossly (see Table 17.1) as to whether they are other than normative in appearance then preserved in appropriate manners (Greaves, 2009, 2012; Haschek et al., 2013a) and processed to optimize evaluation (Gray, 1964). Experimental design may call for an interim necropsy (to allow for evaluation of progression of lesions or observation of indications of adaptive change by animals) and/or a recovery group (usually additional numbers of high-dose and control animals in which treatment is discontinued at the time of the main necropsy). Such recovery animals are maintained without further manipulation or treatment for a period of time after the termination of the main study animals (usually a month), allowing for an assessment of treatment-free regression or progression of conditions seen at the end of the main study. Once gathered, tissues must be processed, mounted, stained, and examined with great care. The entire set of steps involved in anatomic pathology represent a significant portion of the time required to complete a study and add from 30% to 50% to the cost of the shorter (14, 28, and 90 days) studies.

Nevertheless, the available data suggest that the traditional approach using experimental pharmacology alongside conventional toxicology studies with pathology is usually sufficient to predict important adverse effects and to support the safe conduct of the first clinical studies in humans (Greaves et al., 2004). Indeed, the dosing a rodent and nonrodent species with a new drug up to one month identifies over 90% of adverse effects that will ever be detected in the usual nonclinical safety assessment studies. However, more generally, these studies do not detect all adverse drug effects that can occur in clinical practice, and there remains significant over- and underprediction of human toxicity. Overall, the true positive concordance rate (sensitivity) is of the order of 70% with perhaps 30% of human adverse effects not predicted by safety pharmacology or conventional toxicity studies (Olsen et al., 2000). Moreover, this concordance varies between different organs and tissues. Therefore, each drug-induced pathological finding needs to be assessed on a case-by-case basis for its likely clinical relevance.

17.1.1 Pathological Techniques

Over the past few years, a number of excellent reviews of standardized techniques for use in the histopathology evaluation of toxicology studies have been produced covering tissue selection, blocking and sectioning procedures, immunocytochemical stains for laboratory animals, and other basic techniques (Bregman et al., 2003; Mikaelian et al., 2004).

In addition, the scientific literature is full of interesting techniques and novel reagents that can be applied to tissue sections. Some of these can be very useful in the analysis of pathological alterations in toxicity studies; some fail to work in routinely fixed material. However, it is important that these techniques are used in a judicious manner with clear aims following careful analysis of conventional hematoxylin- and eosin-stained sections. This is particularly true for the application of microarray and bioinformatics technology. While undoubtedly useful in toxicology, these techniques should not be applied in isolation but in combination with other information, particularly pathology.

17.1.2 Organ Weights

Regulatory guidelines indicate that certain organs should be weighed during the course of the necropsy in repeat-dose toxicity studies (Alder and Zbinden, 1988). The extent to which organs are weighed varies between laboratories, but organ weighing is a useful adjunct to macroscopic assessment. Therefore, the selection of organs for weighing is the primary responsibility of the study pathologist. Weighing helps to focus the histopathological examination on key target organs, such as the liver and kidney, the weights of which are frequently altered upon administration of xenobiotics (Peters and Boyd, 1996).

Heart weight is a guide to potential cardiac alterations and especially important in the assessment of cardiovascular drugs. Likewise, the lungs are weighed in inhalation studies as this can provide a useful indication of the extent of edema or accumulation of exudate. Brain weight is employed as a stable reference point in adult animals as it is fairly independent of body weight changes. The weights of endocrine organs are useful guides to alterations in the endocrine status of laboratory animals (Pfeiffer, 1998). However, weighing a small and firmly attached organ such as the thyroid can severely disrupt its quality and orientation in the sections and thus offset any apparent advantage (Michael et al., 2007).

Testicular weights correlate with testicular toxicity, and weights can be compared with in-life measurement of testicular size (Heywood and James, 1978; Creasy, 2003). Weighing the testis is a useful precaution at the early phase of development of a novel drug prior to any assessment of male fertility. By contrast, ovarian weight is highly variable as a consequence of cyclical ovarian development and is therefore a less sensitive indicator of treatment-induced changes in the female reproductive system (Long et al., 2001).

17.2 CLINICAL PATHOLOGY

Clinical pathology is the evaluation of changes (or lack of changes) in the formed blood elements and their characteristics—the most common of these parameters are listed in Table 17.4. These parameters reflect the homeostasis and function of both the hematopoietic system and associated metabolic systems. Beutler et al. (1995) provide an extensive and detailed overview of these systems, though primarily from the perspective of the human system. These measures have the advantage that samples can be taken (and therefore evaluations made) at multiple points over the course of drug administration and at points subsequent to the discontinuation of such administration (i.e., during “recovery”).

At the same time, there is the disadvantage that these are frequently indirect measures of what is happening at specific target sites (primarily the bone marrow). The actual target organ effects can generally only be evaluated after termination of the test animals.

Actual evaluation of meaning and relevance and mechanism of cause of observed changes requires of course consideration of not individual parameters in isolation but rather of the entire set of measures and the relationships/correlations of these changes. This evaluation is discussed in the earlier chapter on “Repeat-Dose Toxicity Studies.”

17.2.1 Clinical Chemistry

One of the portions of the information employed into a pathological evaluation which is not terminally collected comes

from samples of blood and urine. These can be analyzed for the presence and activity of enzyme and endogenous physiologic components (such as electrolytes), including those listed in Table 17.4, which are collected and how they are analyzed is largely simply following what is done in human beings during clinical evaluation. Some adaptations have been made, and indeed the measurement methods (and their validation) and interpretation are essentially modified for the specific species in question.

The interpretation of these parameters is primarily addressed in the chapter on the repeat-dose studies, though there are some excellent references on the field (Loeb and Quimby, 1999; Lewandrowski, 2003; Burtis et al., 2012). The last of these best addresses modern biomasses for organ damage. The issue of sampling in nonclinical safety studies is a multifaceted one. First, each species presents limitations on how much (and how often) sample can be drawn. Mice are the most limiting, with large nonrodent species (dogs, primates, and pigs) the least. The proximity of sample collection of the time of drug to dosing or organ damage means that there is a strong emphasis on a need for frequent sample collection. One must not lose sight of the fact that we only see where we look, that is, only where we sacrifice.

17.2.2 Target Organ Toxicity Biomarkers

As this is written, FDA/EMA continues to work on qualifying new biomarkers for target organ toxicity. These serve to significantly improve the performance of nonclinical safety studies in identifying potential drug-related toxicities.

TABLE 17.4 Examples of Basic Tests Applicable to Most Rat, Dog, and Monkey Studies

Hematology and Coagulation	Clinical Chemistry	Urinalysis
RBC count	Glucose	Color and clarity
Hemoglobin	Urea nitrogen (or urea)	Overnight volume (e.g., 16h)
Hematocrit	Creatinine	Urine specific gravity
Mean corpuscular volume	Total protein	Reagent strip test, pH, protein, glucose, ketones, bilirubin, urobilinogen, blood
Mean corpuscular hemoglobin	Albumin	Microscopic examination of sediment: cells, casts, crystal, bacteria, sperm
Mean corpuscular hemoglobin concentration	Globulin (calculated)	
RBC morphology	A/G ratio (calculated)	
WBC count	Cholesterol	
WBC differential count	Total bilirubin	
Platelet count	Alanine aminotransferase	
Blood and bone marrow smears	Aspartate aminotransferase	
Prothrombin time (PT)	Alkaline phosphatase	
Activated partial thromboplastin time (APTT)	Gamma-glutamyltransferase	
	Creatine kinase	
	Calcium	
	Inorganic phosphorus	
	Sodium	
	Potassium	
	Chloride	

The prototype set is for nephrotoxicity, where the two agencies have qualified a set of seven biomarkers—Kim-1, albumin, total protein, cystatin C, B2-microglobulin, urinary clustering, and urinary trefoil factor. Two of these (albumin and total protein) have been part of the clinical chemistry parameter set for decades. As with traditional clinical chemistry and clinical pathology measures, these biomarkers should be considered as sets not in isolation.

17.2.3 Integrated Analysis of Available Data

Pathologists have led our understanding that the most accurate and relevant information of the findings from nonclinical safety assessment studies require careful selection of animal models and a comprehensive and integrated assessment of all the available data from a well-conducted study. (Haschek et al., 2021; Steinbach et al., 2019). Such an assessment cannot be limited to qualitative and quantitative evaluations of tissue changes, but must also incorporate clinical chemistry data, patterns of changes in organ weights, and available biomarkers (Willmott, 2021; Hukkanen et al., 2020; Elmore, 2017).

17.2.4 Oly Examination of Brain for CNS Active Drugs

With increased interest in CNS drugs, particularly centered scheduled drugs, FDA has began the requirement of specific histopath evaluation of brain tissues. In systemic toxicity studies (usually short-term studies), the sampling of special stains and examination are called an Olney examination (Olney, 1989; Bolon, 2018).

IRRITATION AND LOCAL TISSUE TOLERANCE IN PHARMACEUTICAL SAFETY ASSESSMENT

18.1 INTRODUCTION

Local tissue tolerance (and their subset, irritation) studies assess the short-term hazard of pharmaceutical agents in the immediate region of their application, administration, or installation. In particular, these studies are done (expected) to assess topically or parenterally administered drug formulations. Note that these are all hazard tests, properly performed using the intended clinical formulation. While most of what nonclinical safety assessment requirements cover arises from ICH and specific regulatory authority guidelines, these requirements come from older pharmacopeial requirements; and they are focused on final (formulated) drug product rather than on active ingredients. While there have been continuous efforts to replace these *in vivo* (animal) based tests with alternatives, there has been minimal regulatory acceptance for drugs. The exception is use of the limulus assay for endotoxin based pyrogenicity for drugs, the FDA expects that an *in vitro* alternative be used rather than the rabbit eye irritation or the bovine corneal opacity (BCOP) study.

Topical local tolerance effects are almost entirely limited to irritation. Though this usually means dermal irritation, it can also be intracutaneous, mucosal, penile, perivascular, vaginal, bladder, rectal, nasal, or ocular, depending on the route of drug administration. All but ocular irritation uses some version of a common subjective rating scale (see Table 18.1) to evaluate responses. The outcome of all of these tests primarily evaluates the response of the first region of tissue (which is exposed to the highest concentration) to an administered drug substance. In general, any factor which enhances absorption through the contacted tissue is likely to decrease tissues tolerance. Wilhelm et al. (2012) and Gad and Chengelis (1998)

should be referred to for a more detailed coverage of the subject of topical tissue toxicology.

While these studies are among the oldest to have regulatory guidelines (think—Draize et al., 1944), they have and continue to evolve (see ISO, 2021 for recent changes). For the skin, this scale is used in the primary dermal irritation (PDI) test, which is performed for those agents that are to be administered to patients by application to the skin. As with all local tolerance tests, it is essential that the material be evaluated in “condition of use”—that is, in the final formulated form, applied topically to the dermis to test animals in the same manner that the agent is to be used clinically.

TABLE 18.1 Evaluation of Local Tissue Reactions in Tissue Irritation Studies

Skin Reaction	Value
<i>Erythema and eschar formation</i>	
No erythema	0
Very slight erythema (barely perceptible)	1
Well-defined erythema	2
Moderate to severe erythema	3
Severe erythema (beet redness) to slight eschar formation (injuries in depth)	4
Necrosis (death of tissue)	+N
Eschar (sloughing or scab formation)	+E
<i>Edema formation</i>	
No edema	0
Very slight edema (barely perceptible)	1
Slight edema (edges of area well defined by definite raising)	2
Moderate edema (raised ~1 mm)	3
Severe edema (raised more than 1 mm and extending beyond the area of exposure)	4
Total possible score for primary irritation	8

18.2 FACTORS AFFECTING IRRITATION RESPONSES AND TEST OUTCOME

The results of local tissue irritation tests are subject to considerable variability due to relatively small differences in test design or technique. Weil and Scala (1971) arranged and reported on the best known of several intralaboratory studies to clearly establish this fact. Though the methods presented previously have proven to give reproducible results in the hands of the same technicians over a period of years (Gad et al., 1986) and contain some internal controls (the positive and vehicle controls in the PDI) against large variabilities in results or the occurrence of either false positives or negatives, it is still essential to be aware of those factors that may systematically alter test results. These factors are summarized in the following:

- A. In general, any factor that increases absorption through the stratum corneum or mucous membrane will also increase the severity of an intrinsic response. Unless this factor mirrors potential exposure conditions, it may, in turn, adversely affect the relevance of test results.
- B. The physical nature of solids must be carefully considered both before testing and interpreting results. Shape (sharp edges), size (small particles may abrade the skin due to being rubbed back and forth under the occlusive wrap), and rigidity (stiff fibers or very hard particles will be physically irritating) of solids may all enhance an irritation response.
- C. Solids frequently give different results when they are tested dry than if wetted for the test. As a general rule, solids are more irritating if moistened (going back to Item A, wetting is a factor that tends to enhance absorption). Care should also be taken as to moistening agent—some (few) batches of US Pharmacopeia physiological saline (used to simulate sweat) have proven to be mildly irritating to the skin and mucous membrane on their own. Liquids other than water or saline should not be used.
- D. If the treated region on potential human patients will be a compromised skin surface barrier (e.g., if it is cut or burned), some test animals should likewise have their application sites compromised. This procedure is based on the assumption that abraded skin is uniformly more sensitive to irritation. Experiments, however, have shown that this is not necessarily true; some materials produce more irritation on abraded skin, while others produce less (Guillot et al., 1982; Gad et al., 1986).
- E. The degree of occlusion (in fact, the tightness of the wrap over the test site) also alters percutaneous absorption and therefore irritation. One important quality control issue in the laboratory is achieving a

reproducible degree of occlusion in dermal wrappings.

- F. Both the age of the test animal and the application site (saddle of the back vs. flank) can markedly alter test outcome. Both of these factors are also operative in humans, of course (Mathias, 1983), but in dermal irritation tests, the objective is to remove all such sources of variability. In general, as an animal ages, sensitivity to irritation decreases. For the dermal test, the skin middle of the back (other than directly over the spine) tends to be thicker (and therefore less sensitive to irritations) than that on the flanks.
- G. The sex of the test animals can also alter study results because both regional skin thickness and surface blood flow vary between males and females.
- H. Finally, the single most important (yet also most frequently overlooked) factor that influences the results and outcome of these (and, in fact most) acute studies is the training of the staff. In determining how test materials are prepared and applied and in how results are “read” against a subjective scale, both accuracy and precision are extremely dependent on the technicians involved. To achieve the desired results, initial training must be careful and all-inclusive. As important, some form of regular refresher training must be exercised—particularly in the area of scoring results. The use of a set of color photographic standards as a training and reference tool is strongly recommended; such standards should clearly demonstrate each of the grades in the Draize dermal scale.
- I. It should be recognized that the dermal irritancy test is designed with a bias to preclude false negatives and, therefore, tends to exaggerate results in relation to what would happen in humans. Findings of negligible irritancy (or even in the very low mild irritant range) should therefore be of no concern unless the product under test is to have large-scale and prolonged dermal contact.

18.3 PRIMARY DERMAL IRRITATION (PDI) TEST

The prototypical test to use to illustrate the principles underlying all other irritation tests is the PDI. It looks at the potential for a single exposure of a chemical to the skin to cause inflammation (erythema and edema) or damage to that skin. It uses the albino white rabbit as a model and a subjective (but reproducible) classification style grading system to score results.

A. Rabbit Screening Procedure

1. A group of at least 4–6 New Zealand white rabbits are screened for the study.

2. All rabbits selected for the study must be in good health; any rabbit exhibiting snuffles, hair loss, loose stools, or apparent weight loss is rejected and replaced.
3. One day (at least 18 h) prior to application of the test substance, each rabbit is prepared by clipping the hair from the back and sides using a small animal clipper. A size No. 10 blade is used to remove long hair, and then a size No. 40 blade is used to remove the remaining hair.
4. Six animals with skin sites that are free from hyperemia or abrasion (due to shaving) are selected. Skin sites that are in the telogen phase (resting stage of hair growth) are used; those skin sites that are in the anagen phase (stage of active growth, indicated by the presence of a thick undercoat of hair) are not used.
7. If the test substance is a solid or a semisolid, a 0.5 g portion is weighed and placed on the gauze patch. The test substance patch is placed on the appropriate skin site and secured. The patch is subsequently moistened with 0.5 mL of physiological saline.
8. When the test substance is in flake, granule, powder, or other particulate form, the weight of the test substance that has a volume of 0.5 mL (after compacting as much as possible without crushing or altering the individual particles, such as by tapping the measuring container) is used whenever this volume is less than 0.5 g. When applying powders, granules, and the like, the gauze patch designated for the test sample is secured to the appropriate skin site with one of the four strips of the tape at the most ventral position of the animal. With one hand, the appropriate amount of sample measuring 0.5 mL is carefully poured from a glycine weighing paper onto the gauze patch that is held in a horizontal (level) position with the other hand. The patch containing the test sample is then carefully placed into position onto the skin and the remaining three edges secured with tape. The patch is subsequently moistened with 0.5 mL of physiological saline.

B. Study Procedure

1. As many as four areas of skin, two on each side of the rabbit's back, can be utilized for sites for administration.
2. Separate animals are not required for an untreated control group. Each animal serves as its own control.
3. Besides the test substance, a positive control substance (a known skin irritant—1% sodium lauryl sulfate in distilled water) and a negative control (untreated patch) are applied to the skin. When a vehicle is used for diluting, suspending, or moistening the test substance, a vehicle control patch is required—especially if the vehicle is known to cause any toxic dermal reactions or if there is insufficient information about the dermal effects of the vehicle.
4. The intact (free of abrasion) sites of administration are assigned a code number. Up to four sites can be used, as follows:
 - #1 Test substance
 - #2 Negative control
 - #3 Positive control
 - #4 Vehicle control (if required)
5. Application sites should be rotated from one animal to the next to ensure that the test substance and controls are applied to each position at least once.
6. Each test or control substance is held in place with a 1 in. × 1 in. 12-ply surgical gauze patch. The gauze patch is applied to the appropriate skin site and secured with 1 in.-wide strips of surgical tape at the four edges, leaving the center of the gauze patch nonoccluded.
9. If the test substance is a liquid, a patch is applied and secured to the appropriate skin site. A 1 mL tuberculin syringe is used to measure and apply 0.5 mL of test substance to the patch.
10. The negative control site is covered with an untreated 12-ply surgical gauze patch (1 in. × 1 in.).
11. The positive control substance and vehicle control substance are applied to a gauze patch in the same manner as a liquid test substance.
12. The entire trunk of the animal is covered with an impervious material (such as Saran Wrap) for a 24 h period of exposure. The Saran Wrap is secured by wrapping several long strips of athletic adhesive tape around the trunk of the animal. The impervious material aids in maintaining the position of the patches and retards evaporation of volatile test substances.
13. An Elizabethan collar is fitted and fastened around the neck of each test animal. The collar remains in place for the 24 h exposure period. The collars are utilized to prevent removal of wrappings and patches by the animals while allowing the animals' food and water *ad libitum*.
14. The wrapping is removed at the end of the 24 h exposure period. The test substance skin site is wiped to remove any test substance still remaining.

When colored test substances (such as dyes) are used, it may be necessary to wash the test substance from the test site with an appropriate solvent or vehicle (one that is suitable for the substance being tested). This is done to facilitate accurate evaluation for skin irritation.

15. Immediately after removal of the patches, each 1 in. × 1 in. test or control site is outlined with indelible marker by dotting each of the four corners. This procedure delineates the site for identification.

C. Observations

1. Observations are made of the test and control skin sites 1 h after removal of the patches (25 h post-initiation of application). Erythema and edema are evaluated and scored on the basis of designated values presented earlier in Table 18.1.
2. Observations are again performed 48 and 72 h after application and scores are recorded.
3. If necrosis is present or the dermal reaction is unusual, the reaction should be described. Severe erythema should receive the maximum score (4), and +N should be used to designate the presence of necrosis and +E the presence of eschar.
4. When a test substance produces dermal irritation that persists 72 h post-application, daily observations of test and control sites are continued on all animals until all irritation caused by the test substance resolves or until day 14 post-application.

D. Evaluation of Results

1. A *subtotal irritation value* for erythema or eschar formation is determined for each rabbit by adding the values observed at 25, 48, and 72 h post-application.
2. A *subtotal irritation value* for edema formation is determined for each rabbit by adding the values observed at 25, 48, and 72 h post-application.
3. A *total irritation value* is calculated for each rabbit by adding the subtotal irritation value for erythema or eschar formation to the subtotal irritation value for edema formation.
4. The *primary dermal irritation index* (PDII) is calculated for the test substance or control substance by dividing the sum of the total irritation scores by the number of observations (3 days × 3 animals = 9 observations).
5. The categories of the PDII are as follows (this categorization of dermal irritation is a modification of

the original classification described by Draize et al. (1944)):

PDII = 0.0	Nonirritant
>0.0–0.5	Negligible irritant
>0.5–2.0	Mild irritant
>2.0–5.0	Moderate irritant
>5.0–8.0	Severe irritant

Other abnormalities, such as atonia or desquamation, should be noted and recorded.

18.4 OTHER NONPARENTERAL ROUTE IRRITATION TESTS

The design of vaginal, rectal, and nasal irritation studies is less formalized but follows the same basic pattern as the PDI test. The rabbit is the preferred species for vaginal and rectal irritation studies, but the monkey and dog have also been used for these (Eckstein et al., 1969; Gad and Chengelis, 1998). Both the rabbit and rat have commonly seen use for nasal irritation evaluations. Defined quantities (typically 1.0 mL) of test solutions or suspensions are instilled into the orifice in question. For the vagina or rectum inert, bungs are usually installed immediately thereafter to continue exposure for a defined period of time (usually the same period of hours as future human exposure). The orifice is then flushed clean, and 24 h after exposure, it is examined and evaluated (graded) for irritation using the scale in Table 18.1.

18.5 OCULAR IRRITATION TESTING

Ocular irritation is significantly different from the other local tissue irritation tests on a number of grounds. For the pharmaceutical industry, eye irritation testing is performed when the material is intended to be put into the eye as a means or route of application for ocular therapy (Chan and Hayes, 2014). There are a number of special tests applicable to pharmaceuticals or medical devices that are beyond the scope of this volume, since they are not intended to assess potential acute effects or irritation. In general, however, it is desired that an eye irritation test that is utilized by this group be both sensitive and accurate in predicting the potential to cause irritation in humans. Failing to identify human ocular irritants (lack of sensitivity) is to be avoided, but of equal concern is the occurrence of false positives.

The primary eye irritation test was originally intended to predict the potential for a single splash of chemical into the eye of a human being to cause reversible and/or permanent damage. Since the introduction of the original Draize test more than 60 years ago (Draize et al., 1944), ocular irritation testing in rabbits has both developed and diverged. Indeed,

clearly there is no longer a single test design that is used, and different objectives are pursued by different groups using the same test. This lack of standardization has been recognized for some time, and attempts have been made to address standardization of at least the methodological aspects of the test, if not the design aspects.

One widely used study design, which begins with a screening procedure as an attempt to avoid testing severe irritants or corrosives in animals, goes as follows:

A. Test Article Screening Procedure

1. Each test substance will be screened in order to eliminate potentially corrosive or severely irritating materials from being studied for eye irritation in the rabbit.
2. If possible, the pH of the test substance will be measured.
3. A PDI test will be performed prior to the study.
4. The test substance will not be studied for eye irritation if it is a strong acid (pH of 2.0 or less) or strong alkali (pH of 12.0 or greater) and/or if the test substance is a severe dermal irritant (with a PDII of 5–8) or causes corrosion of the skin.
5. If it is predicted that the test substance does not have the potential to be severely irritating or corrosive to the eye, continue to Section B, Rabbit Screening Procedure.

B. Rabbit Screening Procedure

1. A group of at least six New Zealand white rabbits of either sex are screened for the study. The animals are removed from their cages and placed in rabbit restraints. Care should be taken to prevent mechanical damage to the eye during this procedure.
2. All rabbits selected for the study must be in good health; any rabbit exhibiting snuffles, hair loss, loose stools, or apparent weight loss is rejected and replaced.
3. One hour prior to installation of the test substance, both eyes of each rabbit are examined for signs of irritation and corneal defects with a handheld slit lamp. All eyes are stained with 2.0% sodium fluorescein and examined to confirm the absence of corneal lesions. *Fluorescein staining:* Cup the lower lid of the eye to be tested and instill one drop of 2% (in water) sodium fluorescein solution onto the surface of the cornea. After 15 s, thoroughly rinse the eye with physiological saline. Examine the eye, employing a handheld long-wave ultraviolet

(UV) illuminator in a darkened room. Corneal lesions, if present, appear as bright yellowish-green fluorescent areas.

4. Only three of the six animals are selected for the study. The three rabbits must not show any signs of eye irritation and must show either a negative or minimum fluorescein reaction (due to normal epithelial desquamation).

C. Study Procedure

1. At least 1 h after fluorescein staining, the test substance is placed in one eye of each animal by gently pulling the lower lid away from the eyeball to form a cup (conjunctival cul-de-sac) into which the test material is dropped. The upper and lower lids are then gently held together for 1 s to prevent immediate loss of material.
2. The other eye remains untreated and serves as a control.
3. For testing liquids, 0.01 mL of the test substance is used.
4. For solids or pastes, 100 mg of the test substance is used.
5. When the test substance is in flake, granular, powder, or other particulate form, the amount that has a volume of 0.01 mL (after gently compacting the particles by tapping the measuring container in a way that will not alter their individual form) is used whenever this volume weighs less than 10 mg.
6. For aerosol products, the eye should be held open and the substance administered in a single 1-s burst at a distance of about 4 in. directly in front of the eye. The velocity of the ejected material should not traumatize the eye. The dose should be approximated by weighing the aerosol can before and after each treatment. For other liquids propelled under pressure, such as substances delivered by pump sprays, an aliquot of 0.01 mL should be collected and instilled in the eye as for liquids.
7. The treated eyes of the three rabbits are not washed following the instillation of the test substance.
8. The treated eyes of the remaining three rabbits are irrigated for 1 min with room-temperature tap water, starting 20 s after instillation.
9. To prevent self-inflicted trauma by the animals immediately after instillation of the test substance, the animals are not immediately returned to their cages. After the test and control eyes are examined and graded at 1 h postexposure, the animals are returned carefully to their respective cages.

D. Observations

1. The eyes are observed for any immediate signs of discomfort after instilling the test substance. Blepharospasm and/or excessive tearing are indicative of irritating sensations caused by the test substance, and their duration should be noted. Blepharospasm does not necessarily indicate that the eye will show signs of ocular irritation.
2. Grading and scoring of ocular irritation are performed in accordance with Table 18.2. The eyes are examined and grades of ocular reactions are recorded. To aid in the standardization of grading, the CPSC published an illustrated guide in 1976 (CPSC, 1976), which is reproduced in Gad and Chengelis (1998).
3. If signs of irritation persist at day 7, readings are continued on days 10 and 14 after exposure or until all signs of reversible toxicity are resolved.
4. In addition to the required observation of the cornea, iris, and conjunctiva, serious effects (such as pannus, rupture of the globe, or blistering of the conjunctivae) indicative of a corrosive action are reported.
5. Whether or not toxic effects are reversible depends on the nature, extent, and intensity of damage. Most lesions, if reversible, will heal or clear within 21 days. Therefore, if ocular irritation is present at the 14-day reading, a 21-day reading is required to determine whether the ocular damage is reversible or nonreversible.

More than three decades of work have been done on efforts to develop, validate, and accept alternatives to the *in vivo* eye irritation test and to modify it to use fewer animals (successful here in reducing the number of rabbits from 9 to 3) and reduce potential discomfort to test animals (also successful—see Gad et al., 1986, which proposed the current OECD schema for using a sequential method to avoid the severe and marked ocular irritation outcome in rabbits without exposing humans to potential harm). Gad (2000, 2009) survey these efforts.

Starting in 2015, at least one division of the FDA has asked for the *in vitro* bovine corneal opacity and permeability (BCOP) test (Gautheron et al., 2004) rather than the traditional *in vivo* study.

18.6 VAGINAL IRRITATION

Few, if any, products are administered via the vagina that are intended for systemic absorption. Thus, this route has not been as widely studied and characterized as others. On the other hand, large numbers of different products (douches,

TABLE 18.2 Scale of Weighted Scores for Grading the Severity of Ocular Lesions^a

Reaction Criteria	Score
I. Cornea	
A. Opacity degree of density (area that is most dense is taken for reading)	
1. Scattered or diffuse area, details of iris clearly visible	1
2. Easily discernible translucent area, details of iris slightly obscured	2
3. Opalescent areas, no details of iris visible, size of pupil barely discernible	3
B. Area of cornea involved	
1. One-quarter (or less) but not zero	1
2. Greater than one-quarter, less than one-half	2
3. Greater than one-half, less than whole area	3
4. Greater than three-quarters up to whole area	4
Scoring equals A × B × 5; total maximum = 80 ^b	
II. Iris	
A. Values	
1. Folds above normal, congestion, swelling, circumcorneal ingestion (any one or all of these or combination of any thereof), iris still reacting to light (sluggish reaction is possible)	1
2. No reaction to light, hemorrhage, gross destruction (any one or all of these)	2
Scoring equals A × B (where B is the area of the iris involved, graded as “under cornea”); total maximum = 10	
III. Conjunctivae	
A. Redness (refers to palpebral conjunctivae only)	
1. Vessels definitely injected above normal	1
2. More diffuse, deeper crimson red, individual vessels not easily discernible	2
3. Diffuse beefy red	3
B. Chemosis	
1. Any swelling above normal (includes nictitating membrane)	1
2. Obvious swelling with partial eversion of the lids	2
3. Swelling with lids about half closed	3
4. Swelling with lids about half closed to completely closed	4
C. Discharge	
1. Any amount different from normal (does not include small amount observed in inner canthus of normal animals)	1
2. Discharge with moistening of the lids and hair just adjacent to the lids	2
3. Discharge with moistening of the lids and considerable area around the eye	3
Scoring (A + B + C) × 2; total maximum = 20	

^aThe maximum total score is the sum of all scores obtained for the cornea, iris, and conjunctivae.

^bAll A × B = Σ (1–3) × Σ (1–4) for three animals.

spermicides, antiyeast agents, etc.) have been developed that require introduction into the vagina in order to assert their localized effects. Increased research into different birth control and antiviral prophylaxis will result in more vaginal products in the future. All these must be assessed for vaginal irritation potential, and this serves as an example of the other tissue tolerance issues.

Considerable research (Eckstein et al., 1969; Auletta, 1994) has indicated that the rabbit is the best species for assessing vaginal irritation. There are those investigators, however, who consider the rabbit too sensitive and recommend the use of ovariectomized rats. Ovariectomy results in a uniformly thin, uncornified epithelium which is more responsive to localized effects. This model is used when the results from a study with rabbits are questionable (Auletta, 1994). The routine progression of studies consists of first doing an acute primary vaginal irritation study, then a 10-day repeated-dose study in rats. These protocols are summarized later. Longer-term vaginal studies have been conducted in order to assess systemic toxicity of the active agents when administered by these routes (while the intended effects may be local, one cannot assume that there will be no systemic exposure). Since the mid 2010's FDA has (except for ophthalmic drugs) changed their requirements from *in vivo* rabbit eye irritation tests to the *in vitro* bovine corneal opacity and permeability (BCOP) assay.

18.7 ACUTE PRIMARY VAGINAL IRRITATION STUDY IN THE FEMALE RABBIT

This study is used to assess tolerance for drugs (or devices) placed in the vagina to achieve either local or systemic exposure.

1. *Overview of study design:* One group of three adult rabbits received a single vaginal exposure and observed for 3 days with periodic examination (1, 24, 48 and 72 h postdosing) of the genitalia. Animals are then euthanized and the vagina is examined macroscopically.
2. *Administration*

Route: The material is generally introduced directly into the vagina using a lubricated 18 French rubber catheter attached to a syringe for quantification and delivery of the test material. Gentle placement of the catheter is important because one needs to ensure complete delivery of the dose without mechanical trauma. For rabbits, the depth of insertion is about 7.5 cm, and the catheter should be marked to about that depth. After delivery is completed, the tube is slowly withdrawn. No attempt is made to close or seal the vaginal orifice. Alternative methods may be used to administer more viscous materials. The most common is to backload a

lubricated 1 mL tuberculin syringe and then warm the material close to the body temperature. The syringe is then inserted into the vagina and the dose administered by depressing the syringe plunger.

Dosage: The test material should be the one (concentration, vehicle, etc.) that is intended for human application.

Frequency: Once.

Duration: 1 day.

Volume: 1 mL per rabbit.

3. Test system

Species, age, and weight range: Sexually mature New Zealand white rabbits are generally used, weighing between 2 and 5 kg. The weight is not as important as the fact that the animals need to be sexually mature.

Selection: Animals should be multiparous and non-pregnant. Animals should be healthy and free of external genital lesions.

Randomization: Because there is only one group of animals, randomization is not a critical issue.

4. In-life observations

Daily observations: At least once daily for clinical signs.

Detailed physical examination: Once during the week prior to dosing.

Body weight: Day of dosing.

Vaginal irritation: Scored at 1, 24, 48, and 72 h post-dosing. Scoring criteria are shown in Table 18.3.

TABLE 18.3 Scoring Criteria for Vaginal Irritation

Value	
	<i>Erythema</i>
0	No erythema
1	Very slight erythema (barely perceptible)
2	Slight erythema (pale red in color)
3	Moderate to severe erythema (definite red in color)
4	Severe erythema (beet or crimson red)
	<i>Edema</i>
0	No edema
1	Very slight edema (barely perceptible)
2	Slight edema (edges of area well defined by definite raising)
3	Moderate edema (raised ~1 mm)
4	Severe edema (raised more than 1 mm and extending beyond area of exposure)
	<i>Discharge</i>
0	No discharge
1	Very slight discharge
2	Slight discharge
3	Moderate discharge
4	Severe discharge (moistening of considerable area around the vagina)

5. *Postmortem procedures*: Rabbits are euthanized by lethal dose of a barbiturate soon after the last vaginal irritation scores are collected. The vagina is opened by longitudinal section and examined for evidence of mucosal damage such as erosion, localized hemorrhage, etc. No other tissues are examined. No tissues are collected. After the macroscopic description of the vagina is recorded, the animal is discarded.

18.7.1 Repeated-Dose Vaginal Irritation in the Female Rabbit

If there is to be a repeated exposure/administration by the vaginal route, a repeat-exposure study should be conducted to assess cumulative effects

1. *Overview of study design*: Four groups of three adult rabbits each receive a single vaginal exposure daily for 10 days. The genitalia are examined daily. Animals are then euthanized and the vagina is examined macroscopically and microscopically.

2. Administration

Route: The test materials are introduced directly into the vagina using a lubricated 18 French rubber catheter using the techniques described previously for acute studies.

Dosage: The test material should be the one (concentration, vehicle, etc.) that is intended for human application. There will also be a sham–negative control (catheter in place but nothing administered), a vehicle control, and a positive control (generally 2% nonoxynol-9).

Frequency: Once daily.

Duration: 10 days.

Volume: 1 mL per rabbit for each material.

3. Test system

Species, age, and weight range: Sexually mature New Zealand white rabbits are generally used, weighing between 2 and 5 kg. The weight is not as important as the fact that the animals need to be sexually mature.

Selection: Animals should be nulliparous and non-pregnant. Animals should be healthy and free of external genital lesions.

Randomization: At least 14 animals should be on pre-test. Randomization to treatment groups is best done using a computerized blocking by body weight method or a random number generation method.

4. In-life observations

Daily observations: At least once daily for clinical signs.

Detailed physical examination: Once during the week prior to dosing and immediately prior to necropsy.

Body weight: First, fifth, and last day of dosing.

Vaginal irritation: Scored once daily. Scoring criteria shown in Table 18.3.

5. *Postmortem procedures*: Rabbits are euthanized by lethal dose of a barbiturate soon after the last vaginal irritation scores are collected. The vagina is isolated using standard prosection techniques and then opened by longitudinal section and examined for evidence of mucosal damage such as erosion, localized hemorrhage, etc. No other tissues are examined. The vagina and cervix are collected and fixed in 10% neutral buffered formalin. Standard hematoxylin/eosin-stained, paraffin-embedded histologic glass slides are prepared by routing methods. Three levels of the vagina (low, mid, and upper) are examined and graded using the scoring system shown in Table 18.4. Each level is cored separately and an average is calculated. Irritation is rated as follows:

TABLE 18.4 Microscopic Scoring Procedure for Vaginal Sections

	Value
<i>Epithelium</i>	
Intact—normal	0
Cell degeneration or flattening of the epithelium	1
Metaplasia	2
Focal erosion	3
Erosion or ulceration, generalized	4
<i>Leukocytes</i>	
Minimal—<25 per high-power field	1
Mild—25–50 per high-power field	2
Moderate—50–100 per high-power field	3
Marked—>100 per high-power field	4
<i>Injection</i>	
Absent	0
Minimal	1
Mild	2
Moderate	3
Marked with disruption of vessels	4
<i>Edema</i>	
Absent	0
Minimal	1
Mild	2
Moderate	3
Marked	4

Source: Data from Eckstein et al. (1969).

Score	Rating
0	Nonirritating
1–4	Minimal irritation
5–8	Mild irritation
9–11	Moderate irritation
12–18	Marked irritation

The score for each rabbit is then averaged and acceptability ratings are given as follows:

Average Score	Acceptability Ratings
0–8	Acceptable
9–10	Marginal
11 or greater	Unacceptable

18.7.2 Repeated-Dose Vaginal Irritation in the Ovariectomized Rats

This study is very similar in design to that described previously for rabbits, with the following (sometimes obvious) exceptions. Mature ovariectomized female rats can be obtained from a commercial breeder. A 15% surplus should be obtained. Ten animals per group should be used (40 total for the study). The vaginal catheter is placed to a depth of approximately 2.5 cm, and the treatment volume should be 0.2 mL.

18.8 PARENTERAL IRRITATION/TOLERANCE

There are a number of special concerns about the safety of materials that are routinely injected (parenterally administered) into the body. By definition, these concerns are all associated with materials that are the products of the pharmaceutical and (in some minor cases) medical device industries. Such parenteral routes include three major ones—intravenous (IV), intramuscular (IM), and subcutaneous (SC)—and a number of minor routes (such as intra-arterial) that are not considered here.

18.8.1 Parenteral Routes

There are at least 13 different routes by which to inject material into the body, including the following:

1. Intravenous
2. Subcutaneous
3. Intramuscular
4. Intra-arterial
5. Intradermal
6. Intralesional

7. Epidural
8. Intrathecal
9. Intracisternal
10. Intracardiac
11. Intraventricular
12. Intraocular
13. Intraperitoneal

Only the first three are discussed in any detail here. Most of these routes of administration place a drug directly or indirectly into systemic circulation. There are a number of these routes, however, by which the drug exerts a local effect, in which case most of the drug does not enter systemic circulation (e.g., intrathecal, intraventricular, intraocular, intracisternal). Certain routes of administration may exert both local and systemic effects depending on the characteristics of the drug and excipients (e.g., SC).

The choice of a particular parenteral route will depend on the required time of onset of action, the required site of action, and the characteristics of the fluid to be injected, among other factors.

These unusual concerns include irritation (vascular, muscular, or SC), pyrogenicity, blood compatibility, and sterility (Avis, 1985). The background of each of these, along with the underlying mechanisms and factors that influence the level of occurrence of such an effect, is briefly discussed later.

18.8.1.1 Irritation Tissue irritation upon injection, and the accompanying damage and pain, is a concern that must be addressed for the final formulation, which is to be either tested in humans or marketed, rather than for the active ingredient. This is because most irritation factors are either due to or influenced by aspects of formulation design (see Avis, 1985, for more information on parenteral preparations). These factors are not independent of the route (IV, IM, or SC) that will be used and, in fact (as discussed later), are part of the basis for selecting between the various routes.

The lack of irritation and tissue damage at the injection site is sometimes called *tolerance*. Some of the factors that affect tolerance are not fully under the control of an investigation and are also unrelated to the material being injected. These include body movement, temperature, and animal age. Factors that can be controlled, but that are not inherent to the active ingredient, include solubility, tonicity, and pH. And, finally, the active ingredient and vehicle can have inherent irritative effects and factors such as solubility (in the physiological milieu into which they are being injected), concentration, volume molecular size, and particle size. Gray (1978) and Ballard (1968) discuss these factors and the morphological consequences that may occur if they are not addressed.

18.8.1.2 Blood Compatibility It is important that cellular components of the blood are not disrupted and that serum- or plasma-based responses are not triggered by parental administration. Therefore, two mechanisms must be assessed regarding the blood compatibility of component materials. These include the material's effect on cellular components that cause membrane destruction and hemolysis and the activation of the clotting mechanism resulting in the formation of the thromboemboli.

Many of the inactive, ingredient-related physicochemical factors that influence irritation (e.g., tonicity, pH, and particle size) also act to determine blood compatibility. But the chemical features of a drug entity itself—its molecular size and reactivity—can also be of primary importance.

18.8.1.3 Sterility Sterility is largely a concern to be answered in the process of preparing a final clinical formulation, and it is not addressed in detail in this chapter. However, it should be clear that it is essential that no viable microorganisms are present in any material to be parenterally administered (except for vaccines).

Bolus Versus Infusion Technically, for all the parenteral routes (but in practice only for the IV route), there are two options for injecting a material into the body. The bolus and infusion methods differentiated on the single basis of rate of injection, but they actually differ on a wide range of characteristics.

The most commonly exercised option is the bolus, or “push,” injection, in which the injection device (syringe or catheter) is appropriately entered into the vein and a defined volume of material is introduced through the device. The device is then removed. In this operation, it is relatively easy to restrain an experimental animal, and the stress on the animal is limited. Though the person doing the injection must be skilled, it takes only a short amount of time to become so. And the one variable to be controlled in determining dosage is the total volume of material injected (assuming dosing solutions have been properly prepared).

There are limitations and disadvantages to the bolus approach, however. Only a limited volume may be injected, which may prohibit the use of bolus when volumes to be introduced are high (due to, e.g., low active compound solubility or a host of other reasons). Only two devices (syringe and catheter) are available for use in the bolus approach. If a multiple-day course of treatment is desired (say, every day for 15 days), separate injections must be made at discreet entry sites.

The infusion approach involves establishing a fixed entry point into the vein, and then slowly passing the desired test material through that point over a period of time (30 min is about minimum, while continuous around-the-clock treatment is at least therapeutically possible). There are a number of devices available for establishing their entry point; catheter, vascular port (Garramone, 1986), or osmotic

pump (Theeuwes and Yum, 1976). Each of these must, in turn, be coupled with a device to deliver the dosing solution at a desired rate. The osmotic pump, which is implanted, is also its own delivery device. Other options are gravity-driven “drips,” handheld syringes (not practical or accurate over any substantial period of time), or syringe pumps. Very large volumes can be introduced by fusion over a protracted period of time, and only a single site need be fitted with an entry device.

However, infusions also have their limitations. Skilled labor is required, and the setup must be monitored over the entire period of infusion. Larger animals must be restrained, while there are special devices that make this requirement unnecessary for smaller animals. Restraint and protracted manipulation are very stressful on animals. Over a period of time, one must regularly demonstrate patency of a device—that is, that entry into the vascular system continues to exist. Finally, one is faced with having to control two variables in controlling the dose—both total volume and rate.

When are the two approaches (bolus and infusion) interchangeable? And why select one over the other? The selection of infusion is usually limited to two reasons: (i) when a larger volume must be introduced than is practical in a bolus injection or (ii) tolerance is insufficient if the dose is given all at once (i.e., an infusion will “clear” a higher daily dose than will a bolus injection). For safety studies, when a bolus can be used to clear a human infusion, dosing is a matter of judgment. If the planned clinical infusion will take less than a half an hour, practicality dictates that animal studies be accomplished by bolus. In other situations, pharmacokinetics (in particular, the half-life of the drug entity) should be considered in making the decision.

18.8.2 Test Systems for Parenteral Irritation

There are no regulatory guidelines or suggested test methods for evaluating agents for muscular or vascular irritation. Since such guidelines are lacking but the evaluation is necessary, those responsible for these evaluations have tried to develop and employ the most scientifically valid procedures.

Hagan (1959) first suggested a method for assessing IM irritation. His approach, however, did not include a grading system for evaluation of the irritation, and the method used the sacrospinalis muscles, which are somewhat difficult to dissect or repeatedly inject.

Shintani et al. (1967) developed and proposed the methodology that currently seems to be more utilized. It uses the lateral vastus muscle and includes a methodology for evaluation, scoring, and grading of irritation. Additionally, Shintani et al. investigated the effects of several factors such as the pH of the solution, the drug concentration, the volume of injection, the effect of repeated injections, and the time to maximum tissue response.

18.8.2.1 Acute Intramuscular Irritation in the Male Rabbit (USP, 2017; Adejare, 2021)

1. Overview of study design

Each rabbit is injected as follows:

Site (M. Vastus Lateralis)	Treatment (1.0 mL site ⁻¹)
Left	(Test article)
Right	(Vehicle)

Day 1: Injection of all treatment groups—nine rabbits

Day 2: Sacrifice and evaluation: 24 h posttreatment group—three rabbits

Day 3: Sacrifice and evaluation: 48 h posttreatment group—three rabbits

Day 4: Sacrifice and evaluation: 72 h posttreatment group—three rabbits

2. Administration

2.1 *Route*: The test article is injected into the vastus lateralis of each rabbit.

2.2 *Dose*: The dose selected is chosen to evaluate the severity of irritation and represents a concentration that might be used clinically. This volume has been widely used in irritation testing.

2.3 *Frequency*: Once only.

2.4 *Duration*: 1 day.

2.5 *Volume*: 1.0 mL site⁻¹.

3. Test system

3.1 *Species, age, and weight range*: Male New Zealand white rabbits weighing 2–5 kg are used. The New Zealand white rabbit has been widely used in muscle irritation research for many years and is a reasonable sized, even-tempered animal that is well adapted to the laboratory environment.

3.2 *Selection*: Animals to be used in the study are selected on the basis of acceptable findings from physical examinations and body weights.

3.3 *Randomization*: Animals are ranked by body weight and assigned a number between one and three. The order of number assigned (e.g., 1–3–2) is chosen from a table of random numbers. Animals assigned number 1 are in the 24 h posttreatment group; those assigned number 2 are in the 48 h posttreatment group; and those assigned number 3 are in the 72 h posttreatment group.

4. In-life observations

4.1 *Daily observations*: Once daily following dosing.

4.2 *Physical examinations*: Once within the 2 weeks before the first dosing day.

4.3 *Body weight*: Should be determined once before the start of the study.

4.4 Additional examinations may be done by the study director to elucidate any observed clinical signs.

5. Postmortem procedures

5.1 *Irritation is evaluated as follows*: Three rabbits are sacrificed by a lethal dose of barbiturate at approximately 24, 48, or 72 h after dosing. The left and right lateral vastus of each rabbit are excised. The lesions resulting from the injection are scored for muscle irritation on a numerical scale of 0–5 as follows (Shintani et al., 1967):

Reaction Criteria	Score
No discernable gross reaction	0
Slight hyperemia	1
Moderate hyperemia and discoloration	2
Distinct discoloration in comparison with the color of the surrounding area	3
Brown degeneration with small necrosis	4
Widespread necrosis with an appearance of “cooked meat” and occasionally an abscess involving the major portions of the muscle	5

The average score for the nine rabbits is then calculated, and a category of irritancy is then assigned based on the following table:

Average Score	Grade
0.0–0.4	None
0.5–1.4	Slight
1.5–2.4	Mild
2.5–3.4	Moderate
3.5–4.4	Marked
4.5 or greater	Severe

18.8.2.2 Acute Intravenous Irritation in the Male Rabbit The design here is similar to the IM assay, except that injections are made into the veins in specific muscle masses.

1. Overview of study design

Rabbits will be injected as follows:

Group	No. of Animals	Treatment Site	Evaluation (h)
1	2	M. vastus lateralis (left) and cervicodorsal subcutis (left)	24
		M. vastus lateralis (right) and cervicodorsal subcutis (right)	24
2	2	M. vastus lateralis (left) and cervicodorsal subcutis (left)	72
		M. vastus lateralis (right) and cervicodorsal subcutis (right)	72
3	2	Auricular vein (left)	24 and 72
		Auricular vein (right)	

Day 1: Injection of all groups (six rabbits)
Day 2: Evaluation of Group 3 (two rabbits). Sacrifice and evaluation of Group 1 (two rabbits)
Day 4: Evaluation of Group 3 (two rabbits). Sacrifice and evaluation of Group 2 (two rabbits)

2. Administration

- 2.1 *Intramuscular:* M. vastus lateralis
- 2.2 *Subcutaneous:* Cervicodorsal subcutis.
- 2.3 *Intravenous:* Auricular vein.
- 2.4 *Dose:* The doses and concentration selected are chosen to evaluate the severity of irritation. The dose volumes have been widely used in irritation testing.
- 2.5 *Frequency:* Once only.
- 2.6 *Duration:* 1 day.
- 2.7 *Volume:* M. vastus lateralis and cervicodorsal subcutis: 1.0 mL site⁻¹; auricular vein: 0.5 mL site⁻¹.

3. Test system

- 3.1 *Species, age, and weight range:* Male New Zealand white rabbits, weighing 2–5 kg, are used.
- 3.2 *Selection:* Animals to be used in the study are selected on the basis of acceptable findings from physical examinations.
- 3.3 *Randomization:* Animals are ranked by body weight and assigned a number between 1 and 3. The order of numbers assigned (e.g., 1–3–2) is chosen from a table of random numbers. Animals assigned number 1 are in Group 1; those assigned number 2 are in Group 2; and those assigned number 3 are in Group 3.

4. In-life observations

- 4.1 *Daily observations:* Once daily following dosing.
- 4.2 *Physical examinations:* Once within the 2 weeks before the first dosing day.
- 4.3 *Body weight:* Determined once before the start of the study.
- 4.4 Additional examinations may be done by the study director to elucidate any observed clinical signs.

5. Postmortem procedures

- 5.1 *IM irritation is evaluated as follows:* Rabbits are sacrificed by lethal dose of barbiturate approximately 24 and 72 h after dosing. The left and right lateral vastus muscles of each rabbit are excised. The reaction resulting from injection is scored for muscle irritation using the scale shown on page 232.
- 5.2 *SC (intracutaneous) irritation is evaluated as follows:* Rabbits are sacrificed by a lethal dose of barbiturate approximately 24 and 72 h after dosing. The SC injection sites are exposed by dissection, and the reaction is scored for irritation on a

scale of 0–5 as follows (Shintani et al., 1967; USP, 2017):

Reaction Criteria	Score
No discernible gross reaction	0
Slight hyperemia and discoloration	1
Moderate hyperemia and discoloration	2
Distinct discoloration in comparison with the color of the surrounding area	3
Small areas of necrosis	4
Widespread necrosis, possibly involving the underlying muscle	5

Average Score per Site	Irritancy Grade
0.0–0.4	None
0.5–1.4	Slight
1.5–2.4	Mild
2.5–3.4	Moderate
3.5–4.4	Marked
4.5 or greater	Severe

5.3 *IV irritation is evaluated as follows:* Rabbits are sacrificed by a lethal dose of barbiturate following the 72 h irritation evaluation. The injection site and surrounding tissue are grossly evaluated at approximately 24 and 72 h after dosing on a scale of 0–3 as follows:

Reaction Criteria	Score
No discernible gross reaction	0
Slight erythema at injection site	1
Moderate erythema and swelling with some discoloration of the vein and surrounding tissue	2
Severe discoloration and swelling of the vein and surrounding tissue with partial or total occlusion of the vein	3

Average Score per Site	Irritancy Grade
0.0–0.4	None
0.5–1.4	Slight
1.5–2.4	Moderate
2.5 or greater	Severe

5.4 Additional examinations may be done by the study director to elucidate the nature of any observed tissue change.

18.9 PROBLEMS IN TESTING (AND THEIR RESOLUTIONS)

Some materials, by either their physicochemical or toxicological natures, generate difficulties in the performance and evaluation of dermal irritation tests. The most commonly

encountered of these problems are presented in the following text:

- A. *Compound volatility*: One is sometimes required or requested to evaluate the potential irritancy of a liquid that has a boiling point between room temperature and the body temperature of the test animal. As a result, the liquid portion of the material will evaporate off before the end of the testing period. There is no real way around the problem; one can only make clear in the report on the test that the traditional test requirements were not met, though an evaluation of potential irritant hazard was probably achieved (for the liquid phase would also have evaporated from a human that it was spilled on).
- B. *Pigmented material*: Some materials are strongly colored or discolor the skin at the application site. This makes the traditional scoring process difficult or impossible. One can try to remove the pigmentation with a solvent; if successful, the erythema can then be evaluated. If use of a solvent fails or is unacceptable, one can (wearing thin latex gloves) feel the skin to determine if there is warmth, swelling, and/or rigidity—all secondary indicators of the irritation response.
- C. *Systemic toxicity*: On rare occasions, the dermal irritation study begun only to have the animals die very rapidly after test material is applied.

18.9.1 Alternatives to *In Vivo* Parenteral Tests

IM and IV injections of parenteral formulations of pharmaceuticals can produce a range of discomfort including pain, irritation, and/or damage to muscular or vascular tissue. These are normally evaluated for prospective formulations before use in humans by histopathologic evaluation of damage in intact animal models, usually the rabbit. Attempts have been made to make this *in vivo* methodology both more objective and quantitative based on measuring the creatinine phosphokinase released in the tissue surrounding the injection site (Sidell et al., 1974). Currently, a protocol utilizing a cultured skeletal muscle cell line (L6) from the rat as a model has been evaluated in an interlaboratory validation program among 11 pharmaceutical laboratories. This methodology (Young et al., 1986) measures creatine kinase levels in media after exposure of the cells to the formulation of interest and predicts *in vivo* IM damage based on this end point. It is reported to give excellent rank-correlated results across a range of antibiotics (Williams et al., 1987). The current multilaboratory evaluation covers a broader structural range of compounds and has shown a good quantitative correlation with *in vivo* results for antibiotics and a fair correlation for a

broader range of parenteral drug products. Likewise, Kato et al. (1992) have proposed a model that uses cultured primary skeletal muscle fibers from the rat. Damage is evaluated by the release of creatinine phosphokinase. An evaluation using six parenterally administered antibiotics (ranking their EC₅₀ values) showed good relative correlation with *in vivo* results.

Another proposed *in vitro* assay for muscle irritancy for injectable formulations is the red blood cell hemolysis assay (Brown et al., 1989). Water-soluble formulations in a 1:2 ratio with freshly collected human blood are gently mixed for 5 min. The percentage red blood cell survival is then determined by measuring differential absorbance at 540 nm; this value is then compared to values for known irritants and non-irritants. Against a very small group of compounds (four), this assay reportedly accurately predicts muscle irritation.

18.10 PHOTOTOXICITY

The potential for sunlight (or selected other light frequencies) to transform a drug or product is both a useful tool for activating some drugs and a cause of significant adverse effects for others (such as the quinolone antibiotics [Horio et al., 1995; Lambert et al., 1996]).

18.10.1 Theory and Mechanisms

The portion of the solar spectrum containing the biologically most active region is from 290 to 700 nm.

The UV part of the spectrum includes wavelengths from 200 to 400 nm. Portions of the UV spectrum have distinctive features from both the physical and biological points of view. The accepted designations for the biologically important parts of the UV spectrum are UVA, 400–315 nm; UVB, 315–280 nm; and UVC, 280–220 nm. Wavelengths less than 290 nm (UVC) do not occur at the earth's surface because they are absorbed predominantly by ozone in the stratosphere. The most thoroughly studied photobiological reactions that occur in skin are induced by UVB. The quinolones, for example, absorb light strongly in the 300–400 nm wavelength range. Although UVB wavelengths represent only approximately 1.5% of the solar energy received at the earth's surface, they elicit most of the known chemical phototoxic and photoallergic reactions. The visible portions of the spectrum, representing about 50% of the sun's energy received at sea level, include wavelengths from 400 to 700 nm. Visible light is necessary for such biological events as photosynthesis, the regulation circadian cycles, vision, and pigment darkening. Furthermore, visible light in conjunction with certain chromophores (e.g., dyes, drugs, and endogenous compounds which absorb light and therefore “give” color) and molecular oxygen induces photodynamic effects.

Understanding the toxic effects of light impinging on the skin requires knowledge of both the nature of sunlight and the skin's optical properties. Skin may be viewed as an optically heterogeneous medium, composed of three layers that have distinct refractive indices, chromophore distributions, and light-scattering properties. Light entering the outermost layer, the stratum corneum, is in part reflected—4–7% for wavelengths between 250 and 3000 nm (Anderson and Parrish, 1981)—due to the difference in refractive index between air and the stratum corneum. Absorption by urocanic acid (a deamination product of histidine), melanin, and proteins containing the aromatic amino acids tryptophan and tyrosine in the stratum corneum produces further attenuation of light, particularly at shorter UV wavelengths. Approximately 40% of UVB is transmitted through the stratum corneum to the viable epidermis. The light entering the epidermis is attenuated by scattering and, predominantly, absorption. Epidermal chromophores consist of proteins, urocanic acid, nucleic acids, and melanin. Passage through the epidermis results in appreciable attenuation of UVA and UVB radiation. The transmission properties of the dermis are largely due to scattering, with significant absorption of visible light by melanin, β -carotene, and the blood-borne pigments bilirubin, hemoglobin, and oxyhemoglobin. Lightly traversing these layers of the skin is extensively attenuated, most drastically for wavelengths less than 400 nm. Longer wavelengths are more penetrating. It has been noted that there is an “optical window”—that is, greater transmission—for light at wavelengths of 600–1300 nm, which may have important biological consequences.

Normal variations in the skin's optical properties frequently occur. The degree of pigmentation may produce variations in the attenuation of light, particularly between 300 and 400 nm, by as much as 1.5 times more in blacks than in Caucasians (Pathak, 1967). Alterations in the amount or distribution of other natural chromophores account for further variations in skin optical properties. Urocanic acid, deposited on the skin's surface during perspiration (Anderson and Parrish, 1981), and UV-absorbing lipids, excreted in sebum, may significantly reduce UV transmission through the skin. Epidermal thickness, which varies over regions of the body and increases after exposure to UVB radiation, may significantly modify UV transmission.

Certain disease states also produce alterations in the skin's optical properties. Alterations of the skin's surface, such as by psoriatic plaques, decrease transmitted light. The effect may be lessened by application of oils whose refractive index is similar to that of skin (Anderson and Parrish, 1981). Disorders such as hyperbilirubinemia, porphyrias, and blue skin nevi result in increased absorption of visible light due to accumulation or altered distribution of endogenous chromophoric compounds.

The penetration of light into and through dermal tissues has important consequences. This penetration is demonstrated

FIGURE 18.1 Schematic portraying penetration of light of varying wavelengths into skin.

in Figure 18.1. Skin, as the primary organ responsible for thermal regulation, is over-perfused relative to its metabolic requirements (Anderson and Parrish, 1981).

It is estimated that the average cutaneous blood flow is 20–30 times than necessary to support the skin's metabolic needs. The papillary boundaries between epidermis and dermis allow capillary vessels to lie close to the skin's surface, permitting the blood and important components of the immune system to be exposed to light. The equivalent of the entire blood volume of an adult may pass through the skin, and potentially be irradiated, in 20 min. This corresponds to the time required to receive 1 or 2 MEDs (the MED is defined as the minimal dose of UV irradiation that produces definite, but minimally perceptible, redness 24 h after exposure). The accessibility of incidence radiation to blood has been exploited in such regimens and phototherapy of hyperbilirubinemia in neonates, where light is used as a therapeutic agent. However, in general, there is a potential for light-induced toxicity due to irradiation of blood-borne drugs and metabolites.

18.10.2 Factors Influencing Phototoxicity/Photosensitization

There are a number of factors which can influence an agent acting either as a phototoxin or a photoallergen. In addition to all those factors previously reviewed in Chapter 5, there are also the following:

1. The quantity and location of photoactive material present in or on the skin
2. The capacity of the photoactive material to penetrate into normal skin by percutaneous absorption as well as into the skin altered by trauma, such as maceration, irritation, and sunburn
3. The pH, enzyme presence, and solubility conditions at the site of exposure
4. The quantity of activating radiation to which the skin is exposed
5. The capacity of the spectral range to activate the materials on or within the skin
6. The ambient temperature and humidity
7. The thickness of the horny layer
8. The degree of melanin pigmentation of the skin
9. The inherent “photoactivity” of the chemical; does it weakly or strongly absorb light?

Basically, any material that has both the potential to absorb UV light (in the UVA or UVB regions) and the possibility of dermal exposure or distribution into the dermal region should be subject to some degree of suspicion as to potential phototoxicity. As shown in Table 18.5, a large number of agents have been identified as phototoxic or photoallergenic agents. Of these, tetrachlorosalicylanilide (TCSA) is the most commonly used as a positive control in animal studies.

18.10.3 Predictive Tests for Phototoxicity

Before we start on our description of the different methods, we will first cover some basic on light dosimetry. The intensity of the irradiation used in phototoxicity testing is determined with a light meter, which provides output as watts per square meter. The shelves on which the animals rest during the exposure periods are normally adjustable in order to control the dose of light to the exposure area. The irradiation from fluorescent lights will vary somewhat from day to day, depending on temperature, variations in line current, and so on. The dose the animals receive is generally represented as joules per square centimeter. A joule is equal to 1 W s^{-1} . Therefore, the dose of light is dependent on the time of exposure. For example, in their review, Lambert et al. (1996) discuss dosages of UVA light of 9 or 10 J cm^{-2} in the UVA spectral region. If the irradiation from the light is found to be 20 W m^{-2} at the exposure site, then the time of exposure required to obtain the target dose of light (in joules) is calculated as

$$(\text{Time of exposure}) = \frac{\text{Ws}}{\text{J}} \frac{9\text{J}}{\text{cm}^2} \frac{\text{m}^2}{20\text{W}} \frac{10^4\text{cm}^2}{\text{m}^2} \frac{\text{min}}{60\text{s}} = 75\text{min}$$

If, with the same set of lights, 2 weeks later the irradiation is determined to be 19 W m^{-2} , then the exposure period would have to be 79 min.

The ICH promulgated a new guidance for phototoxicity testing in 2015 (ICH, 2015). It provides separate recommendations for drugs given systemically and drugs administered dermally/topically. In both cases, it limits concerns to drugs

TABLE 18.5 Known Phototoxic Agents

In Humans		In Animals	
Compounds	Route	Compounds	Route
Aminobenzoic acid derivatives	Topical	Acridine	Topical
Amyldimethylamino benzoate, mixed <i>ortho</i> and <i>para</i> isomers	Topical	Amiodarone	Oral
Anthracene acridine	Topical	Anthracene	Topical
Bergapten (5-methoxypsoralen)	Topical	Bergapten (5-methoxypsoralen)	Topical
Cadmium sulfide	Tattoo	Bithionol	Topical
Chlorothiazides	Oral	Chlordiazepoxide	ip
Coal tar (multicomponent)	Topical	Chlorothiazide	ip
Dacarbazine	Infusion	Chlorpromazine	Topical
Disperse blue 35 (anthraquinone-based dye)	Topical	Demeclocycline	ip
Nalidixic acid	Oral	Griseofulvin	ip
Padimate A or Escalol 506 (amyl- <i>p</i> -dimethylamino benzoate)	Topical	Kynurenic acid	Oral
Psoralens	Oral, topical	Nalidixic acid	Oral
Quinolone (antibacterial)	Oral	Prochlorperazine	ip
		Quinoline methanol	ip
		Quinolone (antibacterial)	Oral
		Tetracyclines	ip, topical
		Xanthotoxin (8-methoxypsoralen)	Oral, ip, im
Tetracyclines	Oral		
Xanthotoxin (8-methoxypsoralen)	Topical, oral		

having absorption between 290 and 700nm with the 3T3 *in vitro* assay the primary screen for phototoxicity if there is absorption in this case.

For systemically administered drugs, a negative 3T3 precludes the need for further testing. If the 3T3 is positive, an *in vivo* phototoxicity study is called for.

For drugs administered by dermal routes, a positive 3T3 evokes the need for *in vivo* phototoxicity and photosensitization tests.

18.10.4 3T3 *In Vitro* Test

The first is an *in vitro* alternative success story—the 3T3 NRU phototoxicity test, which uses BALB/c 3T3 (murine) cell line with cytotoxicity determination based on neutral red uptake to measure cell viability (OECD, 2004). While not a direct replacement alternative (as there is no *in vivo* equivalent test), it is an accepted screen for phototoxicity potential by FDA.

18.10.5 Rabbit Phototoxicity Test

The next test uses the rabbit. The traditional methodology for a predictive test for phototoxicity has been an intact rabbit test (Marzulli and Maibach, 1970). This test is conducted as follows (and illustrated diagrammatically in Figure 18.2):

A. Animals and animal husbandry

1. *Strain/species*: Female New Zealand white rabbits.
2. *Number*: Six rabbits per test; two rabbits for positive control.
3. *Age*: Young adult.
4. *Acclimation period*: At least 7 days prior to study.
5. *Food and water*: Commercial laboratory feed and water are freely available.

B. Test article

1. A dose of 0.5 mL of liquid or 500 mg of a solid or semisolid will be applied to each test site.
2. Liquid substances will be used undiluted.
3. For solids, the test article will be moistened with water (500 mg test article/0.5 mL water or another suitable vehicle) to ensure good contact with the skin.
4. Positive control material will be a lotion containing 1% 8-methoxypsoralen.

C. Experimental procedures

1. Animals will be weighed on the first day of dosing.
2. On the day prior to dosing, the fur of the test animals will be clipped from the dorsal area of the trunk using a small animal clipper, and then shaved clean with a finer bladed clipper.
3. On the day of dosing, the animals will be placed in restraints.
4. One pair of patches (~2.5 × 2.5 cm²) per test article will be applied to the skin of the back, with one patch on each side of the backbone.
5. A maximum of two pairs of patches may be applied to each animal, and the patches must be at least 2 in. apart.
6. The patches will be held in contact with the skin by means of an occlusive dressing for the 2-h exposure period.
7. After the 2-h exposure period, the occlusive dressing, as well as the patches on the right side of the animal, will be removed (aluminum foil).
8. The left side of the animal will be covered with opaque material.
9. The animal will then be exposed to approximately 5 J cm⁻² of UVA (320–400 nm).

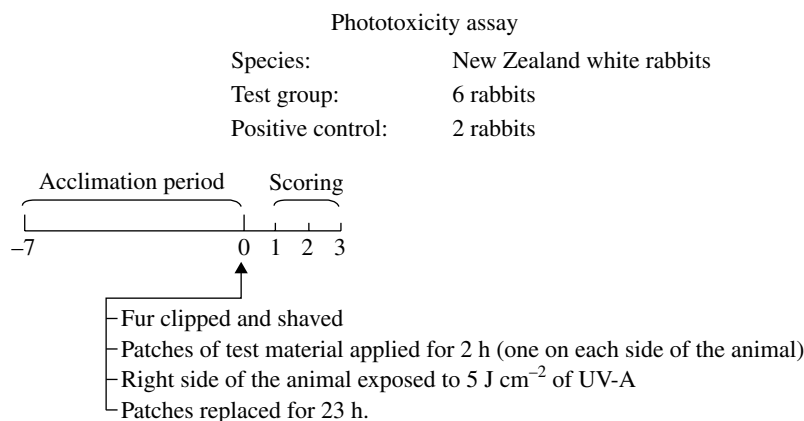

FIGURE 18.2 Line chart for design and conduct of phototoxicity assay using rabbits.

10. After exposure to the UVA light, the patches on the right side of the animal, as well as the occlusive dressing, will be replaced.
11. The dressing will again be removed approximately 23 h after the initial application of the test article. Residual test article will be carefully removed, where applicable, using water (or another suitable vehicle).
12. Animals will be examined for signs of erythema and edema and the responses scored at 24, 48, and 72 h after the initial test article application according to the Draize reaction grading system previously presented in this volume.
13. Any unusual observation and mortality will be recorded.

D. Analysis of data

The data from the irradiated and nonirradiated sites are evaluated separately. The scores from erythema and eschar formation, and edema at 24, 48, and 72 h, are added for each animal (six values). The six values are then divided by three, yielding six individual scores. The mean of the six individual animal irritation scores represents the mean primary irritation score (maximum score = 8, as in the PDI study). This method was developed after a human model had been developed.

18.10.6 Guinea Pig

Recently, a standardized protocol for using the guinea pig for phototoxicity testing has been proposed (Nilsson

et al., 1993), which has been the subject of an international validation exercise. This is detailed in Figure 18.3.

A. Animals and animal husbandry.

1. *Strain/species*: Male Hartley guinea pig.
2. *Number*: At least 10 (two groups).
Irradiation control: Four animals.
Test material treated: Six animals.
3. *Age*: Young adult, 300–500 g.
4. *Acclimation period*: At least 5 days.
5. *Feed/water*: *Ad libitum*.

B. Test material

1. *Vehicle*: Test assumes that material will be in solution. Use the most volatile, nonirritating organic solvent possible, for example, ethanol, acetone, dimethylacetamide, or some combination.
2. *Treatment*: There can be up to four sites per animal, each measuring 1.5 × 1.5 cm (2.25 cm²). In general, one side should be for a vehicle control and another for a positive control (8-methoxypsoralen (8-MOP), 0.005% in ethanol).
3. *Dosage*: A dose of 0.025–0.050 mL is applied using a micropipette to each site.

C. Experimental procedure

1. Animals will be weighed on the first day of dosing.
2. *Preparation*: Approximately 48 h prior to treatment, removed the hair from a 6 × 8 cm area on the back

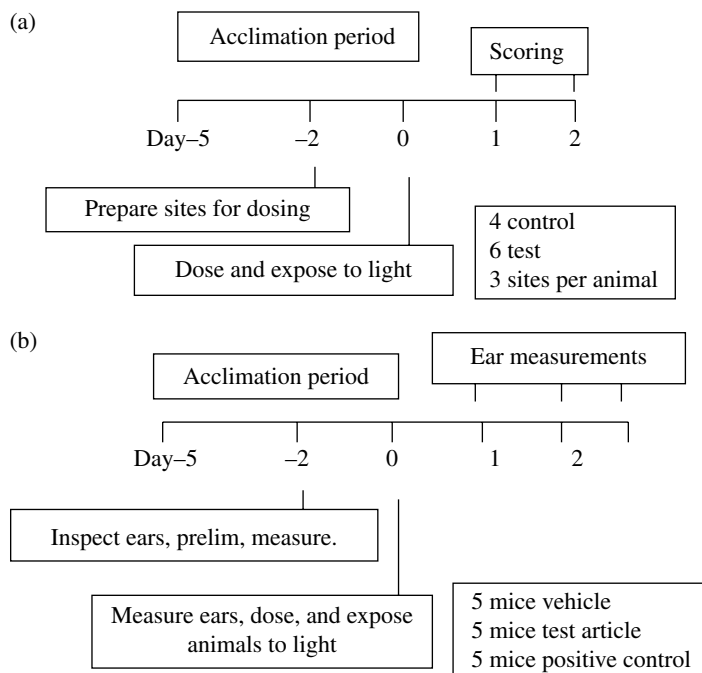

FIGURE 18.3 (a) Guinea pig and (b) mouse for phototoxicity testing.

with a fine clipper. On the day of dosing, animals are dosed as described previously. Tests are situated as to prevent mixing of test solutions after application. No patches or wraps are used.

3. Immediately after the dose application, the animals are placed in a restraint while keeping the test sites uncovered. Prior to irradiation the heads are covered to prevent ocular damage from the light exposure.
4. Thirty minutes after dosing, animals are exposed to a nonerythrogenic dose of light in the UVA band (should have peak intensity between 335 and 365 nm). The dose of light should be 9 or 10 J cm⁻² for UVA and 0.1–0.3 J cm⁻² for UVB.
5. Immediately after light exposure, the animals are wiped clean if necessary and returned to their home cages.
6. Animals are inspected and scored at 24- and 48-h postexposure according to the following:

- 0, no reaction
- 1, slight erythema
- 2, moderate erythema
- 3, severe erythema, with or without edema

The reader should note that this scoring scheme is the same one used for dermal sensitization scoring, whereas the scoring method for the rabbit model discussed previously is that used for dermal irritation studies.

7. Any unusual clinical signs noted during exposure should be noted. The following descriptive parameters can be calculated from the data:

$$\begin{aligned} \text{Phototoxic irritation index (PTII)} \\ = \frac{\text{Number of positive sites} \times 100}{\text{Number of exposure sites}} \end{aligned}$$

$$\text{Phototoxicity severity index (PSI)} = \frac{\text{Total of scores}}{\text{Total of observations}}$$

Lovell and Sanders (1992) had previously proposed a similar model of assessing topical phototoxicity potential in the guinea pig. Their model differed from that proposed by Nilsson et al. (1993) with regard to the following:

- Only one test site per animal was used.
- Test sites were smaller (about 1.6 cm²).
- Amounts applied were less (about 10 μL).
- Light intensity was set at 15 J cm⁻².
- Their paper made no reference to the use of a restrainer.
- Assessments were conducted at 4, 24, 48, and 72 h.

The scoring system was as follows:

- 0, normal
- 2, faint/trace erythema
- 4, slight erythema
- 6, definite erythema
- 8, well-developed erythema

(Intermediate scores were indicated by odd numbers.)

They recommended the use of acidine (weak phototoxin) or anthracene (strong phototoxin) for positive controls.

18.10.7 Pyrogenicity

Pyrogenicity is the induction of a febrile (fever) response induced by the parenteral (usually IV or IM) administration of exogenous material. Pyrogenicity is usually associated with microbiological contamination of a final formulation, but it is now of increasing concern because of the growing interest in biosynthetically produced materials. Generally, ensuring sterility of product and process will guard against pyrogenicity for traditional pharmaceuticals. For biologically produced products, the FDA has promulgated the general guideline that no more than 5.0 units of endotoxin may be present per milligram of drug substance.

The US Pharmacopeia describes a pyrogen test using rabbits as a model (USP, 2012). This test, which is the standard for limiting risks of a febrile reaction to an acceptable level, involves measuring the rise in body temperature in a group of three rabbits for 3 h after injection of 10 mL of test solution.

18.10.7.1 Apparatus and Diluents Render the syringes, needles, and glassware free of pyrogens by heating at 250°F for not less than 30 min or by any other suitable method. Treat all diluents and solutions for washing and rinsing of devices or parenteral injection assemblies in a manner that will ensure that they are sterile and pyrogen free. Periodically perform control pyrogen tests on representative portions of the diluents and solutions that are used for washing or rinsing of the apparatus.

18.10.7.2 Temperature Recording Use an accurate temperature-sensing device, such as a clinical thermometer or thermistor or similar probe, that has been calibrated to ensure an accuracy of ±0.1° and has been tested to determine that a maximum reading is reached in less than 5 min. Insert the temperature-sensing probe into the rectum of the test rabbit to a depth of not less than 7.5 cm and, after a period of time not less than that previously determined as sufficient, record the rabbit's temperature.

18.10.7.3 Test Animals Use healthy, mature rabbits. House the rabbits individually in an area of uniform temperature

(between 20 and 23°C) free from disturbances likely to excite them. The temperature should vary no more than $\pm 3^\circ\text{C}$ from the selected temperature. Before using a rabbit for the first time in a pyrogen test, condition it for not more than 7 days before use by a sham test that includes all of the steps as directed under procedure, except injection. Do not use a rabbit for pyrogen testing more frequently than once every 48 h, nor prior to 2 weeks following a maximum rise in its temperature of 0.6° or more while being subjected to the pyrogen test, or following its having been given a test specimen that was adjusted to be pyrogenic.

18.10.7.4 Procedure Perform the test in a separate area designated solely for pyrogen testing and under environmental conditions similar to those under which the animals are housed. Withhold all food from the test rabbits during the period of the test. Access to water is allowed at all times but may be restricted during the test. If probes measuring rectal temperature remain inserted throughout the testing period, restrain the rabbits with loose-fitting Elizabethan collars that allow the rabbits to assume a natural resting posture. Not more than 30 min prior to the injection of the test dose, determine the “control temperature” of each rabbit; this is the base for the determination of any temperature increase resulting from the injection of a test solution. In any one group of test rabbits, use only those rabbits whose control temperatures do not vary by more than 1°C from each other, and do not use any rabbit having a temperature exceeding 39.8°C .

Unless otherwise specified in the individual protocol, inject 10 mL of the test solution per kilogram of body weight into an ear vein in each of the three rabbits, completing each injection within 10 min after the start of administration. The test solution is either the product, constituted if necessary as directed in the labeling, or the material under test. For pyrogen testing of devices or injection assemblies, use washing or rinsing of the surfaces that come in contact with the parenterally administered material or with the injection site or internal tissues of the patient. Ensure that all test solutions are protected from contamination. Perform the injection after warming the test solution to a temperature of $37 \pm 2^\circ\text{C}$. Record the temperature at 1, 2, and 3 h subsequent to the injection.

18.10.7.5 Test Interpretation and Continuation Consider any temperature decreases as zero rises. If no rabbit shows an individual rise in temperature of 0.6° or more above its respective control temperature, and if the sum of the three individual maximum temperature rises does not exceed 1.4° , the product meets the requirements for the absence of pyrogens. If any rabbit shows an individual temperature rise of 0.6° or more, or if the sum of the three individual maximum temperature rises exceeds 1.4° , continue the test using five other rabbits. If not more than three of the eight rabbits show

individual rises in temperature of 0.6° or more, and if the sum of the eight individual maximum temperature rises does not exceed 3.7° , the material under examination meets the requirements for the absence of pyrogens.

In Vitro Pyrogenicity *In Vitro* pyrogenicity testing (or bacterial endotoxin testing) is one of the great success stories for *in vitro* testing. Some 15 years ago, the limulus amoebocyte lysate (LAL) test was developed, validated, and accepted as an *in vitro* alternative (Cooper, 1975; Weary and Baker, 1977) to the rabbit test. An *in vitro* test for estimating the concentration of bacterial endotoxins that may be present in or on a sample of the article(s) to which the test is applied uses LAL that has been obtained from aqueous extracts of the circulating amoebocytes of the horseshoe crab, *Limulus polyphemus*, and that has been prepared and characterized for use as an LAL reagent for gel-clot formation. The test's limitation is that it detects only the pyrogens of gram-negative bacteria. This is generally not significant, since most environmental contaminants that gain entrance to sterile products are gram negative (Devleeshouwer et al., 1985).

Where the test is conducted as a limit test, the specimen is determined to be positive or negative to the test judged against the endotoxin concentration specified in the individual monograph. Where the test is conducted as an assay of the concentration of endotoxin, with calculation of confidence limits of the result obtained, the specimen is judged to comply with the requirements if the result does not exceed (i) the concentration limit specified in the individual monograph and (ii) the specified confidence limits for the assay. In either case the determination of the reaction end point is made with parallel dilutions of redefined endotoxin units.

Since LAL reagents have also been formulated to be used for turbidimetric (including kinetic) assays or colorimetric readings, such tests may be used if shown to comply with the requirements for alternative methods. These tests require the establishment of a standard regression curve, and the endotoxin content of the test material is determined by interpolation from the curve. The procedure includes incubation for a preselected time of reacting endotoxin and control solutions with LAL reagent and reading the spectrophotometric light absorbance at suitable wavelengths. In the case of the turbidimetric procedure, the reading is made immediately at the end of the incubation period. In the kinetic assays, the absorbance is measured throughout the reaction period, and rate values are determined from those readings. In the colorimetric procedure, the reaction is arrested at the end of the preselected time by the addition of an appropriate amount of acetic acid solution prior to the readings. A possible advantage in the mathematical treatment of results, if the test is otherwise validated and the assay suitably designed, could be the confidence interval and limits of potency from the internal evidence of each assay itself.

18.11 HEMOCOMPATIBILITY

The standard test (and its major modifications) currently used for this purpose is technically an *in vitro* one, but it requires a sample of fresh blood from a dog or other large donor animal. The test was originally developed by the National Cancer Institute for use in evaluating cancer chemotherapeutic agents (Priour et al., 1973) and is rather crude, though definitive.

The variation described here is one commonly utilized. It uses human blood from volunteers, eliminating the need to keep a donor colony of dogs. The test procedure is described in the following text:

1. *Test system:* Human blood. Collect 30 mL heparinized blood for whole blood and plasma (three tubes) and 30 mL clotted blood for serum (two tubes) from each of six donors.
2. *Precipitation potential:*
 - 2.1 For each donor, set up and label eight tubes: 1 through 8.
 - 2.2 Add 1 mL serum to tubes 1 through 4.
 - 2.3 Add 1 mL plasma to tubes 5 through 8.
 - 2.4 Add 1 mL formulation to tubes 1 through 5.
 - 2.5 Add 1 mL vehicle to tubes 2 and 6.
 - 2.6 Add 1 mL physiological saline to tubes 3 and 7 (negative control).
 - 2.7 Add 1 mL 2% nitric acid to tubes 4 and 8 (positive control).
 - 2.8 Observe tubes 1 through 8 for qualitative reactions (e.g., precipitation or clotting) before and after mixing.
 - 2.9 If a reaction is observed in the formulation tubes (tubes 1 and/or 5), dilute the formulation in an equal amount of physiological saline ($\frac{1}{2}$ dilution) and test 1 mL of the dilution with an equal amount of plasma and/or serum. If a reaction still occurs, make serial dilutions of the formulation in saline (i.e., $\frac{1}{4}$, $\frac{1}{8}$, etc.).
 - 2.10 If a reaction occurs in the vehicle tubes (tubes 2 and/or 6), repeat in a manner similar to that in step 2.9.
3. *Hemolytic potential*
 - 3.1 For each donor, set up and label eight tubes: 1 through 8.
 - 3.2 Add 1 mL whole blood to each tube.
 - 3.3 Add 1 mL formulation to tube 1.
 - 3.4 Add 1 mL vehicle to tube 2.
 - 3.5 Add 1 mL of $\frac{1}{2}$ dilution of formulation in saline to tube 3.

- 3.6 Add 1 mL of $\frac{1}{2}$ dilution of vehicle in saline to tube 4.
- 3.7 Add 1 mL of $\frac{1}{4}$ dilution of formulation in saline to tube 6.
- 3.8 Add 1 mL of $\frac{1}{4}$ dilution of vehicle in saline to tube 6.
- 3.9 Add 1 mL of physiological saline to tube 7 (negative control).
- 3.10 Add 1 mL of distilled water to tube 8 (positive control).
- 3.11 Mix by gently inverting each tube three times.
- 3.12 Incubate tubes for 45 min at 37°C.
- 3.13 Centrifuge 5 min at 1000 g.
- 3.14 Separate the supernate from the sediment.
- 3.15 Determine hemoglobin concentrations to the nearest 0.1 g dL⁻¹ on the supernate (plasma).
- 3.16 If hemoglobin concentrations of the above dilutions are 0.2 g dL⁻¹ (or more) greater than the saline control, repeat the procedure, adding 1 mL of further serial dilutions ($\frac{1}{8}$, $\frac{1}{16}$, etc.) of formulation or vehicle to 1 mL of blood until the hemoglobin level is within 0.2 g dL⁻¹ of the saline control.

There are two proposed, true *in vitro* alternatives to this procedure (Mason et al., 1974; Kambic et al., 1976), but neither has been either widely evaluated or accepted.

18.12 EMETIC RESPONSES

Emesis is most frequently (but not always) associated with orally administered therapeutics in response to the drug substance or to a component of the drug product. Rodents do not have the musculature to be able to vomit, but dogs, ferrets, pigs, rabbits, and both human and nonhuman primates can, with dogs being the most prone to the response. Oral emesis is most frequently a response to physiologically evoked rather than to a specific receptor for emesis, also common is a histaminic receptor site which can be blocked by prophylactic administration of an antihistamine such as Benadryl. For drugs with an intended or necessary oral route, emesis can be a serious impediment to clinical development and use. The preferred model to predict emesis is the ferret (Percie du Sert et al., 2011)

PHARMACOKINETICS AND TOXICOKINETICS IN DRUG SAFETY EVALUATION

19.1 INTRODUCTION

Among the cardinal principles of both toxicology and pharmacology is that the means by which an agent comes in contact with or enters the body (i.e., the route of exposure or administration) does much to determine the nature and magnitude of its effects (Goldstein et al., 1974; Pratt and Taylor, 1990). Accordingly, an understanding of routes of administration and their implications for absorption is essential. The therapeutic index (calculated based on plasma and therefore absorbed levels) is the ratio between the levels that cause adverse effects and the levels that cause desired therapeutic effects in humans. This is the clinical analog of the margin of safety in toxicology studies, which used to be based on administered doses but now is based on the plasma levels at different animal doses (Yacobi et al., 1989).

Safety assessment studies usually involve a control group of animals (untreated and/or dosed with formulation only) and at least three treated groups receiving low-, intermediate-, and high-dose levels of the drug entity of interest via a route approximately that is used in man (as closely as possible). Frequently, there will also be “recovery” groups to determine if any observed effects are reversible (and if so, to what extent). In most instances, the high-dose level is expected to elicit some toxic effects in the animals, expressed as anything from decreased food consumption and/or below-normal body weight gain to mortality or actual body weight loss and severe clinical signs, and has been selected after a consideration of earlier data, perhaps from dose range-finding studies, or at least to dose as high as possible by the intended route. The other two dose levels are anticipated to not cause toxic effects or only cause moderate effects. Generally, but not always (e.g., nonsteroidal anti-inflammatory drugs in rodents), the “low-dose” level is a several-fold multiple of the expected

human therapeutic or exposure level (generally more so in rodents than in nonrodents). However, without knowing the true relationship of these dose levels to each other with respect to the absorption, distribution, and elimination of the new molecular entity as reflected by its pharmacokinetics (PKs), it is difficult to see how meaningful extrapolations concerning safety margins can be made from the toxicity data obtained.

Pharmacokinetic studies can provide information on several aspects of the earlier mentioned factors, the knowledge of which greatly facilitates assessment of safety of the therapeutic entity. Six such aspects can be mentioned:

1. Relationship between the dose levels used and the relative extent of absorption of the test compound
2. Relationship between the protein binding of the test compound and the dose levels used
3. Relationship between pharmacological or toxicological effects and the kinetics of the test compound
4. Effect of repeated doses on the kinetics of the test compound
5. Relationship between the age of the animal and the kinetics of the test compound
6. Relationship between the dose regimens of the test compound used in the toxicity studies and those employed clinically in man

ICH guidelines (ICH, 2004a, b) dictate a clearly defined set of objectives for toxicokinetic (TK) studies:

- *Primary* To describe the systemic exposure achieved in animals and its relationship to dose level and the time course of toxicity studies
- *Secondary*

1. To relate the exposure achieved in toxicity studies to toxicological findings and contribute to the assessment of the relevance of these findings to clinical safety
2. To support the choice of species and treatment regimen in nonclinical toxicity studies
3. To provide information which, in conjunction with the toxicity findings, contributes to the design of subsequent nonclinical toxicity studies

These data may be obtained from all animals on a toxicity study, or from representative subgroups, or from satellite groups, or from separate studies.

If toxicology can be described as being the study of the effects of a chemical on an organism, metabolism can be described as the opposite—the effects of the organism on the chemical; metabolism refers to a process by which a drug (xenobiotic) is chemically modified by an organism (Roberts and Renwick, 2014). It is part of the overall process of disposition of xenobiotic (absorption, distribution, metabolism, and excretion, ADME)—the process of how a chemical gains access to the inner working of an organism (absorption), how it moves around inside an organism (distribution), how it is changed by the organism (metabolism), and how it is eventually eliminated from the organism (elimination). The EPA definition of biotransformation or metabolism is “the sum of processes by which a xenobiotic (foreign chemical) is handled by a living organism.” The mathematical formulas used to describe and quantify these processes are collectively known as PKs. The EPA definition of PKs is “quantitation and determination of the time course and dose dependency of the absorption, distribution, biotransformation, and excretion of chemicals.” The acronym ADME has been used to describe the multifaceted biological process. The term “metabolism” has also come into common jargon to describe the entire process. This science has long played a central role in pharmaceutical development but has played less a role in the development of other types of products. The purpose of this chapter is to introduce the basic concepts of PKs (ADME) and describe the practices in the conduct of studies, as described in the regulations under ICH and OECD which require such data for non-pharmaceutical products, and to provide some real-world examples.

19.2 REGULATIONS

FDA believes that data from studies on the absorption, distribution, metabolism, and excretion of a chemical provide insight into mechanisms of toxicity and are essential in the design and evaluation of results from other toxicity studies. Such data should be provided for all drugs and significant impurities. Recommendations for obtaining data on the

metabolism and PKs of these substances are presented in the ICH guidelines and the FDA (2007) Redbook 2000. In general, it is required that this information be obtained as part of initial and subsequent repeat dose studies with a drug. EMEA has promulgated separate guidelines (EMEA, 2006) for evaluating the PKs of protein therapeutics.

19.3 PRINCIPLES

19.3.1 Preliminary Work

Before one ventures into Good Laboratory Practice (GLP) general (systemic) toxicity studies, some initial characterization of comparative species metabolism and understanding of initial routes of metabolism are essential. The studies used for these early characterizations are performed using *in vitro* methods. These can be performed using either enzyme (microsomal) preparations or isolated cells (usually hepatocytes) from the species of interest (initially, humans and a panel of potential animal models—mouse, rat, dog, minipig, and nonhuman primate (NHP)). Valuable assessments to enable subsequent decisions are metabolic stability (how rapidly the drug is metabolized by the microsomes or hepatocytes of different species); comparative metabolic “fingerprinting” by different species (either microsomes or hepatocytes) (see Dow, 2006); identification of potential metabolites, in which cytochrome P450 (CYP) isozymes are involved in the drug’s metabolism; and identification if the drug inhibits or induces a higher rate of metabolic activity by a panel of CYPs (therefore, allowing a preliminary understanding of potential drug/drug interactions (DDIs)). USFDA (2020) has recently provided guidance to aid in the planning and evaluation of studies to determine the DDI potential of an investigational drug product. Remembering that it is only the “free” molecules of a drug which have therapeutic (or toxicological) potential, one can also evaluate plasma protein binding *in vitro* (Smith and Kerns, 2010).

The design and analysis of PK studies require a broad understanding of the underlying concepts and principles inherent in the ADME process and in our current (and evolving) technology for studying such. Each of these four principal areas is overviewed from a practical basis as it relates to toxicology. First, however, one should consider the fundamental terminology used in PK studies (Table 19.1).

19.3.2 Absorption

Absorption describes the process by which a chemical crosses a biological membrane to gain access to the inner workings of an organism. For mammals, this process results in the entry of the chemical into the bloodstream or systemic circulation. In this case, the process is also called systemic

TABLE 19.1 Fundamental Terms Used in PK Studies

Absolute bioavailability	The bioavailability of a dosage form relative to an intravenous administration
Absorption	The process by which a xenobiotic and its metabolites are transferred from the site of absorption to the blood circulation
Accumulation	The progressive increase of chemical and/or metabolites in the body. Accumulation is influenced by the dosing interval and half-life of the chemical. The process can be characterized by an “accumulation factor,” which is the ratio of the plasma concentration at steady state to that following the first dose in a multiple dosing regimen
Analyte	The drug entity assayed in biological samples
Area under the curve (AUC)	The concentration of chemical and/or metabolites in the blood (or plasma/serum) integrated over time. This is typically considered the best indicator of exposure
Bioavailability	The rate and extent to which a xenobiotic entity enters the systemic circulation intact, following oral or dermal administration. It is sometimes expanded to include therapeutically active metabolites. Also known as the comparative bioavailability
Biotransformation	The process by which a xenobiotic is structurally and/or chemically changed in the body by either enzymatic or nonenzymatic reactions. The product of the reaction is a different composition of matter or different configuration than the original compound
Clearance (Cl)	The volume of biological fluid which is totally cleared of xenobiotic in a unit time
C_{max}	The maximum mean concentration of the chemical in the plasma. Also known as the peak plasma concentration
Concomitant TKs	Toxicokinetic measurements performed in the toxicity study, either in all animals or in representative subgroups or in satellite groups
Disposition	All processes and factors which are involved from the time a chemical enters the body to the time when it is eliminated from the body, either intact or in metabolite form
Distribution	The process by which an absorbed xenobiotic and/or its metabolites partition between blood and various tissues/organs in the body
Dosage form	The formulation (diet, lotion, capsule, solution, etc.) administered to animals or man
Dose proportionality	The relationship between doses of a chemical and measured parameters, usually including tests for linearity
Enterohepatic circulation	The process by which xenobiotics are emptied via the bile into the small intestine and then reabsorbed into the hepatic circulation
Enzyme induction	The increase in enzyme content (activity and/or amount) due to xenobiotic challenge, which may result in more rapid metabolism of a chemical
Enzyme inhibition	The decrease in enzymatic activity due to the effect of xenobiotic challenge
Excretion	The process by which the administered compound and/or its biotransformation products are eliminated from the body
Exposure	Exposure is represented by PK parameters demonstrating the local and systemic burden on the test species with the test compound and/or its metabolites. The area under the matrix level concentration-versus-time curve (AUC) and/or the measurements of matrix concentrations at the expected peak concentration time C_{max} , or at some other selected time $C_{(time)}$, are the most commonly used parameters. Other parameters might be more appropriate in particular cases
First-order kinetics	Kinetic processes, the rate of which is proportional to the concentration
First-pass effect	The phenomenon whereby xenobiotics may be extracted or metabolized following enteral absorption before reaching the systemic circulation
Flux	Term (which takes area into consideration) used to describe the movement of a chemical across a barrier. Most typically used to describe the absorption of a chemical across the skin as micrograms per square centimeter per hour
Half-life ($T_{1/2}$)	The time elapsed for a given chemical entity concentration or amount to be reduced by a factor of two
Hepatic clearance	The rate of total body clearance accounted for by the liver
Kel	The elimination constant for a chemical in plasma. Typically calculated using the formula $Kel = -\ln[10] \times b$, where b is the slope of the linear regression line of the log of the mean plasma concentrations versus time from t_{max} to 24 h
Lag time	The interval between compound administration and when the compound concentration is measurable in blood
Metabolite characterization	The determination of physicochemical characteristics of the biotransformation product(s)
Metabolite identification	The structural elucidation of the biotransformation product(s)

(Continued)

TABLE 19.1 (Continued)

Absolute bioavailability	The bioavailability of a dosage form relative to an intravenous administration
Metabolite profile	The chromatographic pattern and/or aqueous/nonaqueous partitioning of the biotransformation products of the administered compound
Monitor	To take a small number of matrix samples (e.g., 1–3) during a dosing interval to estimate $C_{(time)}$ and/or C_{max}
Nonlinear kinetics (saturation kinetics)	Kinetic processes, the rate of which is not directly proportional to the concentration
Presystemic elimination	The loss of that portion of the dose that is not bioavailable. This would include, among others, loss through intestinal and gut-wall metabolism, lack of absorption, and first-pass hepatic metabolism
Profile	To take (e.g., 4–8) matrix samples during a dosing interval to make and estimate C_{max} and/or $C_{(time)}$ and area under the matrix level concentration-versus-time curve (AUC)
Protein binding	The complexation of a xenobiotic and/or its metabolite(s) with plasma or tissue proteins
Relative bioavailability	The bioavailability relative to a reference or a standard formulation or an agent
Renal clearance	The rate of total body clearance accounted for by the kidney. Its magnitude is determined by the net effects of glomerular filtration, tubular secretion and reabsorption, renal blood flow, and protein binding
Satellite	Groups of animals included in the design and conduct of a toxicity study, treated and housed under conditions identical to those of the main study animals, but used primarily for TKs
Steady state	An equilibrium state where the rate of chemical input is equal to the rate of elimination during a given dose interval
Support	In the context of a toxicity study—to ratify or confirm the design of a toxicity study with respect to PK and metabolic principles. This process may include two separate steps: 1. Confirmation using TK principles that the animals on a study were exposed to appropriate systemic levels of the administered compound and/or its metabolite(s) 2. Confirmation that the metabolic profile in the species used was acceptable (the data to support this will normally be derived from metabolism studies in animals and in humans)
T_{max}	The sampling time point at which C_{max} occurs
Total clearance	The volume of biological fluid totally cleared of xenobiotic per unit time, usually including hepatic clearance and renal clearance
TKs	The study of the kinetics of absorption, distribution, metabolism, and excretion of toxic or potentially toxic chemicals
Validate	In the context of an analytical method—to establish the accuracy, precision, reproducibility, response function, and specificity of the analytical method with reference to the biological matrix to be examined and the analyte to be quantified
Volume of distribution (V_d)	A hypothetical volume of body fluid into which the chemical distributes. It is not a “real” volume, but is a proportionality constant relating the amount of chemical in the body to the measured concentration in blood or plasma

absorption. Pharmaceutical products, procedures, and devices, such as hypodermic needles or catheters, can be used to bypass biological barriers. Other products gain access to the systemic circulation via the oral, dermal, buccal, or inhalatory route of administration.

For a material to be toxic (local tissue effects are largely not true toxicities by this definition), the first requirement is that it be absorbed into the organism (for which purpose being in the cavity of the gastrointestinal (GI) tract does not qualify). Most pharmaceuticals are intended to gain such access.

There are characteristics which influence absorption by the different routes, and these need to be understood by any person trying to evaluate and/or predict the toxicities of different moieties. Some key characteristics and considerations are summarized in the succeeding text by route.

A. Oral and Rectal Routes (Gastrointestinal Tract)

1. Lipid-soluble compounds (nonionized) are more readily absorbed than water-soluble compounds (ionized):
 - a. Weak organic bases are in the nonionized, lipid-soluble form in the intestine and tend to be absorbed there.
 - b. Weak organic acids are in the nonionized, lipid-soluble form in the stomach and one would suspect they would be absorbed there, but the intestine is more important because of time and area of exposure.
2. Specialized transport systems exist for some moieties: sugars, amino acids, pyrimidines, calcium, and sodium.

3. Almost everything is absorbed—at least to a small extent (if it has a molecular weight below 10 000).
 4. Digestive fluids may modify the structure of a drug.
 5. Dilution increases toxicity because of more rapid absorption from the intestine, unless stomach contents bind the moiety.
 6. Physical properties are important—for example, dissolution of metallic mercury is essential to allow absorption.
 7. Age—neonates have a poor intestinal barrier.
 8. Effect of fasting on absorption depends on the properties of the chemical of interest.
- B. Inhalation (Lungs)
1. Aerosol deposition:
 - a. Nasopharyngeal—5 μm or larger in man, less in common laboratory animals.
 - b. Tracheobronchial—1 to 5 μm
 - c. Alveolar—1 μm
 2. If a solid, mucociliary transport may serve to clear from lungs to GI tract.
 3. Lungs are anatomically good for absorption:
 - a. Large surface area (50–100 m²)
 - b. High blood flow
 - c. Close to blood (10 μm between gas media and blood)
 4. Absorption of gases is dependent on the solubility of the gas in blood:
 - a. Chloroform, for example, has high solubility and is all absorbed; respiration rate is the limiting factor.
 - b. Ethylene has low solubility and only a small percentage is absorbed; blood flow limited absorption.
 - c. Parenteral routes.
 - d. Dermal routes.

As a generalization, there is a pattern of relative absorption rates which extend between the different routes that are commonly employed. This order of absorption (by rate from fastest to slowest and, in a less rigorous manner, in degree to absorption from most to least) is IV > inhalation > IM > IP > SC > oral > ID > other dermal.

Absorption (total amount and rate), distribution, metabolism, and species similarity in response are the reasons for selecting particular routes in toxicology. In acute studies, however, these things are rarely known to us. So the cardinal rule for selecting routes of use in acute testing is to use those routes which mirror the intended route for human exposure. If this route of human exposure is uncertain or if there is the potential for either a number of routes or the human absorption rate and pattern being greater, then the common practice

becomes that of the most conservative approach. This approach stresses maximizing potential absorption in the animal species (within the limits of practicality) and selecting from among those routes commonly used in the laboratory that which gets the most material into the animal's system as quickly and completely as possible to evaluate the potential toxicity.

In general, drugs cross biological barriers by one of three mechanisms: active transport, facilitated transport, and passive transport. In active transport, the chemical is specifically recognized by the organism, which then expends energy to take the chemical up, even against a concentration gradient. In facilitative transport, the organism produces a carrier molecule which reacts with the target molecule to form a complex which more easily traverses the membrane, but no energy is expended to take up the complex. Such complexes do not flow against a concentration barrier. The simplest mechanism is passive transport or diffusion. Here, a drug flows down a concentration gradient (from high concentration to a lower concentration) and must passively (no energy expended by organism) cross a biological membrane. Passive transfer or diffusion is the most common (if not the only) mechanism involved in the absorption of the vast majority of approved drugs. It should be remembered that for purposes here, "concentration gradient" must be considered in relationship to partition coefficient. That is, a gradient will reflect the relative solubilities of drug in polar (water) and nonpolar (lipid) matrices or tissues. The other mechanisms involved in absorption will not be further discussed here.

Drugs in solution have a natural tendency (more rigorously defined by the laws of thermodynamics) to move down a concentration gradient. That is to say, the individual molecules of solute tend to move from a region of high concentration toward regions of lower concentration. Also, the movement of a chemical across a permeable barrier, such as a biological membrane, is a process called diffusion, as illustrated by Figure 19.1. For most products, these biological barriers are either the wall of the GI tract, the lining of the pulmonary system, or the skin.

Absorption from the GI tract is controlled by a variety of factors. These include the acid/base characteristics of the chemical (described as the $\text{p}K_a$), the solubility, the nature of the delivery (e.g., diet vs. gavage), the nature of any vehicle (suspensions vs. solutions or aqueous vs. nonaqueous), and the GI tract of the species under study. Gad (2007, 2015) provides much greater detail on this subject.

Ionized or charged organic moieties do not readily pass through the lipophilic cell membranes of the epithelial cells that line the GI tract. Thus, more acidic molecules tend to be more readily absorbed from the stomach, while more alkaline materials tend to be absorbed from the small intestine. This is because at the acidic pH of the stomach, acidic chemicals tend to be nonionized. More alkaline chemicals tend to be more ionized in the stomach and less ionized in the gut. The

FIGURE 19.1 Passage of chemical moieties from GI tract into bloodstream.

TABLE 19.2 Receptors Slowing Gastric Emptying

Receptor (Site)	Stimulus	Example	Sensitivity
Osmoreceptor (duodenum)	Osmotic effect (except tryptophan)	Glucose Amino acids Electrolytes	Least
Acid receptor (proximal duodenum and jejunum)	Acids with $pK_a < 5$	Citric acid HCl	Intermediate
Fat receptor (jejunum)	Fatty acids	Sodium myristate	Most
Tryptophan receptor (duodenum and jejunum)	Tryptophan	Tryptophan	—

Source: Adapted from Hunt and Knox (1968) and Minami and MacCallum (1984).

equilibrium reaction for acidic dissociation can be represented by this equation:

Like all chemical equations, this one has an equilibrium constant. The discussion of basic chemistry is outside the purview of this book. Readers who may need a refresher are referred to Tse and Jaffe (1991). For every chemical, a pK_a can be calculated based on equilibrium constant, which represents the proportion of ionized and unionized material in solution. The lower the pK_a of a molecule, the more likely it is to be nonionized in the stomach.

One can manipulate the movement of a drug through the GI tract (and particularly the stomach) by formulation and/or by feeding, concurrent with drug administration. Some of the

factors which slow gastric emptying (and therefore some to increase drug absorption) are presented in Table 19.2.

19.3.2.1 Absorption from the Pulmonary System Of the three routes discussed here, absorption from the pulmonary system is perhaps the most rapid. Systemic absorption of inhaled materials is highly dependent on the physical properties of the inhaled materials which dictate how easily the materials reach the alveoli of the deep lung. Proteins may be readily absorbed when instilled in the deep lungs—as an example, note the inhalable insulins. Gases and vapors easily penetrate into the deep lung. For mists and dusts, absorption will be highly dependent on particle size. In general, the larger the particles, the less they will penetrate the pulmonary system. The term “impaction” describes the deposition of particles in the respiratory tract. Particles of less than $0.2 \mu\text{m}$ are preferentially deposited in the pulmonary portion of the

respiratory system, whereas particles over 2 μm do not reach the alveolar epithelium in great number. Particles from 1 to 4 μm tend to be distributed over the length of the system, whereas particles over 4 μm tend to be deposited in the nasal region. Aerosolized particles of greater than 20 μm do not commonly occur in nature. Tidal volume will also influence impaction. In general, the larger the tidal volume, and thus the more forceful the inhalation process, the more deeply particles of all sizes tend to be driven into the lung.

Once deposited, materials must be in solution before they can be absorbed. Hence, materials in an aerosolized solution will be more readily absorbed than materials that are delivered as solid particles (e.g., dusts). Solid materials must be able to go into solution *in situ* in order to be absorbed. Particle size influences dissolution rate. Large particles dissolve more slowly (for any given material) than small particles due to the differences in surface area. Once in solution, the same laws of passive diffusion apply to materials in the lung as they apply to material in the GI tract. The large surface area and the rich blood flow at the alveoli make for ideal conditions for rapid absorption into the systemic circulation. Absorption across the mucosa lining the upper airways is less rapid. Materials that do not dissolve are ingested by pulmonary macrophages and either broken down there or moved out of the lungs by the upward movement of the bronchociliary tree.

For gases and vapors, the amount absorbed is highly dependent on the partial pressure and solubility of the gas in blood. Let us take the simple case of a gas that is not metabolized and is excreted by exhalation (e.g., an anesthetic gas or a Halon-type fire-extinguishing agent). At any given concentration (or partial pressure) in the atmosphere, the concentration in the blood will reach a steady state. Accordingly, prolonged exposure does not lead to continual buildup.

At equilibrium, the concentration in the blood is depicted by the formula (also known as the Ostwald coefficient) $X_b/X_a = S$, where X_b is the concentration in the blood and X_a is the concentration in the inspired air. Thus, if one knows the S for a given chemical and the target concentration for a given exposure, one can predict what the resulting concentration may be at equilibrium. Additionally, the lower the S value (i.e., the lower the solubility in blood), the more rapidly the chemical will achieve equilibrium.

19.3.2.2 Absorption across the Skin An aqueous carrier may be used for a variety of dermal products. In fact, carriers can be designed to limit the transportation or the penetration of the active ingredient (such as an insect repellent) if the desired effect is to keep the active ingredient on the surface of the skin. Once again, however, only those materials that are dissolved will be available for penetration across the skin to gain access to the systemic circulation. For almost all drugs in or about to enter clinical trials,

dermal penetration is a passive process. The relative thickness of the skin makes absorption (into the systemic circulation) slower than the absorption across the GI or pulmonary barriers. This is compounded by the fact that the stratum corneum function is to be impervious to the environment. One of the skin's major functions is protection from infection. Once a drug penetrates into the dermis, it may partition into the subcutaneous fat. Essentially, absorption across the skin is a two-step process with the first being penetration and deposition into the skin and the second being release from the skin into the systemic circulation. The pattern of blood levels obtained via dermal penetration is generally one with a delayed absorption and slow buildup to more of a plateau than a peak. Blood levels of chemicals absorbed via the dermal route are generally low (Garner and Matthews, 1998).

Given the overwhelming influence of the physical properties of skin in determining bioavailabilities via the dermal route, assessment of dermal penetration is one area in metabolism and toxicology where the use of *in vitro* methods can be effectively used to predict *in vivo* results and to screen chemicals. Apparatus and equipment that one can use to maintain sections of skin (obtained from euthanized animals or from human cadavers or surgical discard) for such experiments exist (Holland et al., 1984; Bronaugh, 1998). These apparatus are set up to maintain the metabolic integrity of the skin sample between two reservoirs: the one on the stratum corneum side, called the application reservoir, and the one on the subcutaneous side, called the receptor reservoir. One simply places radiolabeled test material in the application reservoir and collects samples at various time points from the receptor fluid.

The rate of penetration can be presented by the traditional kinetic formulas to obtain a penetration rate constant. Given that exposed surface area also plays a role in the amount of material absorbed, the concept of flux is also important.

Major considerations in determining the quantity of material that is absorbed into the skin, and eventually released into the systemic circulation, are primarily dependent on three factors: the surface area exposed, the volume and concentration of the material applied, and the nature of the vehicle:

Surface area: All things being equal, it is clear that the greater the surface exposed, the higher the achieved internal dose.

Volume: The volume of material will obviously play a role in total dose, but it is not as straightforward as the relationship to surface area. Theoretically, the maximum absorption is obtained when the material is spread as thin and uniform as possible; piling material on so that it is literally rolling off the animal serves no practical purpose. In fact, it is not a sound practice when dealing with an *in vivo* animal experiment as it makes it more likely for the material to be available for oral ingestion.

Concentration: The higher the concentration in a formulation, the higher the flux achieved of drug molecules across the skin. Of course, the nature of the vehicle that the drug is being carried in may also have a profound influence on absorption.
